considerable extension of the layer-formation region in the CaO–SiO_2 system is observed when "strong" cations (Mg, Fe, Zn, etc.) – with atomic radii somewhat less than the atomic radius of O^{2-} (O^{2-} – 1.32A) – are introduced. In such ternary systems (MO–CaO–SiO_2), as Greig showed [4], the layer-separation region extends continuously from the CaO–SiO_2 side of the triangle to the MO–SiO_2. A special position is occupied by the Ba ion (Ba^{2+} – 1.43A). Being a strong ion, it has an ionic radius less than that of Pb but greater than those of the above-indicated bivalent cations. Hence, the interaction forces of Ba^{2+} with oxygen will be greater than those of Pb^{2+}, but less than those of Ca^{2+}, Mg^{2+}, and Sr^{2+}. Whereas in the binary system PbO–SiO_2 no region of layer-separation is formed, and in the systems CaO–SiO_2 and MgO–SiO_2 there are considerable layer-separation regions, in the system BaO–SiO_2 there is only a tendency for layer-separation to occur. No clearly defined microheterogeneous regions occur. Our investigation has shown that, when BaO is introduced into the system CaO–SiO_2, a considerable layer-separation region is formed, but this region, demarcated by the binodal curve in Fig. 1, does not reach the BaO–SiO_2 side of the triangle, as is characteristic for the addition of, for example, MgO, when the layer-separation region extends continuously from one side of the triangle (CaO–SiO_2) to the other (MgO–SiO_2).

The $3CaO \cdot 2SiO_2$ Field. Tricalcium disilicate melts at 1475° with decomposition into calcium orthosilicate and liquid. In the binary system CaO–SiO_2 the liquidus line for tricalcium disilicate has a range of only 1% – from 54.5% CaO to 55.5% CaO. In presence of barium oxide, $3CaO \cdot 2SiO_2$ melts with decomposition into a solid solution of calcium and barium orthosilicates and liquid. Hence, the figurative point for the composition $3CaO \cdot 2SiO_2$ lies outside its primary-crystallization field. The $3CaO \cdot SiO_2$ field occupies a very narrow strip, stretching almost to the center of the triangle in the ternary diagram; it borders on fields of calcium metasilicate and solid solutions. In spite of the very narrow width of the field, it was found to be possible to define its position fairly accurately. Table 3 gives the results of the determination of crystalline phases for compositions in the neighborhood of $3CaO \cdot 2SiO_2$.

In samples from the calcium metasilicate field, the secondary phase was tricalcium disilicate, and in no test sample was a solid solution found. When, however, a composition from the solid-solution field was crystallized, the grains of solid solution that formed in the first place disappeared as the temperature fell, and tricalcium disilicate appeared. This course of the crystallization can be seen in the photomicrographs of Fig. 4, which show the crystalline phases obtained by the quenching of test samples of a given composition, 42% CaO, 20% BaO, and 38% SiO_2; the figurative point of this composition lies in the solid-solution field.

Field of Solid Solutions of Orthosilicates, Calcium Oxide, and Barium Oxide

The boundaries between the fields of solid solutions and of the compounds $BaO \cdot SiO_2$, $2CaO \cdot BaO \cdot 2SiO_2$, $3CaO \cdot SiO_2$ were established by the quenching method. In the study of the remaining sections of these fields, the methods of crystal growing and determination of the beginning of crystallization and melting – as described above – were used. Fig. 5 shows the positions of three sections studied, which have constant barium oxide contents of 20%, 50%, and 70%. The inclination of the fusion curves obtained are in accord with data of microscopic analysis for the determination of the primary phases. The points for the maxima a, b, and c, lie on the connecting line of the components of the solid solution; the points for the minima a', b', and c' are on the boundary between the solid-solution field and the calcium oxide field.

The photomicrograph in Fig. 6a shows a solid solution forming large grains of irregular form. Calcium oxide in Fig. 6b appears as small, mainly round grains, sometimes forming clusters. When etched for a short time with water vapor, the calcium oxide grains acquire yellowish and bluish shades. Finally, barium oxide (Fig. 6 c) does not give regular crystals, giving continuous grayish formations, probably owing to its extremely rapid hydration.

Fig. 6. Photomicrographs: a) solid solution; b) calcium oxide; c) barium oxide. (Reflected light; ×420)

Ternary Diagram of $CaO - BaO - SiO_2$

The fields of stability of crystalline phases, apart from those discussed above, were studied by the usual quenching method. The phase diagram of the system $CaO-BaO-SiO_2$ with plotted isotherms is given in Fig.1. The diagram consists of 12 stability fields for the following phases: I – layer-separation region; II – cristobalite; III – tridymite; IV – calcium metasilicate ($CaO \cdot SiO_2$); V – tricalcium disilicate ($3CaO \cdot 2SiO_2$); VI – solid solutions of barium and calcium orthosilicates; VII – calcium oxide (CaO); VIII – barium oxide (BaO); IX – barium metasilicate ($BaO \cdot SiO_2$); X – solid solutions $2BaO \cdot 3SiO_2$–$BaO \cdot SiO_2$; XI – barium disilicate ($BaO \cdot 2SiO_2$); and XII – the ternary compound $2CaO \cdot BaO \cdot SiO_2$. Eight invariant points were established in the system, six being eutectics and two reaction points. Table 4 gives the compositions and temperatures of the invariant points. The division of the diagram into phase triangles is shown in Fig. 7. The course of the crystallization within the limits of each of these triangles can be established by known methods.

SUMMARY

1. On the basis of study of the ternary system $CaO-BaO-SiO_2$ its phase diagram was constructed.

2. The phase diagram consists of twelve stability fields of different phases.

3. The compositions and temperatures at the invariant points were determined.

4. The limits and liquidus temperatures were determined for the field of solid solutions of orthosilicates.

5. The limits of the region of layer-separation and its upper critical point were established, as also was the temperature for the coexistence of a crystalline phase (SiO_2) and two liquids.

THE DENSITIES OF AQUEOUS URANYL NITRATE SOLUTIONS, AND THE APPARENT MOLAR VOLUMES OF URANYL NITRATE

A. F. Kapustinsky and I. I. Lipilina

The densities of aqueous uranyl nitrate solutions have been the subject of several investigations. Vasilyev [1] examined 18 concentrations over the range 2.8-54.8% by weight at 17°. The results of the remaining authors refer to a very limited number of solutions of various compositions. Thus, Bromer [2] studied two concentrations at 19°. Grant, Darch, Bowden, and Jolines [3] investigated six concentrations over the range 5-25%; this work differs from the remainder in that the densities of the solutions were determined over a wide temperature range (0-100° in steps of 5-20°). Seven dilute solutions (0.4-3.8%) were studied by Gomez [4] at 25°. Some density determinations on uranyl nitrate solutions are reported by de Coninck [5], but these data are rendered valueless by the fact that de Coninck did not state the formula of his salt and the atomic weight assumed for uranium, it being pointed out by Vasilyev [6] that in some of his investigations de Coninck incorrectly assumed that the atomic weight of uranium is 120. The results of Germann [7] are not sufficiently accurate; the third decimal place is found by graphical interpolation.

Although, as will be seen, uranyl nitrate solutions have been investigated by many chemists, not a single investigation has been made in which the densities of these solutions have been studied over the widest possible range of concentrations at a standard temperature (25°) with an accuracy that ensures the possibility of calculating partial molar quantities, i.e. with a probable error of the order of 0.01%. It was with the object of filling this gap that we undertook the present investigation, which finally enabled us to determine the apparent molar volume of the uranyl ion in an aqueous medium.

EXPERIMENTAL

We determined the densities of the solutions pycnometrically. We used a pycnometer of the type employed in one of the most accurate methods of determining densities of solutions – the method of paired quartz pycnometers [8] – but we used only one such pycnometer, thus appreciably simplifying and speeding up the measurements while maintaining adequate accuracy.

The pycnometer (Fig. 1 a), which was constructed of clear fused quartz, had a volume of 38 ml and a weight of 23 g; the internal diameter of the capillary was 1.7 mm. The pycnometer was closed with a quartz cap, ground to fit. One side of the neck of the pycnometer – the side from which measurements were made – was made flat in order to eliminate errors due to refraction. The filling of the pycnometer with water or solution was carried out with the aid of a funnel having a capillary end (Fig. 1b); before being filled, the pycnometer was dried for 48 hours at 130°. Filling, although slow (15-20 minutes) was not difficult; removal of air through the capillary neck of the pycnometer proceeded smoothly. We therefore did not use any supplementary apparatus for, for example, filling in a vacuum or applying excess pressure above the funnel. For the removal of liquid from the pycnometer we used a bent glass tube, one end of which was drawn out into a capillary (Fig. 1c). The liquid was poured out through the capillary neck of the pycnometer and air entered simultaneously through the capillary tube. The pycnometer had one horizontal calibration mark on the neck.

The graduation of the pycnometer, i.e. the determination of the volume it contained when filled up to a level lying within ± 3 cm of the mark on the neck, was carried out with water. In the graduation, the pycnometer was filled with water up to a certain level and immersed in a thermostat, in which it was kept until the level of

the miniscus in the capillary neck of the pycnometer ceased to change. The distance of the meniscus from the mark was determined accurate within 0,01 mm with the aid of a Fmos cathetometer. Thermal equilibrium was generally attained within 20–30 minutes after immersion of the pycnometer in the thermostat. When the meniscus had taken up a constant position, this was read and the pycnometer was closed with the cap. It was then dried with filter paper, allowed to attain the temperature of the analytical balance, and weighed on this balance accurate within one unit in the fifth place of decimals. The correction for weighing in air was made by means of formula:

$$d = d' + 0{,}0012\,(1 - d'),$$

in which d' is the density uncorrected to vacuum-weighing conditions. In the calculation of the volume of water in the pycnometer, the density of water at 25° was taken to be 0,99707 [9]. The results of the graduation of the pycnometer are given in Table 1.

In the determination of the density of a solution, the pycnometer was filled and immersed in the thermostat. When thermal equilibrium had been established and the meniscus had ceased to move in the capillary, the distance from the level of the solution in the capillary to the mark was determined with the cathetometer. The volume of the solution was found by interpolation between the volumes at two closely situated graduated levels, it being assumed that over this distance the cross-sectional area of the capillary was constant.

Fig. 1. a) quartz pycnometer; b) funnel for filling; c) tube to assist emptying. (Dimensions shown in mm)

At the end of an experiment the solution was poured out of the pycnometer, which was then rinsed out two or three times with dilute (1:1) nitric acid and ten times with hot water, after which it was dried for two days in a cupboard at 130°. The funnel and bent capillary tube were washed and dried with equal care.

A diagram of the thermostat used for the determination of densities of solutions is shown in Fig. 2. The metal thermostat 1 has the dimensions 430 × 430 × 240 mm; its volume is about 45 liters. Two sides of the thermostat was made of plate glass, so that observations can be made on the apparatus contained in the thermostat. The electric heater 2 consists of nichrome wire wound on a glass frame. The use of the powerful propeller stirrer 3 and the specially constructed large mercury-toluene thermoregulator 4 enables the temperature to be maintained constant within ± 0,002°. All operations are carried out at 25°. The temperature is recorded on the Beckmann thermometer 5, the mercury level in which was established by means of the standard thermometer 6. The pycnometer 7 is held in a clamp so that it is immersed in the water almost up to the cap. During an

TABLE 1

6	+24,15	23,34245	61,51885	38,17640	38,28858

experiment the outside of the pycnometer is sometimes covered with small air bubbles which make it difficult to take readings and retard the establishment of thermal equilibrium. These are therefore quickly removed with a thin glass rod covered at one end with rubber tubing; during the experiment this rod is kept in the thermostat and is at 25°. The Beckmann thermometer is read with the aid of a cathetometer, readings being taken every 30 seconds in the preliminary period, i.e. while the pycnometer is being held in the thermostat, and every 2-3 minutes during the main period, when the meniscus is under observation. The temperature is read on the Beckmann thermometer before each reading of the meniscus is taken. Readings of the height of the meniscus and of the calibration mark on the pycnometer are taken every 2 minutes over a period of 30-40 seconds and are accurate within ± 0.01 mm. The probable error in the determination of densities of solutions is 0.001%.

Fig. 2. Diagram of thermostat for the determination of the density of solutions.

The uranyl nitrate was prepared by dissolving UO_3 (chemically pure grade) in chemically pure redistilled nitric acid. The salt so formed was recrystallized three times from water; in the last recrystallization the middle third of the crystals was taken [10]. This salt was dissolved in water so as to give the most concentrated of the solutions to be studied; it had 52.36 % of $UO_2(NO_3)_2$. In the preparation of more dilute solutions the water added and the original solution were weighed, and the concentration of the solution prepared in this way was determined by calculation. In addition, for a series of the solutions, two parallel gravimetric analyses for uranium were also carried out, a weighed amount of the solution being evaporated down in a platinum crucible and the residue calcined to U_3O_8 at 870-890° (the analyzed solutions are indicated by an asterisk in Table 2). The analysis was accurate within 0.01%.

The preparative and analytical part of the work was carried out with water that had been distilled three times in a quartz apparatus, all parts of which were connected through ground glass joints. The conductivity of the purified water was $8 \cdot 10^{-7} - 1 \cdot 10^{-6}$ ohm^{-1}cm^{-1}.

The results obtained for the density d_4^{25} of aqueous uranyl nitrate solutions are presented in Table 2. The same table gives the results of the calculation of V_4^{25}, i.e. the specific volumes of the solutions at 25° referred to the specific volume of water at 4°, and of the apparent molar volumes φ_V, which were found from the formula:

$$\varphi_V = \frac{V_4^{25}(mM + 1000) - (1000/d_w)}{m}. \qquad (1)$$

in which m is the molal concentration of the solution, M is the molecular weight of the salt (394.086), and d_w is the density of water at 25° (0.99707).

* The concentration of the solution was determined by chemical analysis and by calculation (from weights of original solutions and of added water).

In Fig. 3 the experimental results are presented graphically as a function of concentration, expressed as percent by weight of anhydrous salt. The last column of Table 2 gives values of $\sqrt{m}$, and Fig. 4 gives the relationship between φ_V and $\sqrt{m}$ for aqueous uranyl nitrate solutions. It will be seen that this relationship is linear.

Fig. 3. Densities of aqueous uranyl nitrate solutions at 25°.

As already pointed out, there are data in the literature on the densities of aqueous uranyl nitrate solutions. So that a comparison might be made between our results and the data in the literature, we submitted the latter to the following treatment. As different authors expressed the concentrations of the solutions differently, we recalculated them: in all cases we calculated the molality and percentage by weight (i.e. the amount of anhydrous salt (g) in 100 g of solution) of the solutions; then, from the density data we calculated the specific volumes of the solutions, and hence the apparent molar volumes of the salt in the solutions (φ_V). The results of the calculations are given in Tables 3, 4, 5, and 6.

In Fig. 5 the relationship between φ_V and $\sqrt{m}$ is shown graphically for the results obtained by us in the present investigation, for the results obtained by us previously [11], and for the results of various other authors. We must mention that an arithmetic error was made in the calculation of the densities of aqueous uranyl nitrate solutions in our preliminary communication [11], which was published some years ago. In Table 7 the corrected values are given.

It will be seen from Fig. 5 that in all previous investigations, with the exception of those of Vasilyev, solutions in a comparatively short concentration range were studied. Examining each author's data separately, we

may make the following comments. The data of Gomez [4] refer to 25°; they cover a short range of concentrations in the high-dilution region (from $\underline{m} = 0.01$ to $\underline{m} = 0.10$) and, as will be seen from Fig. 5, cannot be used for the calculation of φ_V both because of the shortness of the concentration range and also because of the excessively wide scatter of the points. The data of Grant, Darch, Bowden, and Johnes refer to more concentrated solutions than those investigated by Gomez, viz. from $\underline{m} = 0.15$ to $\underline{m} = 0.88$, and they again refer to 25°. It will be seen that the scatter of the points is again too great. Bromer's data are too limited: only two measurements at 19°. Vasilyev's data cover a wide range of concentrations, but, as will be seen, the points do not lie on a straight line, probably because the measurements were not sufficiently accurate in the region of dilute solutions.

Fig. 4. Relationship between φ_V and $\sqrt{m}$ for aqueous uranyl nitrate solutions at 25°.

Fig. 5. Relationship between φ_V and $\sqrt{m}$ for aqueous uranyl nitrate solutions according to our data and to recalculated data from the literature: 1) Bromer [2]; 2) Vasilyev [1]; 3) Gomez [4]; 4) Grant, Darch, Bowden, and Johnes [3]; 5) our preliminary results; 6) our final results

As will be seen from Figures 4 and 5, our results cover concentrations ranging from almost saturation to extreme dilution, measurements being taken at very short concentration intervals. The results lie quite satisfactorily on the straight line and can therefore be used as the basis for the determination of the value of φ corresponding to infinite dilution, i.e. $\varphi^0_{VUO_2(NO_3)_2}$. We carried out the extrapolation on the assumption that the points lie on a straight line and the experimental results can be expressed by the equation:

$$\varphi_V = \varphi^0_V + S_V\sqrt{m}, \qquad (2)$$

in which S_V is the proportionality coefficient (the slope of the straight line). The coefficients in Equation 2, φ^0_V and S_V, were found by the method of least squares. As is well known, by this method the sum of the squares of the differences between the calculated and observed values of φ_V is reduced to a minimum.

5	20,56	0,6210	0,6567	1,1903	0,84012	83,2	0,81
6	25,78	0,8260	0,8825	1,2615	0,79271	74,2	0,94

TABLE 5

Recalculated Data of Bromer [2] on the Densities of Aqueous Uranyl Nitrate Solutions at 19°

Experiment No.	Concentration p (% by weight	Concentration molal m	Density (g/ml)	Specific volume (ml/g)	Apparent molar volume φ_V (ml/mole)	$\sqrt{m}$
1	2,85	0,07452	1,0212	0,97924	67,86	0,27
2	12,98	0,37863	1,1161	0,89598	70,60	0,61

The values of φ_V° and S_V were calculated from the formulas:

$$\varphi_V^\circ = \frac{\Sigma m \Sigma \varphi_V - \Sigma(\sqrt{m})\,\Sigma(\varphi_V\sqrt{m})}{n\Sigma m - [\Sigma(\sqrt{m})]^2}, \tag{3}$$

$$S_V = \frac{n\Sigma(\varphi_V\sqrt{m}) - \Sigma(\sqrt{m})\Sigma\varphi_V}{n\Sigma m - [\Sigma(\sqrt{m})]^2}. \tag{4}$$

As a result of the extrapolation the following value was found for the apparent molar volume of uranyl nitrate in aqueous solution:

$$\varphi_{V\,UO_2(NO_3)_2}^\circ = 65,9 \text{ ml/mole}$$

For the slope of the straight line we obtained the value $S_V = 5,23$.

7	4,53	0,12043	1,03550	0,96572	71,52	0,35
8	4,97	0,13270	1,03954	0,96196	70,28	0,36
9	7,16	0,19565	1,05940	0,94393	70,38	0,44
10	7,34	0,20103	1,06123	0,94230	69,70	0,45
11	12,38	0,35842	1,10934	0,90144	72,06	0,60
12	12,38	0,35842	1,10948	0,90132	71,68	0,60

The equation relating the apparent molar volume with molality will have the form:

$$\varphi_{V_{UO_2(NO_3)_2}} = 65{,}9 + 5{,}23\sqrt{m}. \qquad (5)$$

For the value of φ_V° found for $UO_2(NO_3)_2$, we may calculate φ_V° for the UO_2^{2+} ion. In the system of Fajans and Johnson [12] $\varphi^\circ_{V_{NO_3^-}} = 29{,}4$, so that:

$$\varphi^\circ_{V_{UO_2^{2+}}} = \varphi^\circ_{V_{UO_2(NO_3)_2}} - 2\varphi^\circ_{V_{NO_3^-}} = 65{,}9 - 58{,}8 = 7{,}1 \text{ ml/g-ion}$$

Hence, the apparent molar volume of the uranyl ion in infinitely dilute solution at 25° is 7.1 ml/g-ion.

SUMMARY

1. A description is given of the determination of densities of aqueous solutions with the aid of a single quartz pycnometer having a capillary neck. The determination is accurate within 0.001%.

2. The densities of aqueous uranyl nitrate solutions were investigated over the concentration range 0.7-52.4% by weight, the results being accurate within 0.01%.

3. The apparent molar volumes of uranyl nitrate in aqueous solutions at 25° were calculated. They can be expressed by the equation:

$$?_{V_{UO_2(NO_3)_2}} = 65{,}9 + 5{,}23\sqrt{m}.$$

4. The apparent molar volume of the uranyl ion UO_2^{2+} was calculated for infinitely dilute aqueous solution at 25°. In the system of Fajans and Johnson it is 7.1 ml/g-ion.

KINETICS OF THE OXIDATION OF ETHANE IN PRESENCE OF HYDROGEN BROMIDE

M. F. Sedova and N. M. Emanuel

The oxidation of hydrocarbons presents one of the simplest direct means of preparing important products of the heavy organic chemicals industry. However, in spite of the obvious advantages of using oxidation processes for the preparation of aldehydes, ketones, organic acids, alcohols, peroxides, etc., these processes have been realized in industry only in isolated cases.

The existence of this situation is in large measure due to inadequate progress in theoretical investigations into the kinetics and chemistry of oxidation reactions of hydrocarbons; and yet it is through such investigations that we may expect to discover the peculiar features of these oxidation processes, and such knowledge may enable us to make a fresh attack on the problem of the controlled oxidation of hydrocarbons and to solve it. The question of the suitability of a given oxidation process for use in manufacture is mainly resolved purely empirically at present. If change in reaction conditions (temperature, pressure, composition of original mixture, use of catalysts) makes it possible to obtain a satisfactory yield of the desired product, the question is considered to be solved. Such an approach to the solution of the problem is only a first approximation, and a more profound knowledge of the mechanisms of the oxidation processes must reveal new ways of bringing about the reactions, advantage being taken of one or other peculiarity of the mechanism.

In a recent paper [1] one of us discussed the problem of directing chemical reactions and suggested that a contribution to its solution might be made on the basis of the application of some new facts discovered in the homogeneous catalysis of the oxidation reactions of hydrocarbons [2,3]. It was noted that the initiating effect of additions of various substances (homogeneous catalysts) is often associated only with the initial stages of the oxidation processes. The oxidation process, initiated by the addition of a catalyst or initiator (if the added substance is used up) then proceeds as a sequence of two macroscopic stages. Under suitable conditions these stages may be somewhat separated in time, though even then, the second stage will begin while the first is proceeding. It is obvious that, when there is a sequence of macroscopic stages, the oxidation process should be carried out not under conditions that are strictly constant from beginning to end, but under conditions that change during the transition from one stage to the other, so that they are optimum conditions for both stages of the reaction.

The present investigation had the object of discovering the kinetic peculiarities of the oxidation processes of hydrocarbons in presence of hydrogen bromide, the example taken being the oxidation of ethane. The chemical possibilities of the oxidation of hydrocarbons in presence of hydrogen bromide were examined by Rust in a series of papers [4-7]. In our work, we proposed to verify the extent to which the phenomena of limited yields of products and sequences of macroscopic stages are to be found in the mechanism of catalysis with hydrogen bromide, such phenomena having been found in the oxidation of propane, which was investigated by one of us with coworkers [2,3]. Moreover, we wished to establish the kinetic laws of the oxidation reaction of ethane in presence of hydrogen bromide, no information on this being available in the literature.

EXPERIMENTAL

The kinetics of the oxidation of ethane in presence of hydrogen bromide were investigated in a static vacuum apparatus (Fig. 1). An equimolecular mixture of ethane and oxygen was prepared in the flask 1 and a sample was passed into the intermediate vessel 2 until the required pressure was reached, as shown by a mercury manometer. The mixture was transferred by a turn of a tap into the reaction vessel 3, into which, before experiment, hydrogen bromide was introduced from the flask 4. The reaction vessel (diameter 30 mm), which was of ordinary glass, was situated in an electric furnace, the temperature of which was measured with a thermocouple.

The change of pressure in the reaction vessel was observed with the aid of the membrane manometer 5. In order to avoid any distortion of the picture of the pressure variation during the process, due to condensation and partial dimerization of acetic acid at room temperature, the intermediate connections were provided with an electric heater and the manometer space was connected to the reaction vessel only at the moment when the pressure was measured. The apparatus was generally evacuated down to a high vacuum. It should be noted that the reaction studied was found to be only slightly sensitive to the degree of evacuation of the vessel before the experiment.

Fig. 1. Diagram of apparatus.

Samples for the analysis of condensable products were obtained by transference of the mixture from the reaction vessel to the trap 6, which was connected through ground joints; this was previously evacuated carefully and cooled. The products condensed in the trap were analyzed for acetic acid, HBr, bromine, aldehydes, and peroxides. Analysis for total acidity was carried out alkalimetrically, phenolphthalein being used as indicator. The hydrogen bromide content was determined by the Volhard method. The amount of acetic acid was determined from the difference between the total acidity and the hydrogen bromide content. Analysis for aldehydes, which was carried out by the hydroxylamine method after previous neutralization of the sample to bromophenol blue with alkali, did not show the presence of aldehydes in the mixture of products. Even the very sensitive qualitative test for aldehydes with Schiff's reagent was negative. The absence of aldehydes was established also polarographically. With the aid of the polarographic method we assured ourselves that organic peroxides were also absent. Analysis for bromine was carried out iodometrically, this being possible in view of the absence of peroxides. This method revealed the presence of a very slight amount of bromine, mainly formed at the beginning of the reaction when it was carried out at low temperatures (215°, 205°).

Kinetic Laws of the Reaction

The kinetics of the oxidation of ethane in presence of hydrogen bromide were studied at temperatures of 205-245° and at pressures of 100-200 mm. At lower temperatures reaction was too slow, and at higher temperatures it was explosive in vessels of ordinary glass. Reaction was accompanied by appreciable reduction in pressure. The change in pressure agreed fairly closely with the stoichiometric equation of the reaction.

$$C_2H_6 + 1.5O_2 = CH_3COOH + H_2O.$$

All the kinetic results given below were obtained by chemical analytical methods adapted to the peculiar requirements of gaseous reactions.

Most of the experiments were carried out at 230°. Fig. 2 shows typical kinetic curves for the formation of acetic acid at this temperature. In these experiments the total pressure of the mixture was kept constant at 200 mm, and the relative amounts of hydrogen bromide and the equimolecular mixture of ethane and oxygen were varied. The kinetic Curve 1 (Fig. 2), which is for a mixture of 80 mm C_2H_6, 80 mm O_2, and 40 mm HBr, was taken as standard, and all the other curves were compared with it. The remaining kinetic curves were obtained with reduced contents of hydrogen bromide and corresponding increased contents of the equimolecular mixture of ethane and oxygen. The compositions of the mixtures for which these kinetic curves were obtained are indicated below Fig. 2. These results confirm conclusions reported in the literature concerning the formation of acetic acid as the main product of the oxidation reaction in presence of hydrogen bromide. Polarograms

of the condensate of reaction products are "empty" with respect to organic peroxides and aldehydes.

Fig. 2. Kinetic curves for the formation of acetic acid in the oxidation of ethane in presence of various amounts of hydrogen bromide at 230° and p_0 200 mm: 1) 80 mm C_2H_6 + 80 mm O_2 + 40 mm HBr; 2) 85 mm C_2H_6 + 85 mm O_2 + 30 mm HBr; 3) 90 mm C_2H_6 + 90 mm O_2 + 20 mm HBr; 4) 95 mm C_2H_6 + 95 mm O_2 + 10 mm HBr.

Information on the consumption of hydrogen bromide during reaction under the conditions corresponding to Fig. 2 is of interest; this information is given in Fig. 3. As noted previously [8] for the oxidation of propane, hydrogen bromide is consumed only for a short time at the beginning of the reaction; its concentration then becomes constant during the further course of the process (Fig. 2, Curve 3). Owing to the small scale on which the consumption of hydrogen bromide occurs, it is impossible to arrive at any conclusion concerning the kinetic law of its reaction and of the formation of organobromine compounds.

It is evident that the lower the content of hydrogen bromide in the mixture, the less of it is used in the formation of organobromo compounds. In the case of the formation of acetone by the oxidation of propane in presence of hydrogen bromide it was shown that the formation of bromo compounds was a side reaction when considered in relation to the formation of acetone. The formation of the main reaction product, acetone, bore practically no relation to the consumption of hydrogen bromide. In view of the fact that an identical kinetic picture was found in the oxidation of ethane, there is every reason to suppose that the formation of acetic acid also does not demand the consumption of hydrogen bromide, the consumption of which is associated with a side reaction in which bromo compounds are formed.

Fig. 3. Consumption of hydrogen bromide in the oxidation of ethane in mixtures differing in initial HBr content. The mixtures are 80 mm C_2H_6 + 80 mm O_2 + the following amounts of HBr: 1) 40 mm; 2) 30 mm; 3) 10 mm.

It is important to note that with further increase in the hydrogen bromide content, the consumption of hydrogen bromide does not increase (Fig. 4). These experiments were carried out at 230°; a constant amount of an equimolecular mixture of ethane and oxygen (80 mm C_2H_6 + 80 mm O_2) was taken, and to this hydrogen bromide was added in greater and greater amounts (from 10 to 90 mm). In the same experiments the yields of acetic acid were determined at the end of the reaction, and the results again confirmed the existence of a limit to the extent to which the original fuel will enter into oxidation reactions [9] (about 50% of the fuel is consumed). Our experiments provided a further, very clear demonstration of this widely found phenomenon, the mechanism of which has not yet been elucidated. Fig. 5 shows the relation between the yields of acetic acid and the hydrogen bromide content of the mixture. It will be seen that, with additions of hydrogen bromide corresponding to pressure increases of more than 30-35 mm, the yield of acetic acid ceases to rise, its value then being 32 mm, i.e. 40% on the original ethane. When we take account of the fact that the formation of acetic acid is accompanied by the formation of a certain amount of other oxidation products, it is again evident that not more than 50% of the original hydrocarbon reacts in the oxidation process.

It is important to note that kinetic curves of the type shown in Fig. 2 are obtained not only when the catalyst content of the mixture is varied, but also when the relative amounts of the other components (ethane and oxygen) are varied. Fig. 6 shows the kinetic curves determined for constant catalyst content (40 mm HBr) and total pressure of the mixture (p_0 = 200 mm), but varying relative amounts of ethane and oxygen. Both the course of the kinetic curves and the yields of acetic acid were completely identical for both cases, but the extent of reaction was less than for the standard mixture (80 mm C_2H_6 + 80 mm O_2 + 40 mm HBr). It was found that ethane and oxygen – at least, for variation of concentration over the range indicated – behave identically. It is

important only that both of these components should be present.

It is notable that the kinetic curves in Figures 2 and 6 are reminiscent of the kinetic curves of reactions of simple types, in spite of the fact that we are dealing with a complex three-component system. It is easy to show that all the kinetic curves in Figures 2 and 6 can be brought into coincidence with one of them, say Curve 1 in Fig. 2, by simple change in the scale of ordinates. The result of such a superposition is shown in Fig. 7, in which the method of distinguishing the points is the same as in Figures 2 and 6. It is not difficult to show that the formation of acetic acid at 230° is described satisfactorily by the kinetic law of a first-order reaction:

$$p_{CH_3COOH} = (p_{CH_3COOH})_\infty (1 - e^{-kt}) \qquad (1)$$

with this difference, however, that as a measure of complete conversion we take not the initial concentration of one of the reactants, but the amount of the final reaction product formed toward the end of the process $(pCH_3COOH)_\infty$.

Fig. 4. Consumption of hydrogen bromide at different contents of catalyst in the original mixture.

Fig. 5. Relation between the yield of acetic acid in the oxidation of ethane and the HBr content of the mixture. The limit phenomenon for the conversion of ethane into acetic acid.

Fig. 6. Kinetics of the formation of acetic acid in the oxidation of ethane in presence of hydrogen bromide for different relative amounts of ethane and oxygen in the original mixture: Δ) 120 mm C_2H_6 + 40 mm O_2 + 40 mm HBr; □) 40 mm C_2H_6 + 120 mm O_2 + 40 mm HBr.

Fig. 7. Superposition of kinetic curves for the formation of acetic acid at 230° from different proportions ethane, oxygen, and hydrogen bromide with the kinetic Curve 1 in Fig. (2).

If we write $$\frac{p_{CH_3COOH}}{(p_{CH_3COOH})_\infty} = \alpha, \qquad (2)$$

then the first-order equation can be written

$$\alpha = 1 - e^{-kt}. \qquad (3)$$

In this form the fundamental property of unimolecular reactions can be clearly seen: the time required for a definite degree of conversion α to be attained does not depend on the initial concentration of the reactant (in our case, on the final yield of acetic acid) and is determined only by the value of k. In fact,

$$t_\alpha = \frac{1}{k}(1-\alpha), \qquad (4)$$

i.e. in the expression for t_α there are no quantities other than α and k (which is determined by the temperature).

In Fig. 8. the kinetic curve of Fig. 7 is presented in the coordinates log $(1-\alpha)$ and t. The linearity of this relationship is a good illustration of the applicability of the first-order law to the description of the kinetics of the reaction. This result is seen to be very important when examined in the light of the analogy with the kinetic law for the formation of acetone in the oxidation of propane in presence of hydrogen bromide. It is indeed surprising that it is not the initial concentration of a reactant that enters the first-order equation, but the concentration of a product at the end of the reaction. By making use of the analogy with the oxidation reaction of propane, we may form an idea of what kind of mechanism can lead to the kinetic laws observed in the experiments. Let us suppose that, in the initial period of the reaction, a macroscopic reaction occurs which is fairly fast, does not occur on a very large scale, and is markedly self-retarding. We will assume that this initial reaction results in the formation of some intermediate Product I of as yet unknown chemical identity in a concentration of I_0. We will assume also that the intermediate Product I, in decomposing in accordance with a unimolecular law

$$I = I_0 e^{-kt}, \qquad (5)$$

forms an ethyl radical C_2H_5 in each act of decomposition:

$$I \rightarrow C_2H_5.$$

The C_2H_5 radical initiates an oxidation chain:

$$C_2H_5 + O_2 \rightarrow C_2H_5O_2;$$

$$C_2H_5O_2 + C_2H_6 \rightarrow C_2H_5O_2H + C_2H_5;$$

$$C_2H_5O_2H \rightarrow CH_3CHO + H_2O$$

$$(\text{or } C_2H_5O_2 \rightarrow CH_3CHO + OH$$

$$OH + C_2H_6 \rightarrow C_2H_5 + H_2O),$$

$$2CH_3CHO + O_2 (\text{in presence of HBr}) \rightarrow 2CH_3COOH.$$

Hence, at each act of decomposition of the intermediate Product I, a chain of reactions is formed and results in the formation of acetaldehyde, which is very rapidly oxidized to acetic acid in presence of hydrogen bromide [10].

If the chain length is ν, then in the decomposition of $I_0 - I$ molecules of the intermediate product

$$(I_0 - I)\nu = I_0\nu(1 - e^{-kt}) \qquad (6)$$

molecules of acetic acid are formed. When we compare Equations 1 and 6, we see that they are completely identical, $(pCH_3COOH)_\infty$ being equal to $I_0\nu$. In other words, the yield of acetic acid at the end of the reaction $(pCH_3COOH)_\infty$ is directly related to the initial concentration of the intermediate product I_0. Hence, the peculiar form of the first-order law (1) receives a simple explanation.

Less definite conclusions can be drawn from a study of the kinetics of the reaction at different temperatures. Above 230° the first-order law for the formation of acetic acid still holds as before (Fig. 9). Below 230°, however, there are departures from this law (Fig. 10), and the curve determined at 205° is a typical kinetic curve for a zero-order reaction.

Hence, our results indicate a change in the kinetic law with fall of temperature (transition from a first-order to a zero-order law). As the kinetic law of the reaction is different at different temperatures, it did not appear to be possible to calculate the activation energy of the process from the temperature-dependence of the rate constant k. An evaluation of the activation energy from the two constants $k_{230°} = 0.84 \cdot 10^{-2}$ second $^{-1}$ and $k_{245°} = 1.2 \cdot 10^{-2}$ second $^{-1}$ gives the value E = 23 kcal/mole. This value for the activation energy is fairly close to that obtained for the oxidation of propane in presence of hydrogen bromide (25 kcal/mole).

Fig. 8. Semilogarithmic anamorphosis of the kinetic curve of Fig. 7.

Fig. 10. Kinetic curves for the formation of acetic acid at: 1) 205°; 2) 215°.

Fig. 9. Kinetic curve for the formation of acetic acid at 245°.

A study was made also of the effect on the reaction of additions of the final product (acetic acid), and also of acetone and acetaldehyde. The additives were held in the flasks indicated as 7 and 8 in the diagram of the apparatus. Acetone was added with the object of determining whether this substance is a specific "poison" for all oxidation reactions carried out in presence of hydrogen bromide. It was hoped that the experiments with acetaldehyde would provide further confirmation of our conclusion that acetaldehyde is very rapidly oxidized to acetic acid in presence of hydrogen bromide.

It is shown that additions of acetic acid, though in very small amount (11.2 mm, which corresponds to the saturated vapor pressure of acetic acid at room temperature), have no effect on the final yield of acetic acid. In other words, the amount added simply forms an addition to the amount of acetic acid formed as a result of the reaction. It must be pointed out, however, that the addition of acetic acid was small, and the experiments on the addition of acetic acid must be regarded as preliminary work.

The experiments on the addition of acetone were almost negative. Acetone, therefore, is not a specific "poison", general for all oxidation reactions of hydrocarbons in presence of hydrogen bromide. The experiments with additions of acetaldehyde (about 5 mm) showed that the whole of the added acetaldehyde was rapidly oxidized to acetic acid, without having any supplementary initiating effect on the oxidation process. Hence, a stage in which acetaldehyde formed as an intermediary in the oxidation of ethane, is rapidly converted into acetic acid is quite possible when hydrogen bromide is present in the system.

Sequence of Macroscopic Stages in the Mechanism of the Reaction

In previous investigations [3,11], the method used for determining the sequence of macroscopic stages in oxidation reactions of hydrocarbons initiated by homogeneous catalysts was based on a study of the heat evolved in the reaction mixture during the reaction, and the scheme of procedure proposed by Kovalsky and Bogoyavlenskaya [12] was adopted. In our work we adopted the same scheme of procedure. If a homogeneous reaction associated with evolution of heat is proceeding in a gas, then under stationary conditions the temperature distribution over the radius of a cylindrical reaction vessel will be determined by a known differential equation:

$$\frac{d^2T}{dr^2} + \frac{1}{r}\cdot\frac{dT}{dr} + \frac{q_v}{\lambda} = 0, \qquad (V)$$

in which T is the temperature of the reaction mixture at a distance r from the center, λ is the thermal conductivity, q_1 is the heat evolved by chemical reaction in 1 cc of the mixture per second. Assuming, as is usual, that q_1 is independent of temperature, and setting the limiting conditions: 1) $T = T_0$ when $r = R$ (T_0 is the temperature of the walls of the vessel, and R is the radius of the vessel); 2) $\left(\frac{dT}{dr}\right)_{r=0} = 0$ (maximum temperature in the center of the vessel), we obtain the following integral for the differential equation (7):

$$T - T_0 = \frac{q_1}{4\lambda}(R^2 - r^2). \tag{8}$$

The rise in temperature in the center, on the axis of the vessel, will be

$$\Delta T_m = \frac{q_1}{4\lambda} R^2. \tag{9}$$

The rate of evolution of heat q_1 is equal to the product of the reaction rate w and the heat of reaction Q of the corresponding process, provided that these quantities are expressed in corresponding units. If the rate of the chemical reaction w is expressed in millimeters of mercury per second for an experiment carried out at a temperature of T_1, then we obtain the following expression for ΔT_m:

$$\Delta T_m = \frac{QwR^2}{4 \cdot 760 \cdot 22\,400 \cdot \lambda} \cdot \frac{273}{T_1}. \tag{10}$$

In calculations from this formula, Q must be expressed in cal/mole and λ in cal/cm. sec. degree. It will be seen from Equation 10 that, in determining the rise in temperature ΔT_m in the center of the vessel as a function of time, we are in fact measuring the reaction rate w, which is proportional to this rise. It will be clear that, if there is a sequence of macroscopic stages separated in time in the process studied, then, in studying the warming up of the reaction mixture during the reaction, we may hope to register two processes of heat evolution reflecting the existence of these stages. This hope was in fact realized in the study of the oxidation of propane to acetone in presence of hydrogen bromide.

The oxidation of ethane to acetic acid is accompanied by evolution of heat (Q = 144 kcal/mole). On analogy with the oxidation reaction of propane, it may be supposed that the initiating reaction, which is probably a branched-chain oxidation process, will also be associated with evolution of heat. We made a continuous photorecord of the galvanometer readings of the thermocouple current corresponding to the different values of ΔT_m during the reaction (composition of mixture: 100 mm C_2H_6 + 100 mm O_2 + 50 mm HBr). The very first photorecord that we made of the reaction at 266° showed two clearly defined maxima on the heat-evolution curve (Fig. 11). Timing marks (the vertical lines) are made every 30 seconds. It will be seen from the photorecord that, in the case under examination, in spite of the fairly high temperature, the initiating reaction – though rapid in comparison with the process as a whole – is still somewhat slow. For this reason the kinetic curve for the formation of acetic acid (in the vessel in which this study of heat evolution in the initial stage of the process was made) departs somewhat from the form required for a first-order law and approximates to a kinetic curve of the type shown in Fig. 10, i.e. to a curve for a zero-order reaction. It must be pointed out that the vessel in which the heat evolution was studied was made of quartz glass, whereas previous experiments were carried out in a vessel of ordinary glass. It is notable, however, that the fall of the heat-evolution curve after the second maximum (Fig. 11), i.e. definitely after the completion of the initiating reaction, corresponds with extreme exactness to the law

$$\Delta T_m \sim e^{-kt}, \tag{11}$$

which corresponds to a unimolecular law for the decomposition of the intermediate reaction product. The value of k, which is determined from the slope of the semilogarithmic anamorphosis of the fall on the heat-evolution curve, is found to be $2.6 \cdot 10^{-2}$ second $^{-1}$. Also, from the values of the constant found for 230° and 245°, it may be inferred that a value of $2.9 \cdot 10^{-2}$ second $^{-1}$ is to be expected at 266°. This agreement between the constants for the rate of decomposition of the intermediate compound in completely different vessels indicates the homogeneous character of this reaction and of the associated process of formation of acetic acid.

The conclusion that the second stage is homogeneous is confirmed also by a comparison between the heat evolution calculated on the assumption of a completely homogeneous reaction and the heat evolution observed

experimentally. Substituting in Equation 10 the mean value of the thermal conductivity of the reacting gases (ethane, oxygen, hydrogen bromide) $\lambda \approx 8 \cdot 10^{-5}$ cal/cm. sec. degree, $Q = 144000$ cal/mole, $T_i = 539°K$, $R = 1.5$ cm, and the rate of formation of acetic acid corresponding to the time of attainment of the second maximum of heat evolution, which was found to be $\underline{w} = 0.22$ mm/second, we find that

$$\Delta T_m = \frac{144\,000 \cdot 0{,}22 \cdot 2{,}25 \cdot 273}{4 \cdot 760 \cdot 22\,400 \cdot 8 \cdot 10^{-5} \cdot 539} = 6{,}8°.$$

Experiment gives $\Delta T_m = 7.0°$, the agreement being extremely close.

As regards the nature of the initiating reaction, it is undoubtedly a homogeneous-heterogeneous process. The high sensitivity of the extent and duration of the initiating reaction to the state of the vessel surface indicates that its mechanism includes elementary processes associated fundamentally with the wall. At the same time the considerable rise of temperature at the central thermocouple indicates a predominant homogeneous component in the initiation process. Thus, a study of heat evolution in the reaction mixture during the reaction permitted us to establish that, in this case also, there is a sequence of macroscopic stages, displaced from one another in time, in the mechanism of the catalytic process.

Fig. 11. Photorecord of heat evolution in the reacting mixture of 266°.

SUMMARY

1. A study was made of the kinetic laws of the oxidation of ethane to acetic acid in presence of hydrogen bromide. It was shown that the process of acetic acid formation comes to an end long before the reactants are used up. Such "limit phenomena" are explained on the basis of the existence of an initiating reaction that results in the formation of an intermediate product, the amount of which determines the yield of acetic acid.

2. It was established that, whatever method is adopted for initiating the oxidation process by additions of catalyst (hydrogen bromide), the yield of acetic acid cannot be raised above 40% on the amount of ethane taken. The generality of the phenomenon was pointed out; it is found in other slow-oxidation reactions.

3. With the aid of a method based on the study of the evolution of heat in the reaction mixture during the reaction it was shown that the mechanism of the reaction includes a sequence of two macroscopic stages displaced from one another in time. The first stage – the initiating reaction – is a homogeneous-heterogeneous process. The second stage – the formation of acetic acid initiated by the decomposition of the intermediate product obtained in the first stage – is a homogeneous process. These results confirm the prevalence of the phenomenon of successive macroscopic stages in oxidation processes initiated by additions of homogeneous catalysts.

RELATION BETWEEN THE CATALYTIC ACTIVITY OF BINARY COMPOUNDS OF GROUP II METALS WITH NONMETALS AND THE POSITIONS OF THE ELEMENTS IN MENDELEEV'S PERIODIC SYSTEM

COMMUNICATION 1. CATALYTIC DECOMPOSITION OF ISOPROPYL ALCOHOL OVER ALKALINE-EARTH OXIDES

O. V. Krylov, S. Z. Roginsky, and E. A. Fokina

The comparative study of the two directions of decomposition of isopropyl alcohol over various catalysts

$$C_3H_7OH \rightarrow CH_3COCH_3 + H_2 \quad (1)$$

$$C_3H_7OH \rightarrow CH_3CH=CH_2 + H_2O \quad (2)$$

is of great interest for the elucidation of the laws governing the selection of catalysts. In this case, to the usual criterion of catalytic activity we must add selectivity criteria.

According to the classification of catalytic reactions developed in our laboratory [1,2], the first of these reactions (dehydrogenation) can be treated as a reaction of the oxidation-reduction (electronic) type. The data of Myasnikov and Pshezhetsky on the proportionality between the electrical conductivity of zinc oxide and its catalytic activity in this reaction [3] confirm this view. It is natural to regard the second direction of decomposition (dehydration) to be a reaction of the acid-base (ionic) type. This view is confirmed by the considerable increase in decomposition in this direction under the action of small amounts of acids and acid salts held by the catalyst [4,5].

It appears, therefore, that the two directions of decomposition, corresponding to Equations 1 and 2, are representative of two main types of catalysis mechanisms. If this inference is true, the ratio of the rates of the two reactions can be used to characterize the relative efficiencies of a given catalyst in the promotion of the two types of reactions – oxidation-reduction and acid-base.

For our problem, solids of marked chemical properties are of primary interest. The papers that have appeared on the alcohol-decomposition reaction [6-8] contain many data on the catalytic properties of typical acid oxides and oxides of the transitional elements, but there is an almost complete absence of information on the catalytic properties of oxides of the alkaline type (oxides of alkali and alkaline-earth metals) in this process. As a part of the scheme for the systematic study of the dependence of the catalytic properties of solids on the positions of the elements forming them in Mendeleev's periodic system, it was desirable to fill this gap in our knowledge. The present investigation was devoted to a study of the decomposition of isopropyl alcohol over alkaline-earth oxides – CaO, SrO, and BaO.

As alkaline-earth oxides readily absorb water vapor and carbon dioxide, it was necessary to take account of the possibility that the catalytic reaction would occur not only on the surface of the oxide, but also on a carbonate or hydroxide film. Supplementary experiments were therefore carried out on the decomposition of isopropyl alcohol on the corresponding hydroxides and carbonates.

EXPERIMENTAL

Preparation of catalysts. Two samples of calcium oxide were used. The first sample was prepared from the hydroxide by calcination in a vacuum at 800°, the hydroxide being first prepared by the action of steam at 100° on calcined calcium oxide. The second sample was laboratory-reagent calcium oxide (chemically pure grade). Strontium oxide was prepared by precipitation of the hydroxide from strontium nitrate solution with caustic soda, washing of the precipitate, and calcination in a vacuum at 800°. Barium oxide was prepared by decomposition of the peroxide in a vacuum at 800°. The following catalysts were also tested: calcium hydroxide, prepared by precipitation from calcium nitrate solution with caustic soda and washing with water with exclusion of carbon dioxide; barium carbonate (chemically pure grade); and calcium carbonate (chemically pure grade).

Fig. 1. Diagram of flow apparatus for the study of the catalytic decomposition of isopropyl alcohol: (a) manostat; (b) vessel containing silica gel for purifying the air; (c) apparatus for introduction of alcohol; (d) quartz reactor; (e) traps for freezing out liquid reaction products; (f) gas analyzer; (g) calibrated gas holder for collecting gaseous reaction products.

The surface areas of the catalysts were determined on a quartz spring balance by measuring the adsorption of n-heptane vapor at 20°. The area occupied by a heptane molecule was taken to be 59 A^2 [9]. Calculations based on the resulting adsorption isotherm were made by the "BET" method. Depending on the sensitivity of the quartz spring used, the determined specific surfaces were accurate within 2-8 m^2/g.

Before being introduced into the reactor, the catalyst was kneaded with anhydrous isopropyl alcohol and made into tablets, 3-4 mm in diameter and 5-7 mm in length. In some experiments larger tablets were used (up to 10 mm in diameter). Increase in the size of the tablets had practically no effect on the character of the catalytic decomposition of isopropyl alcohol; this fact appears to exclude the possibility that the rate of the process may be controlled by diffusion.

Decomposition of isopropyl alcohol. The reaction was studied in a flow apparatus, which is shown diagrammatically in Fig. 1. The introduction of the alcohol was effected automatically with the aid of compressed air at constant pressure. The rate at which the alcohol was introduced varied from 0.07 to 1.08 ml/minute in various experiments, and in the majority of the experiments it was in the narrower range of 0.27-0.32 ml/minute. The catalyst (25 ml) was placed in a quartz reactor and was covered with a layer (15-20 mm) of broken quartz in order to ensure complete evaporation of the isopropyl alcohol and the better distribution of its vapor through the catalyst. Before the experiment the isopropyl alcohol (chemically pure grade) was allowed to stand over anhydrous copper sulfate and was then distilled (b.p. 81-82°). The temperature was maintained constant within 0.5° with the aid of an ERM-47 thermoregulator. The condensable reaction products and unchanged alcohol were frozen out in two traps cooled with snow. The gaseous reaction products were analyzed continuously with the aid of a gas analyzer based on the measurement of the thermal conductivity of the mixture

and calibrated with various hydrogen-propene mixtures. Also, determinations were made periodically in order to find the content of unsaturated hydrocarbons in the gas; the analysis was carried out in a "VTI" apparatus with bromine water or a solution of mercuric sulfate in concentrated sulfuric acid.

Experimental Results

The table gives the results of experiments on the catalytic decomposition of isopropyl alcohol over the catalysts studied. Column 4 of the table gives the overall rate of gas formation (propene + hydrogen). Column 5 gives the percentage content of unsaturated compounds (propene) in the gas. The figures given here refer to the stationary state, which was generally established after 0.5-2 hours. During this period there was a small fall in the reaction rate and an increase in the yield of unsaturated hydrocarbons. It should be noted that this change in the reaction rate at the beginning of the process was considerably less than that generally observed in the decomposition of alcohols on acid oxides and oxides of transition metals. No carbonization of the catalyst was observed, and there was no visible change in its color. Nevertheless, before each experiment– to remove adsorbed compounds and to bring the catalyst into a standard condition– air was blown over the catalyst at 500°. Columns 6 and 7 give values of the activation energies for dehydrogenation E_{H_2} and for dehydration E_{H_2O} in cal/mole; they were calculated from graphs for the relation between the logarithm of the rate of formation of hydrogen or propene, respectively, and the reciprocal of the temperature (the rate of passage of alcohol being constant). A study of the relation between the rate of gas formation and the time of contact (determined from the rate of passage of alcohol) showed that, at low and medium rates of passage of alcohol, the decomposition follows a first-order law. This fact enables us to calculate activation energies directly from the data presented in the table. The last column gives values of the "selectivity coefficient", which is the ratio of the yield of hydrogen to that of propene at the given temperature (calculated directly from the data in Column 5).

Fig. 2. Determination of the activation energies for the dehydrogenation of isopropyl alcohol over the catalysts: 1) imported CaO; 2) SrO; 3) BaO; 4) $Ca(OH)_2$; 5) $CaCO_3$; 6) $BaCO_3$.

Fig. 3. Determination of the activation energies for the dehydration of isopropyl alcohol over the catalysts: 1) imported CaO; 2) SrO; 3) BaO; 4) $CaCO_3$; 5) $BaCO_3$.

Fig. 2 gives the straight-line graphs for the relation between the logarithm of the rate of gas formation and the reciprocal of the temperature, and, with the aid of these, values of the activation energy for dehydrogenation were calculated. Fig. 3 gives the corresponding straight lines for the calculation of the activation energies for dehydration. The points in Fig. 3 have a wider scatter than those in Fig. 2, this being due to the inadequate accuracy of the experiment.

These experimental data show that the oxides of the main sub-group of Group II of the periodic system have appreciable catalytic effect on the decomposition of isopropyl alcohol. These oxides (CaO, SrO, and BaO), like the oxides of elements of the secondary sub-group [6,7,8], have a predominantly dehydrogenating effect. The activation energy for dehydrogenation is not great; ranging from 6000 cal/mole for BaO to 16,000 cal/mole for CaO obtained by decomposition of the hydroxide. The activation energy for dehydration is high

TABLE

Experimental Results on the Decomposition of Isopropyl Alcohol over Alkaline-earth Oxides and Their Derivatives

Catalyst	Temperature (°C)	Specific surface (sq.m/g)	Rate of gas formation (ml gas per ml alcohol per minute)	Propene content of gas (%)	Activation energy for dehydrogenation E_{H_2} (cal/mole)	Activation energy for dehydration E_{H_2O} (cal/mole)	Selectivity coefficient K_{H_2}/K_{H_2O}
1	2	3	4	5	6	7	8
Imported CaO	314	18	8	2.3	12 000	22 000	43
	384		17	4.9			19

	404	< 5	33	60.5			0.65
	454		100	47			1.13

— much higher than the activation energy for dehydrogenation. No obvious regularity is to be observed in selectivity in the series CaO, SrO, BaO. It can be seen that the activation energy — both for dehydrogenation and for dehydration of isopropyl alcohol — is considerably lower on barium oxide than on calcium and strontium oxides. On the other hand, these quantities are the same order for calcium and strontium oxides. In spite of the low value of activation energy for dehydrogenation over barium oxide, the "selectivity coefficient" over barium oxide has only about one-tenth of its value over calcium and strontium oxides. This indicates that the variation in selectivity is determined not only by the activation energies E_{H_2} and E_{H_2O}, but also by the pre-exponential factors K_{H_2} and K_{H_2O}. The overall rate of decomposition of the alcohol (rate of gas formation); expressed per unit surface area at the given temperature, rises in the series CaO, SrO, BaO, i.e. with rise in the atomic weight of the metal.

On freshly prepared calcium hydroxide the rate and selectivity of the process are close to the corresponding characteristics for the decomposition of the alcohol on the pure oxide. The activation energy for dehydrogenation over the hydroxide is very close to E_{H_2} over calcium oxide. Dehydration proceeds very feebly. Over the temperature range studied, the rate of dehydration over carbonates is close to the rate of dehydrogenation. This catalyst differs greatly from the others in that the activation energy for dehydrogenation is high and is considerably higher than the activation energy for dehydration, and the selectivity coefficient is close to or less than unity.

Discussion of Experimental Results

The closeness of the activation energies for dehydration over carbonates (24,000 cal/mole for $CaCO_3$

and 17,000 cal/mole for $BaCO_3$) to the corresponding values for oxides (22,000-26,000 cal/mole for CaO and 12,000 cal/mole for BaO) makes it probable that the slight dehydration over alkaline-earth oxides (considerable in the case of BaO) is due to partial coverage of the oxides with a carbonate film; in themselves, the oxides have very marked dehydrogenating action. This is probably a special case of the effect of captured anions on the catalytic properties of solids. It is probable that this effect is met in catalysis just as frequently as the effect of cations, but the deforming action of the latter is stronger owing to their smaller radii and is therefore more frequently observed. The position of hydroxides is different; they are always present during the catalytic decomposition of alcohols because water is one of the decomposition products and the equilibrium temperature for the decomposition of the hydroxide is higher than the reaction temperature. The closeness of the values of the activation energies for dehydration over CaO (12,000-16,000 cal/mole) and over $Ca(OH)_2$ (16,000 cal/mole) confirms this view.

The powerful catalytic dehydrogenating action that we have found in solid alkalis used as catalysts for the decomposition of alcohols does not appear to have been specially emphasized by anyone previously. We know only of an observation by Eucken [7], who noted the 100% predominance of dehydrogenation in the decomposition of ethanol over calcium oxide. In this connection we may mention that Zhabrova and Kutseva, in collaboration with one of the present authors [4], showed that the dehydrogenating action of zinc oxide was increased by alkaline additions. The presence of alkaline additions may be the explanation also of the increase in dehydrogenating power observed when alumina prepared by alkaline precipitation was ignited in the experiments of Boreskov and coworkers [10]. Owing to the reduction in the surface area during ignition, the surface concentration of alkali might have been increased in this sample. According to the results of Ohta and Sato [11], the alkaline treatment of metal catalysts suppresses the dehydration of cyclohexanol, but does not affect the rate at which it is dehydrogenated.

Until now, attention has generally been turned on the poisoning effect of alkalis on acidic catalysts (mainly aluminosilicate catalysts for the cracking of hydrocarbons). However, isolated examples can be found in the literature in which alkaline additions have powerful promoting effects on other reactions, which, according to the accepted classification, belong to the oxidation-reduction (electronic) type. For example, alkaline additions increase the activity of oxide catalysts for the synthesis of hydrocarbons from carbon monoxide and hydrogen [12] and for the synthesis of alcohols [13], and they increase also the activity of metal catalysts in hydrogenation reactions [14]. Alkalis accelerate the decomposition of hydrogen peroxide [15] and of ozone [16]. The results of some Japanese investigators indicate that alkalis have an accelerating effect also on some reactions of solids having a similar mechanism to oxidation-reduction reactions. Thus, exchange between oxygen and water proceeds considerably more rapidly on alkaline-earth oxides then on any other oxides, including electronic semiconductors [17]. Alkaline additions accelerate the surface oxidation of carbon [18] and the reduction of ferric oxide with carbon [19].

Comparison of the data in the literature with our results on the dehydrogenation of isopropyl alcohol over solid alkalis leads to the view that catalysis over alkalis is a very prevalent phenomenon. It is a phenomenon that has received very little study, owing to the fact that special methods are required for bringing it about; this arises from the difficulty of preparing alkaline catalysts of high specific surface and the difficulty of keeping them unchanged over a long period. It is probably for this reason that such catalysis has not found wide use in industry. The existence of a special kind of catalysis over alkalis is supported by the rise in catalytic activity with increase in the alkalinity of the oxide in Group II of the periodic system (with increase in the atomic weight of the metal forming the oxide).

Various mechanisms may lie behind the catalytic activity of alkalis:

1. The usual acid-base interaction is possible; with proton transfer as for acid catalysts, but in the opposite direction.

2. Alkaline-earth oxides may act as electronic oxides – semiconductors – with electron transfer at the determining stage. It should be noted that, according to the investigations of Hauffe and Tranckler [20], calcium oxide has semiconductor properties and, under various conditions, can be both an electronic and a "hole" semiconductor. It is not clear, however, whether such a mechanism is possible for the hydroxides $M(OH)_2$, which, according to our results, act in the same way as the oxides MO.

3. It is possible, however, that there is no real antithesis between the first two mechanisms, there being some sort of correlation between the electron-hole and acid-base properties of a solid body. According to the

theory of electrophilic and nucleophilic reactions, there is no fundamental difference between oxidation-reduction and acid-base reactions; but acid and base, on the one hand, and oxidizing agent and reducing agent, on the other, are only special cases of the more general concept of donor and acceptor.

In order to make a choice between these possibilities it is necessary in the first place to carry out experiments with other, still stronger alkalis derived from metals of Group I of the periodic system; such experiments will at the same time indicate the prevalence of catalysis among solid alkalis. It is desirable also to measure the electrical properties of the solid alkaline hydroxides MOH and $M(OH)_2$, though this task will meet great experimental difficulties.

SUMMARY

1. The catalytic activity and selectivity of calcium, strontium, and barium oxides, calcium and barium carbonates, and calcium hydroxide in the decomposition of isopropyl alcohol were studied at atmospheric pressure over the temperature range 314-460° in a flow apparatus.

2. In the series CaO, SrO, BaO the catalytic activity of the oxide rises with increase in the atomic weight of the metal. Over all these oxides, dehydrogenation predominates over dehydration. The activation energies for dehydrogenation over the oxides are less than the activation energies for dehydration.

3. The activation energy for the dehydration of isopropyl alcohol is the same over the oxides of the alkaline-earth metals as it is over the corresponding carbonates. On the basis of this fact it is suggested that carbonate impurities present in the oxides are responsible for dehydration.

4. In the decomposition of isopropyl alcohol over calcium oxide and calcium hydroxide, the activation energies for dehydrogenation are very close in value (12,000-16,000 cal/mole).

5. Data from the literature on the catalytic properties of alkalis are examined. It is suggested that alkaline catalysis is very widespread.

2-AMINOVINYL KETONES

COMMUNICATION 5. ALKYLATION OF 2-DIALKYLAMINOVINYL KETONES. NEW SYNTHESIS OF HYDROXYMETHYLENE KETONES

N. K. Kochetkov, M. G. Ivanova, and A. N. Nesmeyanov

2-Dialkylaminovinyl ketones, which have become accessible owing to the development of a convenient method for their synthesis in our laboratory [1], are highly reactive and are of interest on account of their application in organic synthesis. One of us recently described the reaction of 4-dimethylamino-3-buten-2-one with methyl iodide [2]; this proceeds with transfer of the reaction center, and hydrolysis of the reaction product gives the hydroxymethylene ketone 4-hydroxy-3-methyl-3-buten-2-one:

$$CH_3COCH=CHN(CH_3)_2 + CH_3I \rightarrow CH_3COCH(CH_3)-CH=\overset{+}{N}(CH_3)_2I \xrightarrow{-H_2O} CH_3COC(CH_3)=CHOH + NH(CH_3)_2 \cdot HI.$$

Apart from its theoretical importance, this reaction is of interest from the preparative point of view, since it opens the way to the synthesis of hydroxymethylene ketones. Until now, hydroxymethylene ketones have been prepared exclusively by Claisen formylation of the corresponding ketones [3]. A disadvantage of this method is its equivocality, as a result of which either a mixture of the two possible formylation products is obtained [4], or the hydroxymethylene ketone obtained must be investigated in order to determine its structure, since the position at which the formylation of an unsymmetrical ketone will occur cannot always be predicted [5].

We have now made a more detailed study of the alkylation of 2-dialkylaminovinyl ketones, and we have also extended the method of preparation of the latter [1], particularly to the synthesis of aryl 2-dialkylaminovinyl ketones. Our study of the alkylation of alkyl 2-dimethylaminovinyl ketones with methyl iodide showed that the reaction is general and can form the basis of a new method of synthesizing hydroxymethylene ketones:

$$RCOCH=CHN(CH_3)_2 + CH_3I \rightarrow RCOCH(CH_3)-CH=\overset{+}{N}(CH_3)_2\bar{I} \xrightarrow{H_2O} RCOC(CH_3)=CHOH.$$

In this way we prepared the following hydroxymethylene ketones in 35-55% yield: 1-hydroxy-2-methyl-1--hexen-3-one, 1-hydroxy-2,5-dimethyl-1-hexen-3-one, and 1-hydroxy-2-methyl-1-octen-3-one. It was found that to obtain the most satisfactory result it is not necessary to isolate the intermediate alkylation product, as it was thought to be earlier [2]; it is better to submit the reaction mixture obtained in the alkylation directly to hydrolysis. It is better to carry out the alkylation itself at a high temperature, the mixture of the dialkylaminovinyl ketone and excess of methyl iodide being heated for several hours in autoclave at 100-110°. This gives higher yields than alkylation in boiling methyl iodide [2], for in the latter case the yields of hydromethylene ketones do not exceed 20%.

The hydroxymethylene ketones so obtained are colorless oils, which change slowly when kept. They give a violet color with ferric chloride and form crystalline complex copper salts, which can be used for their identification. In order to prove the structure of these compounds, one of them – 1-hydroxy-2,5-dimethyl-1-hexen--3-one – was hydrolyzed with hot dilute alkali. 5-Methyl-3-hexanone was isolated from the products and was identified by its semicarbazone; a calomel test showed the presence of formic acid in the reaction mixture:

$$(CH_3)_2CHCH_2\overset{\overset{CH_3}{|}}{C}OC{=}CHOH \xrightarrow[NaOH]{H_2O} (CH_3)_2CHCH_2COCH_2CH_3 + HCO_2H.$$

We studied also the possibility of alkylating dialkylaminovinyl ketones with other alkylating agents, but serious limitations were encountered. As we passed from methyl iodide to the higher alkyl halides, the yields of hydroxymethylene ketones fell off sharply. Thus, reaction of 1-dimethylamino-5-methyl-1-hexen-3-one with ethyl iodide gave 5-(hydroxymethylene-2-methyl-4-heptanone, but we could not obtain a yield of above 22%. When we passed to butyl iodide, the corresponding 5-(hydroxymethylene)-2-methyl-4-nonanone was not obtained in ananalytically pure state and the yield was less than 15%. Replacement of alkyl iodides by the corresponding bromides gave negative results. Dimethyl sulfate gave the corresponding hydroxymethylene ketone in 4-5% yield. Negative results were obtained also when dialkylaminovinyl ketones were treated with benzyl chloride, chlorotriphenylmethane, and 1-chloro-3-nitrobenzene. Nevertheless, our results are of interest, for, in spite of its limitations, the new method of synthesizing hydroxymethylene ketones has its advantages and it supplements the only other known method for synthesizing these important compounds.

EXPERIMENTAL

1-Dimethylamino-1-penten-3-one. This was prepared by the general method for the synthesis of alkyl 2-dialkylaminovinyl ketones [1], the reactants being 33.5 g of 1-chloro-1-penten-3-one and 73 ml of a 40% aqueous solution of dimethylamine. The yield was 20.2 g (56.4%). The substance has the following constants: b.p. 95-96° (4 mm); n_D^{20} 1.5400; d_4^{20} 0.9533; found MR 41.84; calculated MR 38.01.

Found %: N 11.45; 11.27. $C_7H_{13}ON$. Calculated %: N 11.01

1-Dimethylamino-1-penten-3-one is a colorless oil which can be preserved a long time without change.

1-Dimethylamino-1-octen-3-one. This was prepared similarly from 67 g of 1-chloro-1-octen-3-one and 120 g of a 40% aqueous solution of dimethylamine. The yield was 51 g (58%). The substance has the following constants: b.p. 157-158° (8 mm); n_D^{20} 1.5232; d_4^{20} 0.9213; found MR 58.14; calculated MR 51.86.

Found %: N 8.33; 8.48. $C_{10}H_{19}ON$. Calculated %: N 8.27

1-Dimethylamino-1-octen-3-one is a colorless oil which can be preserved a long time without change.

3-Dimethylaminoacrylophenone. This was prepared similarly from 34 g of 3-chloroacrylophenone [6] and 60 g of a 30% aqueous solution of dimethylamine. The crystalline substance that separated was filtered off and recrystallized from petroleum ether. The yield was 32 g (88%). 3-Dimethylaminoacrylophenone forms yellowish needles, m.p. 90-91° (the literature [7] gives 91-92°).

4'-Chloro-3-dimethylaminoacrylophenone. A solution of 11 g of 3,4'-dichloroacrylophenone [6] in 15 ml of benzene was added dropwise to 20 ml of a strongly cooled, vigorously stirred 30% aqueous solution of dimethylamine. The reaction mixture was stirred for one hour further, and the precipitate was filtered off and recrystallized from ligroin. The yield of yellowish needles, m.p. 85°, was 9.4 g (82.4%).

Found %: N 7.00; 7.11. $C_{11}H_{12}ONCl$. Calculated %: N 6.68.

The substance is readily soluble in the usual organic solvents, less readily soluble in ligroin, and insoluble in water.

1-Hydroxy-2-methyl-1-hexen-3-one. A mixture of 8 g of 1-dimethylamino-1-hexen-3-one [1] and 16 g of methyl iodide was heated for two hours at 110-120° in a small autoclave. The reaction product had the appearance of a brown resin. It was refluxed in a flask with twice its volume of water for two hours. When cool, the mixture was extracted with ether, the extract was dried over magnesium sulfate, solvent was distilled off, and the residue was vacuum distilled. A fraction of b.p. 65-67° (12 mm) was collected; yield 3.7 g (51%).

After being redistilled, the substance had the following constants: b.p. 63-65° (10 mm); n_D^{20} 1.4599; d_4^{20} 1.0002.

Found %: C 65.55; 65.49; H 9.80; 9.67. $C_7H_{12}O_2$. Calculated %: C 65.59; H 9.45.

1-Hydroxy-2-methyl-1-hexen-3-one is a colorless oil of feeble odor. It is insoluble in water, but dissolves in organic solvents. It darkens when kept for a long time. It gives a violet color with aqueous ferric chloride.

Copper salt. A few drops of 1-hydroxy-2-methyl-1-hexen-3-one was shaken with saturated aqueous cupric acetate. The fine dark-green precipitate was extracted with benzene, the extract was dried over sodium sulfate, benzene was evaporated off, and the residue was crystallized from absolute alcohol. Glistening dark-green crystals, m.p. 145°, were obtained.

Found %: C 53.25; H 6.96. $C_{14}H_{22}O_4Cu$. Calculated %: C 52.89; H 6.97.

1-Hydroxy-2,5-dimethyl-1-hexen-3-one. This was prepared similarly by heating 12 g of 1-dimethylamino--5-methyl-1-hexen-3-one [1] with 22 g of methyl iodide at 100-110° for three hours. The yield was 5.91 g (52%). The substance has the following constants: b.p. 66-68° (9 mm); n_D^{20} 1.4620; d_4^{20} 0.9467.

Found %: C 67.37; 67.49; H 10.24; 1026. $C_8H_{14}O_2$. Calculated %: C 67.57; H 9.92.

1-Hydroxy-2,5-dimethyl-1-hexen-3-one is a colorless oil of feeble odor. It is insoluble in water, but dissolves in organic solvents. It darkens when kept for a long time. It gives a violet color with aqueous ferric chloride.

The copper salt was prepared as before: glistening dark-green crystals, m.p. 161-162° (from absolute alcohol).

Found %: C 55.57; 55.62; H 7.60; 7.46. $C_{16}H_{26}O_4Cu$. Calculated %: C 55.55; H 7.45.

1-Hydroxy-2-methyl-1-octen-3-one. This was prepared similarly by heating 10 g of 1-dimethylamino--1-octen-3-one with 17 g of methyl iodide at 110-120° for two hours. The yield was 3.5 g (38%). The substance has the following constants: b.p. 99-101° (14 mm) n_D^{20} 1.4494; d_4^{20} 0.9428.

Found %: C 62.56; 62.61; H 10.42; 10.51. $C_9H_{16}O_2$. Calculated %: C 62.79; H 10.32.

1-Hydroxy-2-methyl-1-octen-3-one is a colorless oil of feeble odor. It darkens slowly when kept for a long time. It gives an intense violet color with aqueous ferric chloride.

The copper salt was prepared as before: glistening dark-green crystals, m.p. 115° (from absolute alcohol).

Found %: C 58.07; 58.26; H 8.25; 8.38. $C_{18}H_{34}O_4Cu$. Calculated %: C 57.80; H 8.09.

5-(Hydroxymethylene)-2-methyl-4-heptanone. This was prepared similarly by heating 10 g of 1-dimethylamino-5-methyl-1-hexen-3-one with 20 g of ethyl iodide at 110-120° for four hours. The yield was 2.2 g (22%). The substance has the following constants: b.p. 92-93° (9 mm); n_D^{20} 1.4570; d_4^{20} 0.9405.

Found %: C 62.47; 62.49; H 10.55; 10.59. $C_9H_{16}O_2$. Calculated %: C 62.79; H 10.32.

5-(Hydroxymethylene)-2-methyl-4-heptanone is a colorless oil of feeble odor. It darkens slowly when kept for a long time. It gives an intense violet color with aqueous ferric chloride.

Copper salt. A dark-green oil, insoluble in water, soluble in organic solvents.

Hydrolysis of 1-Hydroxy-2,5-dimethyl-1-hexen-3-one. A mixture of 5.2 g of 1-hydroxy-2,5-dimethyl--1-hexen-3-one and 250 ml of 5% aqueous caustic soda was prepared in a 500-ml distilling flask. The mixture was distilled slowly over a period of three hours, and a colorless oil having a pleasant camphorlike odor came over with the steam. The distillate was saturated with sodium chloride and extracted with ether. The extract was dried over sodium sulfate. Solvent was distilled off, and distillation of the residue gave 2.5 g (59%) of 5--methyl-3-hexanone, b.p. 134-136°; n_D^{20} 1.4064; d_4^{20} 0.8090; found MR 34.69; calculated MR 34.53. For 5--methyl-3-hexanone the literature [8] gives b.p. 134.5-135°; d_4^{20} 0.829.

Semicarbazone. This was prepared in the usual way: colorless crystals, m.p. 129-130° (from alcohol) (the literature [9] gives 129°).

Part of the aqueous alkaline solution remaining in the distilling flask was filtered, neutralized with concentrated hydrochloric acid, and rendered alkaline by addition of solid sodium carbonate. Addition of mercuric

chloride to this solution gave a precipitate of calomel (confirmed by reaction with ammonia).

SUMMARY

1. A study was made of the reaction of alkyl 2-dimethylaminovinyl ketones with methyl iodide; after hydrolysis of the reaction mixture, hydroxymethylene ketones are obtained. This reaction provides a new method for the synthesis of hydroxymethylene ketones.

2. It was shown that, with increase in the size of the alkyl radical of the alkylating agent, the alkylation of dimethylaminovinyl ketones becomes more difficult and the yields of hydroxymethylene ketones diminish.

3. The structure of the compounds obtained was proved by hydrolysis.

4. The method of synthesizing 2-dialkylaminovinyl ketones from 2-chlorovinyl ketones was extended to the synthesis of aryl 2-dialkylaminovinyl ketones.

o-PHENYLENE ESTERS OF PYROPHOSPHOROUS ACID

A. E. Arbuzov and F. G. Valitova

Esters of hypophosphoric and pyrophosphoric acids were first prepared in the chemically pure state by A. E. Arbuzov and B. A. Arbuzov [1] in 1932. By the method that they developed they succeeded in preparing pyrophosphorous esters. The present paper gives the results of experiments on the preparation of dialkyl o-phenylene pyrophosphites.

When an ethereal solution of o-phenylene phosphorochloridite [2] was treated with an ethereal solution of sodium diethyl phosphite in an atmosphere of dry nitrogen, reaction occurred with a slight evolution of heat and the separation of a white precipitate of sodium chloride. It was thought that reaction occurred in accordance with the following equation:

However, in the fractionation of the reaction products, instead of the single ester expected, two fractions were obtained: a liquid, and a crystalline solid.

Further investigation showed that the liquid fraction was diethyl o-phenylene pyrophosphite, a colorless liquid of characteristic odor: b.p. 115-116° (1 mm), d_4^{20} 1.1816; and n_D^{20} 1.4800. After being distilled, the second, high-boiling fraction rapidly crystallized in the receiver to a white mass, rapidly deliquescing in the air: b.p. 170-172° (1 mm), d_4^{20} 1.3107, and n_D^{20} 1.5502. We did not succeed in determining the melting point of the crystals, owing to their high hygroscopicity. The results for phosphorus analysis and molecular refraction indicated that the crystalline fraction was di-o-phenylene pyrophosphite. Hydrolysis of the ester with water in a sealed tube at 140° gave an almost theoretical yield of pyrocatechol. The yields of the esters, calculated on the amount of o-phenylene phosphorochloridite taken, were in neither case more than 14%. Replacement of o-phenylene phosphorochloridite by o-phenylene phosphorobromidite [3] did not affect the yields of these esters.

When diethyl o-phenylene pyrophosphite was treated with the calculated amount of cuprous chloride, bromide, or iodide, the temperature of the mixture rose to 58° and a honeylike mass was formed which we were unable to purify and analyze. When cuprous chloride, bromide, or iodide was mixed with di-o-phenylene pyrophosphite, the temperature of the mixture rose to 60° with formation at first of a honeylike mass, which cooled to a white solid mass that was either completely insoluble in the usual solvents, or soluble with decomposition.

Attempts to bring about the addition of sulfur to the two esters were not successful. The expected addition product from sulfur and diethyl o-phenylene pyrophosphite was prepared by another method, namely, by the reactions:

The product was a colorless liquid of unpleasant odor (not so unpleasant in the purified state), and it had the following constants: b.p. 145-147°, d_4^{20} 1.2846, and n_D^{20} 1.5229. Analyses for sulfur and phosphorus gave satisfactory results. When kept for a long time, even in sealed tubes, the liquid became yellow with simultaneous precipitation of sulfur.

When diethyl o-phenylene pyrophosphite was heated at 200° in sealed tubes with bromotriphenylmethane (an equimolecular amount), reaction occurred with separation of ethyl bromide. Hydrolisis of the reaction product with weak hydrochloric acid in sealed tubes at 200° for four hours gave triphenylmethylphosphonic acid and pyrocatechol.

EXPERIMENTAL

Preparation of Diethyl o-Phenylene Pyrophosphite and Di-o-phenylene Pyrophosphite

Dry ether (250 ml) and sodium wire (4.1 g) were placed in a three-necked flask fitted with mechanical stirrer, reflux condenser, and dropping funnel. An ethereal solution of 27 g of freshly distilled diethyl hydrogen phosphite was gradually added from the dropping funnel. When the whole of the sodium had reacted, dry nitrogen was passed, the mechanical stirrer was brought into operation, and an ethereal solution of 32 g of o-phenylene phosphorochloridite was added dropwise. After 4-5 minutes from the start of reaction, a white turbidity appeared and the temperature of the reaction mixture rose slightly. When reaction was complete, the contents of the reaction flask were heated in a water bath at the boiling point of ether for one hour. On the next day the supernatant ether layer was decanted into a distilling flask, and the white precipitate was washed three times by decantation with fresh dry ether. After removal of ether, the yellowish-green oil that remained was distilled from an Arbuzov flask. After three distillations, two fractions were obtained.

Fraction I, amounting to 7.02 g (13.79%), was a colorless mobile liquid having b.p. 115-116° (1 mm), d_4^{20} 1.1816, n_D^{20} 1.4800, found MR 66.78, calculated MR 67.17.

Found %: P 22.83; 22.11. $C_{18}H_{14}O_5P_2$. Calculated %: P 22.46.

Fraction II, amounting to 7.5 g (14.8%), had the following constants: b.p. 170-172° (1 mm), d_4^{20} 1.3107, n_D^{20} 1.5502, found MR 71.47, calculated MR 71.07.

Found %: P 20.96; 20.63. $C_{12}H_8O_5P_2$. Calculated %: P 21.08.

Hydrolysis of 1.05 g of Fraction II in a sealed tube at 140° gave 0.6 g of a crystalline substance, m.p. 103° (pyrocatechol melts at 104°; the amount of pyrocatechol calculated for $C_{12}H_8O_5P_2$ is 0.78 g).

The experiment was repeated under the same conditions but with o-phenylene phosphorobromidite in place of o-phenylene phosphorochloridite. The same yields of the same fractions were obtained.

Action of Bromotriphenylmethane on Diethyl o-Phenylene Pyrophosphite

When 1 g of diethyl o-phenylene pyrophosphite was heated with 1.17 g of bromotriphenylmethane in a sealed tube at 170-175° and the product was hydrolyzed with weak hydrochloric acid, triphenylmethylphosphonic acid was obtained; after recrystallization from alcohol it melted at 276°. Removal of water from the aqueous solution gave crystals of pyrocatechol, which melted at 101° after recrystallization from benzene.

Preparation of Diethyl o-Phenylene Thionohypophosphate

o-Phenylene phosphorochloridite (31 g) was added carefully to a solution of the calculated amount of sodium O,O-diethyl phosphorothioate in gasoline. Reaction proceeded with slight evolution of heat, and toward the end the flask was heated in a water bath for one hour. The mixture was allowed to settle, and the gasoline solution was decanted and vacuum distilled. Two distillations gave 5.8 g (10.6%) of a fraction having b.p. 145-147° (1 mm), d_4^{20} 1.2846, n_D^{20} 1.5229, found MR 73.22, calculated MR 72.89.

Found %: P 19.65; 20.28. $C_{18}H_{14}O_5P_2S$. Calculated %: P 20.12.

Found %: S 10.6; 10.19. $C_{18}H_{14}O_5P_2S$. Calculated %: S 10.38.

SUMMARY

1. Diethyl o-phenylene pyrophosphite and di-o-phenylene pyrophosphite were prepared and their properties were studied.

2. Diethyl o-phenylene thionohypophosphate was prepared.

DERIVATIVES OF 1-AMINOALKYLPHOSPHONIC ACIDS.

1-ISOCYANATOALKYLPHOSPHONIC ESTERS AND THEIR REACTIONS

T. Ya. Medved and M. I. Kabachnik

Study of the properties of aminoalkylphosphonic and aminoalkylphosphonothionic acids and their derivatives has shown that substances of this type are capable of various types of reactions associated with the presence of a free amino group. One or both of the hydrogens of the amino group may be alkylated [1]; exhaustive methylation of these compounds gives the corresponding "phosphonobetaines" [2]; treatment with acid anhydrides and chlorides gives N-acyl derivatives [3]; reaction with chloroformic esters gives organophosphorus urethans [4]; reaction with aryl isocyanates gives organophosphorus urea derivatives [5].

In the present paper we describe organophosphorus isocyanates prepared by the action of phosgene on aminoalkylphosphonic and aminoalkylphosphonothionic esters:

Reaction is very vigorous: it is most convenient to carry the reaction out in toluene solution at not above 0° with a considerable excess of phosgene. The reaction was carried out with diethyl esters of 1-amino-1-methylethylphosphonic, 1-amino-1-methylethylphosphonothionic, and α-aminobenzylphosphonic acids. The products were the corresponding organophosphoric isocyanates: diethyl 1-isocyanato-1-methylethylphosphonate (I), O,O-diethyl 1-isocyanato-1-methylethylphosphonothioate (II), and diethyl α-isocyanatobenzylphosphonate (III):

(I) (II) (III)

The yields of these were 96%, 68%, and 38% respectively. These substances are colorless mobile liquids, readily soluble in organic solvents and decomposed by water. The hydrochlorides of the original substances (IV, V, and VI), which were formed simultaneously, were also isolated and characterized. We have prepared (VI) previously[6].

(IV) (V) (VI)

When the reaction was carried out with the calculated amount of phosgene, organophosphorus urea derivatives were obtained:

Thus, treatment of diethyl 1-amino-1-methylethylphosphonate with phosgene gave the substance (VII).

The analogous derivative of thiourea (VIII) was prepared by reaction between the same ester and carbon disulfide.

Like other isocyanates, the organophosphorus isocyanates that we have prepared readily react with amines and alcohols. By reaction with ammonia in ethereal solution at room temperature, high yields are obtained of monosubstituted organophosphorus ureas:

Treatment of the isocyanates (I) and (II) with ammonia gave the corresponding ureidoalkylphosphonic esters (IX) and (X):

These are colorless crystalline substances, readily soluble in water and alcohol.

Organophosphorus isocyanates react vigorously with the corresponding organophosphorus amines. When the two reactants are mixed, the temperature of the reaction mixture rises rapidly; when cool, the reaction mixture readily crystallizes. In this way the Substances (VII) and (XI) were prepared.

Reaction of (I) with aniline gave the substituted urea (XII), which we had synthesized previously [5] by the action of phenyl isocyanate on diethyl 1-amino-1-methylethylphosphonate. Reaction with p-toluidine went in a similar way, the product being the ester (XIII).

(XII)

(XIII)

Reaction of the isocyanate (I) with glycine ethyl ester gave the Compound (XIV), and hydrolysis of this product with hydrochloric acid gave the tribasic acid (XV).

(XIV)

(XV)

Reaction of the organophosphorus isocyanates with alcohols gave the corresponding urethans:

Reaction with ethanol proceeds readily when the reactants were simply mixed together, and to complete it 10-15 minutes in a boiling water bath is sufficient. The urethan (XVI) so obtained was synthesized by us previously [4] by the action of ethyl chloroformate on diethyl 1-amino-1-methylethylphosphonate.

In the reaction with heptyl alcohol [synthesis of (XVII)], it is necessary to heat the mixture in a boiling water bath for one hour in presence of trimethylamine as catalyst.

(XVI)

(XVII)

Ethanethiol reacts only in presence of a catalyst (trimethylamine), and it is necessary to heat the reaction mixture in a sealed tube in a boiling water bath for a long time. In this way the thiourethans (XVIII) and (XIX) were prepared.

(XVIII)

(XIX)

EXPERIMENTAL

Reaction of phosgene with Diethyl 1-Amino-1-methylethylphosphonate [Synthesis of (I) and (IV)]. A solution of 19 g (0.19 mole) of phosgene in 40 ml of toluene was placed in a round-bottomed flask fitted with stirrer, dropping funnel, thermometer, and reflux condenser. The solution was cooled to a temperature of from −4 to −5°, and was stirred while a solution of 14.7 g (0.075 mole) of diethyl 1-amino-1-methylethylphosphonate in 15 ml of toluene was added. Addition was continued for about one hour, the temperature of the mixture

being maintained in the range 0 to −5°. The mixture was stirred at the same temperature for about four hours, and it was then allowed to attain the room temperature slowly and was left overnight. The precipitated hydrochloride was filtered off. Crystallization of this from absolute ethanol gave 9.7 g of colorless crystals of (IV), m.p. 140°.

Found %: C 36.6, 36.8; H 8.5, 8.4; P 13.5, 13.5; N 6.1, 5.9; Cl 15.3, 15.5. $C_7H_{19}PNO_3Cl$. Calculated %: C 36.3; H 8.3; P 13.4; N 6.1; Cl 15.3.

Phosgene and toluene were distilled from the filtrate under reduced pressure, and the residue was vacuum distilled. Two distillations gave 5.4 g (96%) of (I), b.p. 75-77° (3 mm); n_D^{20} 1.4349; d_4^{20} 1.1014; found MR 52.4, calculated MR 52.7. The ester (I) is a colorless mobile liquid, soluble in organic solvents and slowly decomposed by water.

Found %: C 42.9, 43.2; H 7.5, 7.5; N 6.2, 6.2; P 14.2, 14.2. $C_8H_{16}PO_4N$. Calculated %: C 43.4; H 7.3; N 6.3; P 14.1.

Reaction of Phosgene with O,O-Diethyl 1-Amino-1-methylethylphosphonothioate [Synthesis of (II) and (V)]. The procedure was as above, reaction being between 37 g (0.37 mole) of phosgene in 60 ml of toluene and 31.7 g (0.15 mole) of 0,0-diethyl 1-amino-1-methylethylphosphonothioate in 10 milliliters of toluene. When reaction was complete the mixture remained colorless and clear. Phosgene and toluene were distilled off under reduced pressure. When cooled with an ice-salt mixture, the residue crystallized partially. The crystals were filtered off and recrystallized from petroleum ether, when 18 g of (V), m.p. 108°, was obtained.

Found %: C 33.8, 33.8; H 7.7, 7.6; P 12.6, 12.5; Cl 14.5, 14.4. $C_7H_{15}NPO_2SCL$. Calculated %: C 33.9; H 7.7; P 12.5; Cl 14.3.

The filtrate was vacuum fractionated, and two distillations gave 8.1 g (68%) of (II), b.p. 71-74° (3 mm); n_D^{20} 1.4778; d_4^{20} 1.1102; found MR 60.5; calculated MR 60.2. This compound is a colorless mobile liquid, readily decomposed by water. It has good solubility in organic solvents.

Found %: P 13.3, 13.3. $C_8H_{16}NPO_2S$. Calculated %: P 13.1.

Reaction of Phosgene with Diethyl α-Aminobenzylphosphonate [Synthesis of (III) and (VI)]. Reaction was between 11 g (0.11 mole) of phosgene in 40 ml of toluene and 5.5 g (0.022 mole) of diethyl α-aminobenzylphosphonate in 6 ml of toluene. The precipitated hydrochloride was filtered off. Recrystallization of this from ethanol gave 7.5 g of a colorless crystalline substance, m.p. 157-158° (VI). This substance has been characterized previously [6]. The mixture melting point was 157°.

The filtrate gave 0.72 g (36%) of (III), b.p. 131-134° (2 mm); n_D^{20} 1.5052; d_4^{20} 1.1825; found MR 67.5; calculated MR 67.6. This substance is a colorless liquid, readily decomposed by water, and soluble in organic solvents.

Found %: C 54.1, 54.0; H 5.9, 6.1; P 11.3, 11.4; N 4.8, 4.9. $C_{12}H_{18}NPO_4$. Calculated %: C 53.3; H 6.0; P 11.5; N 5.2.

When dry ammonia was passed into an ethereal solution of the substance, a colorless crystalline precipitate of diethyl α-ureidobenzylphosphonate, m.p. 148-150°, was obtained.

Reaction of the Calculated Amount of Phosgene with Diethyl 1-Amino-1-methylethylphosphonate [Synthesis of (VII)]. The experiment was carried out in the same apparatus. A solution of 9.8 g (0.05 mole) of diethyl 1-amino-1-methylethylphosphonate was cooled to 0° in the flask, and a solution of 1.25 g (0.0125 mole) of phosgene in 4 ml of toluene was added gradually. The temperature of the reaction mixture was maintained in the range 0-5°. The reaction mixture was then stirred for about one hour at 20°, after which the precipitate present was filtered off and recrystallized from absolute ethanol. Colorless crystals (3.3 g) of the salt (IV), m.p. 140°, were obtained. From the filtrate remaining after the removal of the precipitate, phosgene and toluene were distilled off. On the next day the residue crystallized. Three recrystallizations from petroleum ether gave 1 g (20%) of colorless needles, m.p. 72-73°.

Found %: C 43.3, 43.6; H 8.4, 8.4; P 14.9, 15.0; N 6.7, 6.8; $C_{15}H_{34}N_2P_2O_7$. Calculated %: C 43.3; H 8.3; P 14.9; N 6.7.

The substance is soluble in water, alcohol, ether, benzene, and other organic solvents.

Reaction of Carbon Disulfide with Diethyl 1-Amino-1-methylethylphosphonate [Synthesis of (VIII)]. A mixture of 7.8 g (0.04 mole) of diethyl 1-amino-1-methylethlphosphonate, 4.5 g (0.06 mole) of carbon disulfide, and 10 ml of ether was prepared in a flask having a ground-in stopper. The mixture was allowed to stand at room temperature, and after two weeks the precipitate was filtered off and washed with ether. Crystallization from absolute alcohol gave 1.6 g of a colorless crystalline substance, m.p. 273-274°.

Found %: C 36.4, 36.5; H 8.3, 8.5; N 8.4, 8.2; P 18.5, 18.3. $C_5H_{14}NPO_3$. Calculated %: C 35.9; N 8.4; N 8.4; P 18.5.

The analysis corresponded to ethyl hydrogen 1-amino-1-methylethylphosphonate. After it had stood for a further two weeks, the filtrate - a thick sirupy liquid - crystallized. Washing the crystals with ether gave 2.3 g (25%) of the product, m.p. 97-98°.

Found %: C 41.6, 41.6; H 7.8, N 6.5, 6.4; S 7.6, 7.6. $C_{15}H_{32}N_2P_2O_6S$. Calculated %: C 41.6; H 7.9; N 6.5; S 7.4.

Reaction of Diethyl 1-Isocyanato-1-methylethylphosphonate with Ammonia [Synthesis of (IX)]. Dry ammonia was passed through a solution of 0.7 g of the isocyanate (I) in 7 ml of ether cooled to 0°. Filtration gave 0.65 g (86%) of colorless crystals, m.p. 138-139°.

Found %: C 39.9, 39.9; H 8.1, 8.0; P 13.0, 13.2; N 11.8, 11.9. $C_5H_{13}PN_2O_4$. Calculated %: C 40.3; H 8.1; P 13.1; N 11.8.

The substance is readily soluble in water and alcohol, but is insoluble in diethyl ether and in petroleum ether.

Reaction of O,O-Diethyl 1-Isocyanato-1-methylethylphosphonothioate with Ammonia [Synthesis of (X)]. Reaction was carried out as in the preceding experiment with 1 g of the isocyanate (II) and dry ammonia. On reduction to one-third bulk by evaporation of ether, a white crystalline precipitate was formed. The product, which amounted to 0.6 g (61%), melted at 104-106°.

Found %: C 37.9, 38.1; H 7.6, 7.6; N 10.9, 11.0; P 11.9, 11.9; S 12.2, 12.2. $C_5H_{13}N_2PO_3S$. Calculated %: C 37.8; H 7.6; N 11.0; P 12.2; S 12.6.

Reaction of Diethyl 1-Isocyanato-1-methylethylphosphonate with Diethyl 1-Amino-1-methylethylphosphonate [Synthesis of (VII)]. To 0.33 g (0.0017 mole) of diethyl 1-amino-1-methylethylphosphonate, 0.46 g (0.0021 mole) of the isocyanate (I) was added; the temperature of the mixture rose to 45°. The mixture was heated for three minutes in a boiling water bath. After being cooled with an ice-salt mixture and rubbed out with a glass rod, the mixture crystallized. Recrystallization from petroleum ether gave 0.5 g (71.5%) of colorless crystals, m.p. 73-74°. A mixture with the substance obtained in the reaction with phosgene melted at the same temperature.

Reaction of O,O-Diethyl 1-Isocyanato-1-methylethylphosphonothioate with O,O-Diethyl 1-Amino-1-methylphosphonothioate [Synthesis of (XI)]. Reaction was carried out as in the preceding experiment, the reactants being 2.1 g (0.01 mole) of O,O-diethyl 1-amino-1-methylethylphosphonothioate and 3 g (0.0125 mole) of the isocyanate (II). Recrystallization from a small amount of petroleum ether gave 2.8 g (62%) of a colorless substance, m.p. 72-73°.

Found %: C 40.2, 40.2; H 7.7, 7.7; S 13.6, 13.6; P 13.4, 13.7; N 6.2, 6.1. $C_{12}H_{32}N_2P_2S_2O_5$ Calculated %: C 40.2; H 7.7; S 14.3; P 13.8; N 6.3.

Reaction of Diethyl 1-Isocyanato-1-methylethylphosphonate with Aniline [Synthesis of (XII)]. Reaction was carried out as in the preceding experiment, the reactants being 0.6 g (0.0065 mole) of aniline and 1.1 g (0.005 mole) of the isocyanate (I). The crystals were washed with petroleum ether and recrystallized from absolute ethanol. The yield of the colorless crystalline product, m.p. 137-138°, was 1.1 g (73%). The same substance, prepared previously [3] by the action of phenyl isocyanate on diethyl 1-amino-1-methylethylphosphonate, melted at 139-140°. The mixture melting point was 138°.

Reaction of Diethyl 1-Isocyanato-1-methylethylphosphonate with p-Toluidine [Synthesis of (XIII)]. To 0.70 g (0.0065 mole) of p-toluidine in 1 ml of ether, 1.1 g (0.005 mole) of the isocyanate (I) was added. The temperature of the mixture rose from 20° to 27°, and the reaction mixture solidified. The substance was washed with petroleum ether and recrystallized from absolute ethanol. The yield of colorless crystals, m.p. 157-158° was 1.1 g (68%).

Found %: C 54.8, 54.9; H 7.8, 7.7; P 9.3, 9.1; N 8.4, 8.3. $C_{15}H_{23}N_2PO_4$. Calculated %: C 54.9; H 7.7; P 9.4; N 8.5.

Reaction of Diethyl 1-Isocyanato-1-methylethylphosphonate with Glycine Ethyl Ester [Synthesis of (XIV)]. When 4.22 g (0.019 mole) of the isocyanate (I) was added to 2.1 g (0.02 mole) of glycine ethyl ester, the temperature rose to 105°. When cool, the mixture crystallized. The substance was washed with petroleum ether and recrystallized from a mixture of absolute ethanol and petroleum ether. The product, amounting to 5.9 g (96%), melted at 82-83°.

Found %: N 8.4, 8.4; P 9.6, 9.5. $C_{11}H_{21}N_2PO_6$. Calculated %: N 8.6; P 9.6.

Hydrolysis of the Ester (XIV) with Hydrochloric Acid. A mixture of 2 g of the substance obtained in the preceding experiment and 50 ml of 1:1 hydrochloric acid was refluxed for 4.5 hours. Hydrochloric acid was distilled off under reduced pressure, and the dry residue was recrystallized from water. The product (0.6 g) formed colorless crystals, m.p. 127-128°; it crystallized with one molecule of water.

Found %: C 27.8, 27.9; H 6.1, 5.9; N 10.8, 10.6. $C_8H_{13}N_2PO_6 \cdot H_2O$. Calculated %: C 27.9; H 5.9; N 10.8.

Reaction of Diethyl 1-Isocyanato-1-methylethylphosphonate with Ethanol [Synthesis of (XVI)]. The isocyanate (I) (1.1 g) was added to 5 ml of absolute ethanol; the temperature of the mixture rose from 20° to 25°. The mixture was then heated for 15 minutes in a boiling water bath. Excess of alcohol was distilled off, and vacuum distillation of the residue gave 0.77 g (58%) of a colorless mobile liquid, b.p. 110-111° (2 mm) and n_D^{20} 1.4508. As prepared previously by us [4], this substance had b.p. 110-112° (2 mm) n_D^{20} 1.4519.

Reaction of Diethyl 1-Isocyanato-1-methylethylphosphonate with Heptyl Alcohol [Synthesis of (XVII)]. A mixture of 2.2 g of the isocyanate (I), 3.5 g of heptyl alcohol, and 0.5 ml of an ethereal solution of trimethylamine was heated for one hour in a boiling water bath. Excess of the alcohol was distilled off. Vacuum distillation of the residue gave 2.1 g (62%) of a fraction having b.p. 158-159° (2 mm); n_D^{20} 1.4517; d_4^{20} 1.0351; found MR 87.8; calculated MR 87.6.

Found %: C 53.4, 53.3; H 9.7, 9.6; P 9.0, 9.0. $C_{13}H_{28}PO_5N$. Calculated %: C 53.4; H 9.6; P 9.2.

Reaction of Diethyl 1-Isocyanato-1-methylethylphosphonate with Ethanethiol [Synthesis of (XVIII)]. A mixture of 5 g of the isocyanate (I), 7 g of ethanethiol, and 1.0 ml of ethereal trimethylamine was heated in a sealed tube for eight hours in a boiling water bath. When excess of ethanethiol had been distilled off, the residue in the flask crystallized. Recrystallization of the substance from petroleum ether gave 3 g (47%) of colorless crystals, m.p. 64-65°.

Found %: C 42.0, 42.3; H 7.7, 7.6; S 11.3, 11.2; P 10.4, 10.3; N 4.8, 4.7. $C_{10}H_{22}NPSO_4$. Calculated %: C 42.4; H 7.8; S 11.3; P 10.9; N 4.9.

The substance is readily soluble in water, alcohol, benzene, and other organic solvents.

Reaction of O,O-Diethyl 1-Isocyanato-1-methylethylphosphonothioate with Ethanethiol [Synthesis of (XIX)]. A mixture of 5 g of the isocyanate (II), 6.5 g of ethanethiol, and 1.0 ml of ethereal trimethylamine was heated in a sealed glass tube for eight hours in a boiling water bath. Excess of ethanethiol was distilled off. Vacuum distillation of the residue gave 3.1 g (50%) of a fraction of b.p. 132-133° (3 mm); n_D^{20} 1.5075; d_4^{20} 1.1361; found MR 78.5, calculated MR 78.4.

Found %: C 39.6, 39.6; H 7.3, 7.2; P 10.8, 10.8; N 4.5, 4.3. $C_{10}H_{22}NPS_2O_3$. Calculated %: C 40.1; H 7.4; P 10.3; N 4.7.

SUMMARY

1. 1-Isocyanatoalkylphosphonic esters were synthesized, and their reactions were studied.

2. It was shown that 1-aminoalkylphosphonic esters (1-amino-1-methylethylphosphonic, 1-amino-1-methylethylphosphonothionic, and α-aminobenzylphosphonic esters) react with phosgene and, depending on the conditions, the corresponding isocyanates or symmetrical substituted ureas are formed.

3. 1-Isocyanatoalkylphosphonic esters react with ammonia to give the corresponding unsymmetrical ureas, with alcohols to give urethans, with amines to give substituted ureas, and with thiols to give thiourethans.

4. Treatment of a 1-amino-1-methylethylphosphonic ester with carbon disulfide gives a disubstituted thiourea.

ORGANOBORON COMPOUNDS

COMMUNICATION 10. COMPLEX NATURE OF SALTS OF ORGANOBORON ACIDS

B. M. Mikhailov, T. K. Kozminskaya, A. N. Blokhina, and T. A. Shchegoleva

One of us, in collaboration with Vaver [1], recently prepared salts derived from diphenylborinic acid which contained quadricovalent negatively charged boron (I):

$$[(C_6H_5)_2B(OH)_2]M,$$

$$M = Na, K, NH_4. \qquad (I)$$

This observation prompted us to investigate the nature of the salts of other organoboron acids and so determine whether the complex structure of salts of diphenylborinic acid is due to peculiarities in the structure of the acid itself, or is possessed also by other organoboron acids, e.g. boronic acids $RB(OH)_2$.

Michaelis and Becker [2] carried out an investigation on salt formation in the areneboronic acid series, and they considered that benzeneboronic acid forms a normal salt of composition $C_6H_5B(ONa)_2$ with caustic soda and an acid salt $(C_6H_5BO_2H)_2Ca$ with calcium hydroxide. The investigation that we have now carried out has shown that Michaelis and Becker were wrong in considering the salts of benzeneboronic acid to be tercovalent boron derivatives. We found that, when equimolecular amounts of benzeneboronic acid and caustic soda were mixed in aqueous solution and the mixture was evaporated to dryness, crystallization of the residue from a mixture of benzene and methanol gave a sodium salt corresponding in composition to the complex salt sodium trihydroxy (phenyl) borate (II)•:

$$[C_6H_5B(OH)_3]Na \qquad (II)$$

When benzeneboronic acid and caustic soda were mixed in aqueous solution in the proportions of 1 : 2, the same complex salt (II) was obtained, and not the normal salt $C_6H_5B(ONa)_2$. The residue remaining after the evaporation of the aqueous solution of the original acid and caustic soda was not a homogeneous substance, but appeared to be a mixture of caustic soda and sodium trihydroxy(phenyl)borate (II). In this case the isolation of the salt (II) was more difficult, for its solubility in various solvents is similar to that of caustic soda. Nevertheless, by repeated crystallization we succeeded in obtaining the salt (II) in an analytically pure state. Michaelis and Becker did not crystallize the product obtained by the evaporation of an aqueous solution of the acid and caustic soda taken in the proportions of 1:2, but submitted it directly to analysis.

The calcium salt formed by benzeneboronic acid was prepared by boiling an aqueous-alcoholic solution of the acid with calcium hydroxide and evaporating the resulting solution. The analysis of the recrystallized salt corresponded to calcium trihydroxy(phenyl)borate [(III), M = Ca]:

$$[C_6H_5B(OH)_3]_2M. \qquad (III)$$

• As there is no recognized system of nomenclature for these complex salts, they are named by an adaptation of the nomenclature of coordinate compounds, "organic" names, however, being given to radicals (e.g. hydroxy, not hydroxo). The authors' name for the acid $[C_6H_5B(OH)_3]H$ may be transcribed as phenylboronic acid; they regard it as a derivative of $[B(OH)_4]H$, their name for which may be transcribed as boronic acid. — Publisher.

When the calcium salt (III) was treated with carbon dioxide, benzeneboronic acid was obtained, and Michaelis and Becker, in treating the aqueous solution of the reactants with carbon dioxide, could not possibly have obtained calcium benzeneboronate. The barium salt, obtained by the action of barium hydroxide on benzeneboronic acid, was found to have the same structure as the calcium salt [(III), M = Ba].

Apart from salts derived from benzeneboronic acid, we studied the alkali-metal salts formed by o-toluene-, p-bromobenzene-, p-anisole-, and 1-naphthalene-boronic acids. The salts derived from these acids were prepared similarly to those derived from benzeneboronic acid and were purified by crystallization. Like the salts derived from benzeneboronic acid, they were all found to be complex trihydroxy(phenyl)borates (IV):

$$[ArB(OH)_3]M$$
$$Ar = p\text{-}CH_3C_6H_4-,\ p\text{-}CH_3OC_6H_4-,\ p\text{-}BrC_6H_4-,$$
$$1\text{-}C_{10}H_7-;\ M = Na, K. \qquad (IV)$$

Among the salts of alkaneboronic acids, the literature describes the sodium salt of 1-butaneboronic acid; this is assigned the structure of an acid salt containing one-half of a molecule of water of crystallization, $n\text{-}C_4H_9BO_2HNa \cdot 1/2H_2O$ [3]. Actually, the sodium salt derived from 1-butaneboronic acid is quite different in composition and structure. In fact, like the salts derived from areneboronic acids, it is derived from a complex acid – butyltrihydroxyboric acid and has the structure (V):

$$[n\text{-}C_4H_9B(OH)_3]Na. \qquad (V)$$

It follows from these considerations that, in reactions with bases, organoboron acids do not behave as hydrogen acids, i.e. as proton donors, as was universally believed:

but as acceptors of hydroxyl ions:

$$RB(OH)_2 + OH^- \rightarrow [RB(OH)_3]^-.$$

The salts so formed are complex compounds containing quadricovalent negatively charged boron.

EXPERIMENTAL

The salts were analyzed by Wittig's method [4]. The content of alkali or alkaline-earth metal was determined by the titration of aqueous or aqueous-alcoholic solutions of the salts with acid in presence of bromocresol purple. In the determination of boron, the boric acid formed by decomposing the salt with mercuric chloride was titrated in presence of mannitol. After treatment with mercuric chloride, the solution of the salt had a neutral reaction, which indicated that equivalent amounts of aryl groups and metal were present.

1. Sodium Trihydroxy(phenyl)borate

a) A solution of 1.22 g (0.01 mole) of benzeneboronic acid in 5 ml of 2 N NaOH (0.01 mole) was prepared and filtered. It was evaporated down under reduced pressure with exclusion of carbon dioxide. Crystallization of the residue from a mixture of methanol and benzene gave fine needles of the salt.

Found %: Na 14.06, 14.05; B 6.47. $[C_6H_5B(OH)_3]Na$. Calculated %: Na 14.20; B 6.68.

b) A solution of 1.83 g (0.015 mole) of benzeneboronic acid in 15 ml of 2 N NaOH (0.03 mole) was evaporated to dryness. The residue was crystallized twice from a mixture of water (7 ml) and acetone (50 ml), and then from a mixture of methanol (2.5 ml) and benzene (40 ml). The product weighed 1.5 g.

Found %: Na 13.92, 14.12. $C_6H_5B(OH)_3Na$. Calculated %: Na 14.20. $C_6H_5B(ONa)_2$. Calculated %: Na 27.72.

2. Calcium Trihydroxy(phenyl)borate

A stirred mixture of 2.44 g (0.02 mole) of benzeneboronic acid, 0.8 g (0.01 mole) of calcium hydroxide, 120 ml of water, and 60 ml of methanol was boiled for three hours. The hot solution was filtered and evaporated to dryness. The residue was crystallized from a mixture of water (100 ml) and acetone (100 ml).

Found %: Ca 12.47, 12.71; B 6.64. $[C_6H_5B(OH)_3]_2Ca$. Calculated %: Ca 12.58; B 6.80.

A solution of 1.3 g of the calcium trihydroxy(phenyl)borate so obtained in 100 ml of a 1 : 1 mixture of water and methanol was saturated with carbon dioxide. The precipitate (0.35 g) did not contain any organic matter. The filtrate was evaporated to dryness, and 0.83 g of benzeneboronic acid, m.p. 214-216°, was obtained.

3. Barium Trihydroxy(phenyl)borate

A mixture of 1 g (0.008 mole) of benzeneboronic acid, 1.3 g (0.004 mole) of $Ba(OH)_2 \cdot 8H_2O$, and 25 ml of water was boiled for 15 minutes. The warm solution was filtered, and the filtrate was concentrated under reduced pressure (with exclusion of carbon dioxide) in a water bath until the volume was reduced to 10 ml. The barium salt, which separated in the form of six-sided plates, was analyzed for barium content by heating an aqueous solution of the salt for 14 minutes with excess of acid and back-titrating the acid that did not react.

Found %: Ba 32.74; B 5.23. $[C_6H_5B(OH)_3]_2Ba$. Calculated %: Ba 33.07; B 5.21.

4. Sodium Trihydroxy(p-methoxyphenyl)borate

A solution of 1 g (0.0066 mole) of p-anisoleboronic acid in N NaOH (0.0066 mole) was filtered and evaporated to dryness. The residue was crystallized from a mixture of water (10 ml) and acetone (40 ml).

Found %: Na 12.11, 12.09; Ba 5.56; 5.66. $CH_3OC_6H_4B(OH)_3Na$. Calculated %: Na 12.00; Ba 5.63.

5. Sodium (p-Bromophenyl)trihydroxyborate

A solution of 2 g (0.01 mole) of p-bromobenzeneboronic acid in N NaOH (0.01 mole) was filtered and evaporated to dryness. Crystallization of the residue from a methanol-benzene mixture gave fine needles of the salt.

Found %: Na 9.45, 9.37; B 4.31, 4.41 $[BrC_6H_4B(OH)_3]Na$. Calculated %: Na 9.55; B 4.49.

6. Potassium (p-Bromophenyl)trihydroxyborate

The salt was prepared under the conditions described above.

Found %: K 15.20, 15.14; B 4.08, 4.21. $[BrC_6H_4B(OH)_3]K$. Calculated %: K 15.22; B 4.21.

7. Sodium Trihydroxy-o-tolylborate

The salt was prepared under the conditions described above.

Found %: Na 13.24, 13.20; B 5.98, 6.07. $[CH_3C_6H_4B(OH)_3]Na$. Calculated %: Na 13.07; B 6.14.

8. Sodium Trihydroxy-1-naphthylborate

The salt was prepared under the conditions described above.

Found %: Na 10.64, 10.45; B 5.02, 5.15. $[C_{10}H_7B(OH)_3]Na$. Calculated %: Na 10.84; B 5.10.

9. Sodium Butyltrihydroxyborate

Saturated caustic soda solution (30-40 ml) was added to a solution prepared by dissolving 2 g (0.02 mole) of 1-butaneboronic acid in 10 ml of 20% caustic soda solution. The precipitate then formed was filtered off, dried in the air, and dissolved in 20 ml of absolute alcohol. The solution was filtered and 100 ml of acetone was added. The salt that separated was filtered off, washed with ether, and dried in a vacuum desiccator.

Found %: Na 16.22, 16.19; B 7.58, 7.66. $[C_4H_9B(OH)_3]Na$. Calculated %: Na 16.21; B 7.52.

SUMMARY

Contrary to general belief, in reactions with bases organoboron acids do not behave as hydrogen acids, i.e. as proton donors, but as acceptors of hydroxyl ions. The resulting salts are complex compounds containquadricovalent negatively charged boron, e.g. $[RB(OH)_3]M$.

ACTION OF ACTIVE NITROGEN ON ORGANIC SUBSTANCES

COMMUNICATION 2

P. M. Aronovich, N. K. Belsky, and B. M. Mikhailov

In Communication 1 [1] we described the action of active nitrogen on some organic compounds and showed that aromatic hydrocarbons form hydrogen cyanide and a solid polymeric substance. In a further study of the reaction of active nitrogen with benzene we have succeeded in isolating and identifying three further reaction products: phenyl isocyanide, benzonitrile, and pyridine. The formation of the first two substances was suggested a long time ago [2] on the basis of the odor of the reaction mixture, but the presence of pyridine among the reaction products was unexpected. The formation of this substance could be explained on the assumption that on colliding with nitrogen atoms the benzene molecule suffers severe breakdown with formation of fragments containing one or two carbon atoms; these particles (molecules or radicals) then react with hydrogen cyanide with formation of pyridine, just as pyridine is formed from acetylene and hydrogen cyanide. If this assumption is correct, then treatment of other aromatic hydrocarbons, e.g. naphthalene, with active nitrogen should also give pyridine, but spectroscopic investigation of the products of reaction between active nitrogen and naphthalene showed that pyridine was absent, whereas quinoline and isoquinoline were shown to be present.

Our results and previous observations enable us to advance certain views concerning the mechanism of reaction between active nitrogen and aromatic hydrocarbons. In the reaction vessel there is an intense violet glow, characteristic of the CN radical [3], and hydrogen cyanide, with only traces of cyanogen, can be detected in the reaction products [1]; we may therefore suppose that at first CN radicals are formed, and later these are converted into hydrogen cyanide. The formation of hydrogen cyanide may result from the capture of a hydrogen from the aromatic nucleus, and also from combination of the CN radical with atomic hydrogen, the presence of which in the reaction mixture was proved by the formation of stearic from oleic acid [1] and of saturated from unsaturated hydrocarbons [4].

In the primary collision between a nitrogen atom and a benzene molecule, the radicals C_6H_5 and NH are probably formed. By reacting further with active nitrogen, the NH radical will give a nitrogen molecule and a hydrogen atom. The further action of nitrogen on the phenyl radical will give a CN radical and a C_5H_5 residue. When this C_5H_5 radical collides with a nitrogen atom, pyridine will be formed, but as the life of a C_5H_5 radical must be extremely short, the probability of the formation of pyridine will be extremely low. The C_5H_5 radical will generally decompose further with formation of unsaturated compounds or the corresponding radicals, which will copolymerize with the CN radical or hydrogen cyanide, the polymer so formed being deposited on the walls of the reaction vessel.

Formation of phenyl isocyanide and benzonitrile evidently results from collisions between phenyl and CN radicals:

It might be supposed also that NH radicals formed as a result of the primary collision between nitrogen atoms and benzene would react with hydrogen atoms and phenyl radicals (in either order) with formation of aniline, but no aniline could be detected in the reaction mixture.

The course of the reaction between naphthalene and active nitrogen is probably similar to that of the reaction with benzene. The nitrogen can attack either an α- or a β- position, and the naphthyl radicals formed will again react with nitrogen with formation of CN radicals and C_9H_7 residues. By further reaction with nitrogen these residues will give quinoline and isoquinoline:

No naphthylamines were detected among the products of reaction between active nitrogen and naphthalene.

In the investigation of the products of reaction between active nitrogen and benzene, the presence of phenyl isocyanide was proved by its hydrolysis to aniline, which was converted into a dye by diazotization and coupling with 2-naphthol. This reaction provided a proof of the presence of phenyl isocyanide only with it was certain that no aniline was present in the reaction mixture. The detection of aniline in presence of phenyl isocyanide is difficult, owing to the readiness with which the latter is hydrolyzed. Hence, in order to remove phenyl isocyanide, the mixture was first treated with mercuric chloride [5], after which it was shown that aniline was absent. The possibility of the detection of aniline under these conditions was first checked on an artificial mixture of phenyl isocyanide, aniline, and benzene. An attempt was made to apply the reaction with mercuric chloride for the determination of the phenyl isocyanide content of the mixture, the amount of calomel formed being measured. However, experiments on pure phenyl isocyanide gave nonreproducible results. The absence of aniline was confirmed also by spectroscopic determinations. The presence of benzonitrile among the reaction products was proved by the isolation of benzoic acid by alkaline hydrolysis; a substance that was probably terephthalic acid was also isolated.

Pyridine was isolated as a complex compound with mercuric chloride after the reaction products had been treated with hydrochloric acid. The presence of pyridine was confirmed also by spectroscopic measurements. As the hydrochloric acid solution of the reaction product was brown in color, the spectrum was determined on the vapor above the solution (after it had been made alkaline). The absorption spectrum over the range 2000-2800 A was determined, and this was identified with absorption spectrum of pyridine vapor determined under analogous conditions; it agreed also with data in the literature [6]. The positions and character of the bands are given in Table 1 and in the photograph 1, and the spectrum of pyridine vapor is given for comparison (photograph 2).

14	2953	33854	1	Diffuse

1) Absorption spectrum of the vapor of the products of reaction between active nitrogen and benzene; 2) spectrum of pyridine vapor; 3) absorption spectrum of isoquinline vapor; 4) absorption spectrum of the vapor of the products of reaction between active nitrogen and naphthalene; 5) absorption spectrum of quinoline vapor.

Owing to the low yield of products in the reaction between active nitrogen and naphthalene, it was found difficult to identify them by chemical methods. We therefore determined the absorption spectrum of the vapor of the reaction products. The spectrum was distributed over the region 3200-2900 A. The positions and character of the bands are given in Table 2 and in the photograph 4.

The spectrum obtained was compared with the absorption spectra of quinoline [7] and isoquinoline vapors. As there are no data in the literature on the absorption spectrum of isoquinoline vapor, this spectrum was determined under conditions analogous to those used for the spectrum of the vapors of the reaction products, the same spectrograph being employed. The form of the spectrum of isoquinoline vapor, which occurs in the range 3250-2900 A, and the character of the bands are given in Table 3 and in the photograph 3.

TABLE 3

Absorption Spectrum of Isoquinoline Vapor

13	2998	33346	4	Diffuse, broad
14	2976	33592	1	Diffuse

The spectrum of quinoline vapor is given for comparison in the photograph 5. The most intense bands in the spectra of the reaction products were those attributable to isoquinoline.

It may be assumed that more isoquinoline than quinoline is formed in the reaction between active nitrogen and naphthalene, for in the spectra of the solutions quinoline and isoquinoline [8] absorb to approximately the same extent.

EXPERIMENTAL

Experiments with benzene. The reaction between benzene and active nitrogen was carried out in a tube or in a sphere (see Communication 1). The p.d. across the electrodes of the discharge tube was 2200-2300 V, the current strength was 150-160 ma, and the pressure was 10 mm. The reaction products were allowed to accumulate for 25-50 hours. Volatile reaction products were distilled from the contents of the traps (which had been cooled with liquid nitrogen), and the residue was a brown liquid which contained some dark-colored flakes and possessed the sharp odor of an isocyanide. At the end of an experiment of 5-7 hours, the mixture was poured into a flask, and the trap was washed with 2-3 ml of benzene, which was added to the bulk of the mixture. The further treatment of the mixture was carried out in different ways, depending on the object in view.

Determination of aniline. The mixture obtained in the traps in the course of a six-hour experiment was filtered, and 3 ml of a 20% solution of mercuric chloride in absolute alcohol was added to the filtrate. The reaction products obtained on subsequent days (in the course of 25 hours, in all) were also filtered, and the filtrates were added to the mixture containing mercuric chloride. The resulting mixture was a brown liquid containing a light-colored flocculent precipitate. It smelled of bitter almonds, no isocyanide odor being detected. Solvents were distilled off under reduced pressure, and the residue was boiled with 20 ml of 5% hydrochloric acid in order to dissolve the complex compound of aniline and mercuric chloride. The mixture was cooled and filtered, and two drops of 0.05 N nitrite solution were added to the filtrate. There was no coloration when the solution was tested with alkaline 2-naphthol solution.

In order to verify the method of detecting aniline in presence of phenyl isocyanide, 1 ml of a 50% benzene solution of pheayl isocyanide (prepared according to Nef's instructions [9] was mixed with 1 ml of a 2% benzene solution of aniline, and 3 ml of benzene and 1 ml of a 20% solution of mercuric chloride in absolute alcohol were added. The solvents were distilled off, and the residue was boiled with 20 ml of 5% hydrochloric acid.

The mixture was cooled and filtered, and a drop of sodium nitrite solution was added to the filtrate. There was a distinct orange-red coloration when alkaline 2-naphthol solution was added.

Determination of phenyl isocyanide and benzonitrile. At the end of each one-day experiment, the contents of the traps were boiled with 1 ml of 10% hydrochloric acid for 15 minutes in order to hydrolyze the phenyl isocyanide. When the products of reaction for 50 hours – all treated in the same way – had accumulated, the mixture was filtered, and the benzene layer was separated from the aqueous layer.

a) The benzene layer was a light-brown liquid smelling of bitter almonds. After removal of solvent, 120 mg of a mixture of brown oil and crystals was obtained. Alcohol (2 ml) was added to the mixture, and the very small white precipitate was filtered off. Aqueous caustic potash (1 ml of 50%) was added to the alcoholic solution, and the mixture was boiled for two hours, by which time the almond odor had disappeared. The mixture was diluted with 3 ml of water and washed with ether. The aqueous layer was acidified with hydrochloric acid, and the precipitate that formed was extracted with ether (only a part). The residue (15 mg) was filtered off, washed; it sublimed without melting and was soluble in sodium carbonate solution with formation of a brown solution having a bright blue fluorescence. A low-melting gray powder (60 mg) was isolated from the ether solution, and three crystallizations of this from water gave 10 mg of white crystals, m.p. 119-120°; in admixture with benzoic acid it melted at 120-120.5°.

b) The aqueous layer, which was also brown, was titrated under ice cooling with 0.1 N sodium nitrite: 2.72 ml, corresponding to 25.3 mg of aniline, was required. The solution obtained gave an orange-red precipitate with alkaline 2-naphthol solution.

Determination of pyridine. The mixture from the traps was treated as in the determination of phenyl isocyanide and benzonitrile. When the aqueous layer was made alkaline, a pyridine odor appeared. Pyridine was determined in the aqueous layer by two methods.

a) A hot solution of 0.8 g of mercuric chloride in 8 ml of water was added to the hydrochloric acid solution. The mixture was cooled, and gray precipitate present was filtered off, washed with 1 ml of water, and dried in the air. The precipitate (100 mg) melted at 146-165°. After three crystallizations from water it melted at 173-176°. In admixture with $C_5H_5N \cdot HCl \cdot 2HgCl_2$ (m.p. 176-178°) it melted at 174-177°.

b) In the spectrometric determination of pyridine, a hydrochloric acid solution of the reaction products was poured in a thin layer on to the bottom of a quartz tube in the ends of which there were fused-in plane quartz windows. Excess of aqueous alkali was added through a side tube provided with a tap, so that gas was evolved from the solution and filled the tube. The absorption spectrum of the vapor in the tube (length of absorbing layer 17 cm) was determined at room temperature on a Q-12 quartz spectrograph. The light source was a superhigh-pressure krypton-filled lamp, which gave a continuous spectrum in the near ultraviolet. An iron-arc spectrum was used for comparison.

Experiments with naphthalene. The reaction of active nitrogen with naphthalene was carried out in a sphere. The naphthalene was poured directly into the reaction space, and active nitrogen was passed over its surface at a pressure of 13 mm. The p.d. applied to the electrodes of the discharge tube was 2800 V, and the current strength was 200 ma. Owing to the low vapor pressure of naphthalene, reaction was slow at room temperature, and the reaction was therefore carried out at 35-40°, at which temperature the vapor pressure of naphthalene approaches 1 mm.

The reaction products in the traps formed a dark-colored deposit, which was washed out with benzene. The resulting solution was extracted with hydrochloric acid, and the hydrochloric acid solution was filtered and then poured in a thin layer on to the bottom of a quartz tube having plane quartz windows, in which the spectrum was determined; the solution was made alkaline and the absorption spectrum of the vapor of the reaction products was determined on a 17-cm layer with the same spectrograph. The spectrum was determined at 20° and 90°, and the results obtained at 90° are shown in Table 2.

In conclusion we express our deep indebtedness to I. V. Obreimov for his advice and constant interest in our work. We thank also V. I. Dianov-Klokov for designing the apparatus for the preparation of active nitrogen.

SUMMARY

1. In the reaction between active nitrogen and benzene, the products include not only hydrogen cyanide and a deposit on the walls of the reaction vessel, but also small amounts of pyridine, phenyl isocyanide,

benzonitrile, and probably terephthalonitrile. It was shown that quinoline and isoquinoline are present among the products of reaction between active nitrogen and naphthalene.

2. Some views are expressed on the possible mechanism of the reaction between active nitrogen and aromatic hydrocarbons.

SYNTHESIS OF ALKOXY- AND ACETOXY-SILANES CONTAINING AN ETHER OR ESTER GROUPING SUBSTITUTED IN SILICON-ATTACHED ALKYL

K. A. Andrianov and L. I. Makarova

A few alkoxysilanes containing an ether or ester grouping substituted in silicon-attached alkyl are known, but they have received very little study. Some compounds of this type containing an ether grouping were prepared by reaction between alkoxy(chloroalkyl)silanes and a sodium alkoxide in an alcohol medium [1]. Compounds containing an ester grouping were prepared by reaction of (chloromethyl)diethoxymethylsilane with sodiomalonic and sodioacetoacetic esters [2]. Addition of chlorodimethylsilane at the double-bond of undecenoic esters and subsequent replacement of silicon-attached chlorine by ethoxyl gave compounds containing an ester grouping at the end of a silicon-attached chain of eleven carbon atoms [3]. No acetoxysilanes containing an ester grouping in a silicon-attached alkyl have been described. The synthesis of alkoxy- and acetoxy-silanes containing ether and ester groupings is of interest in that these compounds can form the basis of a study of the effect of ether and ester groupings on the stability of the C—Si bond in presence of nucleophilic and other reagents.

In the present investigation, alkoxy- and acetoxy-silanes containing an ether or ester grouping substituted in silicon-containing alkyl were synthesized, namely:

$RSiX(OC_2H_5)_2$, $XSi(OCOCH_3)_3$, and $RSiX(OCOCH_3)_2$, in which R = Alk or Ar, and X = CH_2OR, $CH_2COOC_2H_5$, or CH_2OCOCH_3.

(Alkoxymethyl)alkyldiethoxysilanes were synthesized as follows:

a) $ClCH_2SiCl_2(CH_3) + 2C_2H_5OH \rightarrow ClCH_2Si(OC_2H_5)_2(CH_3) + 2HCl$,

b) $ClCH_2Si(OC_2H_5)_2(CH_3) + C_2H_5ONa \rightarrow C_2H_5OCH_2Si(OC_2H_5)_2(CH_3) + NaCl$.

Alkyl- and aryl-diethoxy(ethoxycarbonylmethyl)silanes were synthesized as follows. An alkyl- or aryltrichlorosilane was first treated with alcohol:

a) $RSiCl_3 + 2C_2H_5OH \rightarrow RSiCl(OC_2H_5)_2 + 2HCl$,

and the alkyl- or aryl-chlorodiethoxysilane was treated with sodium and ethyl bromoacetate:

b) $RSiCl(OC_2H_5)_2 + 2Na + BrCH_2COOC_2H_5 \rightarrow R{-}Si(CH_2COOC_2H_5)(OC_2H_5)_2 + NaCl + NaBr$

Acetoxy(acetoxymethyl)silanes were synthesized as follows:

TABLE

No.	Substance	Formula	B.p. in °C (p in mm)	n_D^{20}	d_4^{20}	MR	
						Found	Calculated

a) $ClCH_2SiCl_2 + 3ClCH_2COOK \rightarrow CH_3OCOCH_2Si(OCOCH_2)_3 + 3KCl;$

b) $ClCH_2SiCl_3 + 4ClCH_2COOK \rightarrow CH_3OCOCH_2{\cdot}Si(OCOCH_2)_3 + 4KCl.$

The properties of the new compounds obtained by the above reactions are given in the table.

EXPERIMENTAL

1. Synthesis of Diethoxy(ethoxycarbonylmethyl)ethylsilane

a) Synthesis of Chlorodiethoxyethylsilane. The reaction was carried out in a three-necked flask fitted with stirrer, reflux condenser, dropping funnel, and thermometer. Absolute ethanol (184.0 g) was added dropwise to 327 g of trichloroethylsilane (b.p. 98°; chlorine content 63.7%); during the addition, the temperature fell to 5°. When the whole of the alcohol had been added, the mixture was heated at 70-80° for 15 hours. The product was distilled from a flask fitted with a fractionating column, 200 mm in length. The product, which amounted to 274 g (75%), came over at 140-144°.

b) Synthesis of Diethoxy(ethoxycarbonylmethyl)ethylsilane. The synthesis was carried out in a three-necked flask fitted with stirrer, dropping funnel, reflux condenser, and thermometer. Sodium (23 g) was heated with xylene in a round-bottomed flask until the xylene boiled. The flask was then closed and shaken vigorously, so that the molten sodium became finely divided. The xylene standing over the sodium was replaced by ether, and the sodium was then transferred to the reaction flask and covered with ether (100 g). The mixture was stirred, and a mixture of 91.3 g of chlorodiethoxyethylsilane and 83.5 g of ethyl bromoacetate was added dropwise. Reaction occurred with evolution of heat, and the rate at which the mixture was added was regulated so that the ether in the reaction flask boiled regularly and gently. When the addition was complete, the reaction mixture was heated at 38-40° for 13 hours. The voluminous precipitate was filtered off (weight 110 g). The filtrate was distilled from a flask through a column: b.p. 149-150°; d_4^{20} 0.9080; n_D^{20} 1.4008; found MR 62.6; calculated MR 61.35

Found %: C 52.14; H 10.12; Si 11.0. $C_{10}H_{22}O_4Si$. Calculated%: C 51.28; H 9.40; Si 11.97.

2. Synthesis of Diethoxy(ethoxycarbonylmethyl)phenylsilane

a) Preparation of Chlorodiethoxyphenylsilane. Absolute ethanol (92 g) was added dropwise to 211.4 g of trichlorophenylsilane (b.p. 202°, chlorine content 49.8%) contained in a three-necked flask fitted with stirrer, dropping funnel, reflux condenser, and thermometer. When the whole of the alcohol had been added, the mixture was heated at 70-80° for 12 hours. Vacuum distillation gave 146.5 g (63.5%) of product, b.p. 92-93° (4 mm), chlorine content 15.03% (theory requires 15.4%).

b) Synthesis of Diethoxy(ethoxycarbonylmethyl)phenylsilane. The procedure was similar to that used in the synthesis of diethoxy(ethoxycarbonylmethyl)ethylsilane. The reactants were sodium (13.8 g), chlorodiethoxyphenylsilane (70 g), and ethyl bromoacetate (50.1 g). The precipitate formed was filtered off, and vacuum distillation of the filtrate gave 21.8 g (33.2%) of diethoxy(ethoxycarbonylmethyl)phenylsilane, b.p. 106-112° (7 mm); d_4^{20} 1.0080; n_D^{20} 1.4600; found MR 72.62; calculated MR 72.16

Found %: C 59.56; H 8.00; Si 10.04. $C_{14}H_{22}O_4Si$. Calculated %: C 59.57; H 7.80; Si 9.92.

3. Synthesis of Diethoxy(ethoxymethyl)methylsilane

a) Synthesis of (Chloromethyl)diethoxymethylsilane. Absolute ethanol (95 g) was added dropwise to 163.5 g of dichloro(chloromethyl)methylsilane contained in a three-necked flask fitted with stirrer, dropping funnel, reflux condenser, and thermometer. The temperature of the reaction mixture fell to 5°. When the whole of the alcohol had been added, the reaction mixture was heated at 70-80° until the evolution of hydrogen chloride ceased (20 hours). The product was distilled from a flask fitted with a Vigreux column. The yield of (chloromethyl)diethoxymethylsilane was 130 g (71.4%); it had b.p. 161-163°, n_D^{20} 1.4117; and chlorine content 19.9% (theory requires 19.4%).

b) Synthesis of Diethoxy(ethoxymethyl)methylsilane. The synthesis was in the same reaction flask. Sodium ethoxide was prepared by adding absolute ethanol (45 g) to finely divided sodium (13.8 g) in xylene (75 g). When the whole of the alcohol had been added, the mixture was heated at 70-80° for one hour. The mixture was cooled, and 113.8 g of (chloromethyl) diethoxymethylsilane was added dropwise, after which the mixture was heated at 70-80° for 12 hours. The voluminous precipitate was filtered off. Distillation of the filtrate through a Vigreux column gave 29.8 g (25.7%) of product, b.p. 148-150°; d_4^{20} 0.9189; n_D^{20} 1.4125; found MR 52.0; calculated MR 52.09.

Found %: C 49.83; H 9.83; Si 14.03. $C_8H_{20}O_3Si$. Calculated %: C 50.00; H 10.41; Si 14.58.

4. Synthesis of Diethoxy(methoxymethyl)methylsilane

The procedure was similar, but toluene was used as solvent. The substances taken in the reaction were sodium (6.9 g), methanol (20.0 g), (chloromethyl)diethoxymethylsilane (54.6 g), and toluene (50 g). Distillation of the filtrate through a column gave 15.8 g (29.5%) of product, b.p. 140-143°; d_4^{20} 0.9233; n_D^{20} 1.4088; found MR 47.64; calculated MR 47.32.

Found %: C 48.63; H 9.62; Si 14.15. $C_7H_{18}O_3Si$. Calculated %: C 47.19; H 10.11; Si 15.73.

5. Synthesis of Diacetoxy(acetoxymethyl)methylsilane

Dichloro(chloromethyl)methylsilane (81.7 g; b.p. 121-124°) was added dropwise to a mixture of 147 g of anhydrous potassium acetate and 200 g of toluene contained in a three-necked flask fitted with stirrer, dropping funnel, reflux condenser, and thermometer. During the addition the temperature of the mixture rose to 60°. When the whole of the silane had been added, the mixture was heated at 90-100° for 20 hours. The precipitate present was then filtered off, and vacuum distillation of the filtrate gave 43.4 g (36.7%) of diacetoxy(acetoxymethyl)methylsilane, b.p. 90-95° (20 mm); d_4^{20} 1.1529; n_D^{20} 1.4321; found MR 52.65; calculated MR 52.09.

Found %: C 41.76; H 6.04; Si 11.49; CH_3COO^- 49.63. $C_8H_{14}O_6Si$. Calculated %: C 41.02; H 5.10; Si 11.50; CH_3COO^- 50.04.

6. Synthesis of Triacetoxy(acetoxymethyl)silane

Trichloro(chloromethyl)silane (42.6 g) was added dropwise to a mixture of 117.8 g of anhydrous potassium acetate and 135 ml of toluene contained in a flask fitted with stirrer, dropping funnel, reflux condenser, and thermometer. During the addition the temperature of the mixture rose to 100°. When the addition was complete, the mixture was heated at 100-110° for 18 hours. The precipitate was then filtered off through a Buchner funnel, and the filtrate was vacuum distilled. The yield of triacetoxy(acetoxymethyl)silane was 21 g (25%); it was obtained in the form of crystals, m.p. 79.5°, b.p. 79-82° (10 mm).

Found %: C 38.14; H 4.90; Si 11.52. $C_9H_{14}O_8Si$. Calculated %: C 38.8; H 5.03; Si 10.0.

SUMMARY

1. An investigation was made into methods for the introduction of a silicon-attached alkyl containing an ether or ester grouping into certain alkoxyalkyl(or aryl)silanes and acetoxyalkylsilanes.

2. By the reaction of sodium and ethyl bromoacetate with chlorodiethoxyethylsilane and with chlorodiethoxyphenylsilane, the following organosilicon compounds were prepared for the first time: diethoxy-(ethoxycarbonylmethyl)ethylsilane and diethoxy(ethoxycarbonylmethyl)phenylsilane.

3. Reaction between alkoxy(chloroalkyl)silanes and sodium alkoxides yielded two new compounds: diethoxy(ethoxymethyl)methylsilane and diethoxy(metnoxymethyl)methylsilane.

4. Reaction between chloro(chloroalkyl)silanes and potassium acetate yielded two new compounds containing an acetoxy group in a silicon-attached alkyl radical: diacetoxy(acetoxymethyl)methylsilane and triacetoxy(acetoxymethyl)silane.

SYNTHESIS AND REACTIONS OF ORGANOSILICON THIOCYANATES AND THIOLS

V. F. Mironov and N. A. Pogonkina

We have already [1] reported the synthesis of the first two organosilicon thiocyanates in which the thiocyanato group is attached to carbon in the α-position with respect to silicon*. These organosilicon α thiocyanates, $(CH_3)_3SiCH_2SCN$ and $(C_2H_5)_2CH_3SiCH_2SCN$ were readily obtained by boiling the corresponding α-chloro compounds with ammonium thiocyanate in an acetone medium:

$$R_3SiCH_2Cl + NH_4SCN \rightarrow R_3SiCH_2SCN. \quad (1)$$

We now report the synthesis of some new α-thiocyanates by the aid of Reaction (1), and also the synthesis of the first α,α'-dithiocyanates and γ-thiocyanates by the Reactions (2), (3), and (4):

$$(CH_3)_2Si(CH_2Cl)_2 + 2NaSCN \rightarrow (CH_3)_2Si(CH_2SCN)_2. \quad (2)$$

$$[ClCH_2(CH_3)_2Si]_2O + 2NaSCN \rightarrow O[Si(CH_3)_2CH_2SCN]_2. \quad (3)$$

$$(CH_3)_3SiCH_2CH_2CH_2Cl + NaSCN \rightarrow (CH_3)_3SiCH_2CH_2CH_2SCN. \quad (4)$$

It was found that 96% ethanol was a better medium than acetone for the synthesis of the organosilicon thiocyanates, for its use enabled us to reduce the reaction volume considerably. It was shown also that in the Reactions (1)-(4), not only ammonium thiocyanate, but also potassium and sodium thiocyanates could be used, and the use of the last two salts resulted in higher yields of α-thiocyanates, even in an acetone medium. The introduction of these modifications into the original procedure enabled us to increase the yield, for example of $(CH_3)_3SiCH_2SCN$ and $(C_2H_5)_2CH_3SiCH_2SCN$, from 50% [1] to 85%. Finally, it was found that reaction between (iodomethyl)trimethylsilane and ammonium thiocyanate in an acetone medium gave $(CH_3)_3SiCH_2SCN$ in 80% yield, whereas Reaction (1), in which (chloromethyl)trimethylsilane was used, gave only a 50% yield of the α-thiocyanate [1].

The rate at which α-thiocyanates are formed in Reaction (1) is greatly reduced by substitution of the methyl radicals attached to silicon by ethyl, propyl, butyl, etc. The formation of the secondary α-thiocyanate $(CH_3)_2SiCH(SCN)CH_3$ is still more difficult. In these cases it is necessary to increase the duration of boiling greatly in order to increase the yields of organosilicon α-thiocyanates. This behavior is in accord with recent results [3] on the rate of ion exchange of the iodine in trialkyl(1-iodoalkyl)silanes, which was found to depend on the character of the radical attached to silicon.

In order to prove that the products of Reactions (1)-(4) were indeed thiocyanates (and not isothiocyanates, which are formed when alkyl- and aryl-chlorosilanes are treated with thiocyanate salts [4]:

$$R_3SiCl + NaSCN \rightarrow R_3SiNCS),$$

we studied the action of Grignard reagents on our products. It is known [5] that with thiocyanates RMgX forms thiols and sulfides, whereas with isothiocyanates it gives thiocarboxylic amides. As we had supposed [5], our products were thiocyanates, for with n-C_3H_7MgBr they gave the corresponding thiols in admixture with sulfides:

$$R_3SiCH_2SCN + n\text{-}C_3H_7MgX \rightarrow R_3SiCH_2SH + R_3SiCH_2SC_3H_7. \quad (5)$$

The synthesis of organosilicon thiols in which the thiol group was on the α-carbon was effected recently by the action of KHS [6] or thiourea [6,7] on the corresponding α-chloro compounds; in the second case the

* Cooper [2] has recently reported the synthesis of three organosilicon α-thiocyanates.

thiol was obtained by the subsequent splitting of the isothiouronium salt with alkali.

By means of Reaction (5) we synthesized four organosilicon α-thiols, and two of these compounds [R_3 = $(CH_3)_3$ and $(C_2H_5)_2CH_3$] were distilled through an efficient column. On the basis of the constants of these compounds, we calculated the refraction of the mercaptomethyl group attached to silicon, the value found being 15.22 ml/mole. The α-thiols for which $R_3 = CH_3(C_2H_5)_2$ and $CH_3(C_4H_9)_2$ were vacuum distilled, but the products appeared to be contaminated with the corresponding sulfides, this view being confirmed by their elementary analyses and molecular refractions. Owing to the low yields of sulfides in Reaction (5), they were not isolated in the pure state.

Reaction between an organosilicon γ-thiocyanate and n-C_3H_7MgBr, unlike the reaction of the α-thiocyanates, gave a considerable yield (37%) of the sulfide, and the γ-thiol was obtained in 40% yield:

$$2(CH_3)_2SiCH_2CH_2CH_2SCN + 2C_3H_7MgBr \longrightarrow$$
$$\longrightarrow (CH_3)_2SiCH_2CH_2CH_2SH + (CH_3)_2SiCH_2CH_2CH_2SC_3H_7. \quad (6)$$

Attempts to convert $(CH_3)_2Si(CH_2SCN)_2$ into $(CH_3)_2Si(CH_2SH)_2$ by the method described were unsuccessful. A substance was isolated, and its elementary analysis, and particularly the result of its cyanoethylation, indicated that the main products of the reaction were a mercapto sulfide and a disulfide:

$$2(CH_3)_2Si(CH_2SCN)_2 + 4C_3H_7MgBr \longrightarrow$$
$$\longrightarrow (CH_3)_2Si(CH_2SH)CH_2SC_3H_7 + (CH_3)_2Si(CH_2SC_3H_7)_2. \quad (7)$$

Cyanoethylation of the mixture of these substances gave a 59% yield of a compound which corresponded in elementary analysis and molecular refraction to

As we had a number of other organosilicon thiols at our disposal, we cyanoethylated them, so continuing our work [1,8] on the cyanoethylation of organosilicon compounds. In presence of sodium methoxide, both α- and γ-thiols add more vigorously to acrylonitrile than organosilicon alcohols [1] and amines [8] do:

$$R_3Si(CH_2)nSH + CH_2 = CHCN \longrightarrow R_3Si(CH_2)nSCH_2CH_2CN,$$

in which n = 1 and 3.

The properties of the compounds prepared in this investigation are given in Tables 1 and 2.

EXPERIMENTAL

Trimethyl(thiocyanatomethyl)silane $NCSCH_2Si(CH_3)_3$. A mixture of 97.3 g (1.2 moles) of sodium thiocyanate dissolved in 500 ml of 96% ethanol and 122.7 g (1 mole) of (chloromethyl)trimethylsilane [9] was prepared in a one-liter flask fitted with reflux condenser. The mixture was boiled for ten hours, the precipitated salt was filtered off, and alcohol was distilled from the filtrate. The liquid residue together with the previously separated salt were treated with water. The organic layer was separated and dried with calcium chloride. Vacuum distillation gave 122 g (84%) of trimethyl(thiocyanatomethyl)silane, b.p. 75° (10 mm). The remaining α-thiocyanates given in Table 1 were prepared under similar conditions.

Dimethylbisthiocyanatomethylsilane $(NCSCH_2)_2Si(CH_3)_2$. A mixture of 62.4 g (0.77 mole) of sodium thiocyanate, 400 ml of alcohol, and 55 g (0.35 mole) of bischloromethyldimethylsilane (formed in association with (dichloromethyl)trimethylsilane in the proportions of 1.8 : 1 in the chlorination of (chloromethyl)trimethylsilane [10]) was boiled for 11 hours. The usual treatment gave 55.9 g (79%) of dimethylbisthiocyanatomethylsilane, b.p. 142.5° (2 mm).

1,1,3,3-Tetramethyl-1,3-bisthiocyanatomethylsiloxane $O[(CH_3)_2SiCH_2SCN]_2$. A mixture of 15.8 g of sodium thiocyanate, 300 ml of acetone, and 22.2 g of 1,3-bischloromethyl-1,1,3,3-tetramethyldisiloxane [11] was boiled for 35 hours. The usual treatment gave 9.3 g (38.4%) of 1-(chloromethyl)-1,1,3,3-tetramethyl-3-(thiocyanatomethyl)siloxane, b.p. 104-105° (1 mm) and 14 g (52.5%) of 1,1,3,3-tetramethyl-1,3-bisthiocyanatomethylsiloxane, b.p. 148° (1 mm).

Trimethyl(3-thiocyanatopropyl)silane $NCSCH_2CH_2CH_2Si(CH_3)_3$. A mixture of 26 g (0.32 mole) of

sodium thiocyanate, 200 ml of alcohol, and 43.7 g (0.29 mole) of (3-chloropropyl)trimethylsilane (b.p.150.5° (744 mm); n_D^{20} 1.4319, and d_4^{20} 0.8789) was boiled for 16 hours. A yield of 36 g (71.5%) of trimethyl(3-thiocyanatopropyl)silane, b.p. 66.8° (1 mm), was obtained.

(Trimethylsilyl)methanethiol $HSCH_2Si(CH_3)_3$. Propylmagnesium bromide was prepared from 122 g (1 mole) of propyl bromide and 1 mole of magnesium in 500 ml of ether in a one-liter flask fitted with reflux condenser, dropping funnel, and stirrer. Trimethyl(1-thiocyanatomethyl)silane (47.3 g) was added dropwise to the Grignard reagent. Reaction was vigorous, and cooling was necessary. On the next day the contents of the flask were boiled for one hour and then decomposed with water and hydrochloric acid. The ether layer together with ether extracts from the aqueous layer was dried with sodium sulfate. Distillation through a column gave 28.1 g (71.5%) of (trimethylsilyl)methanethiol.

The organosilicon α-thiols listed in Table 2 were prepared similarly.

3-(Trimethylsilyl)-1-propanethiol $HSCH_2CH_2CH_2Si(CH_3)_3$. Trimethyl(3-thiocyanatopropyl)silane (34.7 g) was added to propylmagnesium bromide prepared from 15 g of magnesium and 95 g of propyl bromide in 250 ml of ether. The usual treatment gave 13.2 g (40%) of 3-(trimethylsilyl)-1-propanethiol, b.p. 164° and 13.9 g (36.6%) of $(CH_3)_3SiCH_2CH_2CH_2SC_3H_7$, b.p. 206°.

[Dimethyl(propylthiomethyl)silyl]methanethiol $HSCH_2\underset{\underset{CH_3}{|}}{\overset{\overset{CH_3}{|}}{Si}}CH_2SC_3H_7$. Dimethylbisthiocyanatomethylsilane (55 g) was added to propylmagnesium bromide prepared from 40 g of magnesium and 230 g of propyl bromide in 1 liter of ether. The usual treatment gave 42.3 g of a substance, b.p. 74.5° (2 mm); n_D^{20} 0.8674; d_4^{20} 0.8674.

Found %: C 46.38, 46.32; H 9.44, 9.48; S 28.66, 28.73; Si 13.54, 13.51. $C_4H_{12}SiS_2$. Calculated %: C 31.54; H 7.94; S 42.09; Si 18.43. $C_{10}H_{24}SiS_2$. Calculated %: C 43.24; H 9.33; S 32.98; Si 14.43. $C_7H_{18}SiS_2$. Calculated %: C 50.79; H 10.65; S 27.11; Si 11.87.

Cyanoethylation of product confirmed that it was

probably containing some $(C_3H_7SCH_2)_2Si(CH_3)_2$ as impurity.

3-[(Trimethylsilyl)methylthio] propionitrile $(CH_3)_3SiCH_2SCH_2CH_2CN$. One or two drops of sodium methoxide syrup were added to 12.2 g of (trimethylsilyl)methanethiol, and 10 g of acrylonitrile was then added at such a rate that the temperature did not rise above 50-60°. After one day the contents of the flask were washed with water acidulated with hydrochloric acid until they were neutral to litmus, and they were then dried with calcium chloride and distilled. The yield of 3-[(trimethylsilyl)methylthio]propionitrile was 14 g (88.5%); it boiled at 250° (748 mm). The other organosilicon thiols listed in Table 2 were cyanoethylated in a similar way.

SUMMARY

1. For the first time organosilicon compounds were prepared with a thiocyanato or thiol group in the γ-position with respect to silicon and also with two thiocyanato groups in α-positions.

2. It was shown that these organosilicon α- and γ-thiocyanates readily react with RMgX with formation of the corresponding thiols, which proves the structure of the thiocyanates and can form the basis of a new method of synthesizing organosilicon thiols.

3. It was found that organosilicon thiols, both the α and the γ compounds, readily add to acrylonitrile.

REACTION OF HEXAALKYLDISILOXANES WITH IODINE AND ALUMINUM

M. G. Voronkov and Yu. I. Khudobin

One of us recently proposed [1] a new method for the synthesis of trialkylhalosilanes based on the reaction of hexaalkyldisiloxanes with aluminum halides, which proceeds according to the equation:

$$R_3SiOSiR_3 + AlX_3 \longrightarrow 2R_3SiX + OAlX \quad (X = Cl, Br, \text{or } I).$$

This method, which is distinguished by its simplicity and by the high yields obtained, is somewhat inconvenient for the preparation of trialkyliodosilanes, since it demands the use of the unstable aluminum iodide, which is rarely found as a commercial product. For this reason we generally prepared aluminum iodide ourselves immediately before it was required for the reaction; for this purpose aluminum was treated with iodine in carbon disulfide or benzene. In order to obviate this procedure, we later attempted to replace aluminum iodide by a mixture of iodine and aluminum. It was found that trialkyliodosilanes are formed smoothly when a mixture of the hexaalkyldisiloxane, aluminum, and iodine, taken in the molecular proportions 1 : 1.1 : 1.5, is heated until the color of the iodine disappears. Fractional distillation of the reaction mixture gives trialkyliodosilanes in 82-93% yield. In this way we prepared five trialkyliodosilanes (the tributyl and triisopentyl compounds had not been prepared previously). Their physical properties and yields and the analytical data are given in the table.

TABLE

Trialkyliodosilanes R_3SiI

R	B.p. in °C ± 0.5° (p in mm)	d_4^{20} ±0.001	Yield (%)	Found I (%)	Calculated I (%)
CH_3	107.5 (760)	1.422	93	63.8; 64.1	63.42
C_2H_5	191.2 (760)	1.351	89	52.7; 52.5	52.39
$n\text{-}C_3H_7$	238 (760)	1.229	88	44.4; 44.7	44.65
$n\text{-}C_4H_9$*	124.5—125.5 (4)	1.225	85	39.1; 38.5	38.89
$i\text{-}C_5H_{11}$*	151—152 (5)	1.115	82	34.5; 34.0	34.45

* New compound

EXPERIMENTAL

Original hexaalkyldisiloxanes. These were prepared and purified as described previously [2]. Hexaisopentyldisiloxane, which has not been described previously had b.p. 210-211° (8 mm); d_4^{20} 0.8398; n_D^{20} 1.4467; $n_F^{20} - n_C^{20}$ 0.0083; Si 11.49 and 11.30%; calculated Si 11.26%. The other reactants were aluminum fillings, containing 99.6% Al, and chemically pure iodine powder.

Determination of iodine in trialkyliodosilanes. A sample of the substance (0.15-0.3 g) contained in a sealed tube was introduced into a measured amount (20-30 ml) of 0.1 N NaOH contained in a flask having a ground-in stopper. The tube was broken, the contents of the flask were carefully mixed, and the solution was allowed to stand for 15 minutes at room temperature. Excess of alkali was then titrated to phenolphthalein with 0.1 N HCl.

Procedure in the syntheses. The hexaalkyldisiloxane, aluminum, and iodine, taken in the molecular proportions of 1 : 1.1 : 1.5, were introduced into a flask fitted with a 20-cm Vigreux column. The reaction mixture was gradually heated to the boil and maintained at that temperature until the iodine color disappeared (30-60 minutes); it was then distilled under diffuse illumination in a nitrogen atmosphere (in a vacuum in the case of triisopentyliodosilane)•. Reaction was sometimes vigorous, and the distillation flask was cooled with water. The trialkyliodosilanes then obtained were immediately redistilled over copper powder under diffuse illumination in an atmosphere of pure dry nitrogen. High-boiling trialkyliodosilanes were immediately redistilled under a reduced pressure of nitrogen. The trialkyliodosilanes, purified in this way, were quickly sealed in glass tubes filled with nitrogen and were kept in the dark. Analyses and determinations of physical constants were carried out on the trialkyliodosilanes as soon as possible after their preparation. All operations with trialkyliodosilanes were carried out with the appropriate precautions against the introduction of traces of moisture. By way of examples, some of the syntheses are described below.

Synthesis of iodotrimethylsilane. Aluminum filings (5.4 g, i.e. 0.2 g-atom) and iodine powder (67.1 g, i.e. 0.558 g-atom) were added to hexamethyldisiloxane (30.5 g, i.e. 0.186 mole). The mixture was heated at the boil until the iodine color disappeared (1 hour), and it was then distilled under diffuse illumination in an atmosphere of nitrogen. The yield of iodotrimethylsilane, b.p. 105.5-107° (752 mm), was 54.5 g (93%).

Synthesis of tributyliodosilane. A mixture of 62.2 g (0.15 mole) of hexabutyldisiloxane, 4.9 g (0.18 g-atom) of aluminum filings and 57.15 g (0.45 g-atom) of iodine was heated at the boil until the iodine color disappeared (1 hour). Distillation of the reaction mixture under diffuse illumination in an atmosphere of nitrogen gave 83.4 g (85%) of tributyliodosilane, b.p. 280-282.5° (755 mm).

Synthesis of odotriisopentylsilane. A mixture of 25.5 g (0.05 mole) of hexaisopentyldisiloxane, 2.66 g (0.09 g-atom) of aluminum filings, and 19.1 g (0.15 g-atom) of iodine was heated at the boil until the iodine color disappeared (1 hour). Vacuum distillation gave 30.1 g (82%) of iodotriisopentylsilane, b.p. 136-145° (4 mm).

SUMMARY

A method was developed for the synthesis of trialkyliodosilanes by reaction between hexaalkyldisiloxanes, iodine, and aluminum.

STEREOCHEMISTRY OF CYCLIC COMPOUNDS

COMMUNICATION 10. STEREOCHEMISTRY OF THE DIENE CONDENSATION OF 1-VINYL-1-CYCLOHEXENE WITH MALEIC ANHYDRIDE

I. N. Nazarov, V. F. Kucherov, and V. M. Andreev

Our previous investigations on the condensation of 1-vinyl-1-cyclohexene [1] and 1,2,4a,5,8,8a-hexahydro-4a,7-dimethyl-4-vinylnaphthalene [2] with citraconic anhydride enabled us to establish some interesting stereochemical peculiarities of these diene syntheses. These peculiarities, in particular the configurations of the isomers formed and the steric selectivity of the hydrogenation reaction, were established in the greatest detail for the condensation of 1-vinyl-1-cyclohexene with methyl acrylate [3]. In order to carry our study of the stereochemistry of the diene synthesis still further, we investigated the condensation of 1-vinyl-1-cyclohexene with maleic anhydride [4]. It was found that this reaction proceeds extremely readily: simple mixing of the components at room temperature results in a vigorous exothermic reaction with formation of a mixture of adducts, from which only a small amount (10-15%) of the previously described [5] crystalline cis anhydride (I), m.p. 53-54°, could be isolated. When the reaction was carried out under milder conditions (stirring a benzene solution at 2-3° for 120 hours), a 55% yield of the cis anhydride (I) was obtained together with about 15% of a liquid product of the diene synthesis.

In accordance with the results obtained for 1,2,3,5,6,7,8,8a-octahydro-1-naphthoic acid [3], the cis anhydride (I) formed under such mild conditions will have cis configurations of the hydrogen atoms at C-1, C-2, and C-8a [6] and, in accordance with the nomenclature adopted for tetradecahydrophenanthrenes [7], should be referred to as a syn-cis anhydride. When boiled with water, it is readily hydrolyzed with formation of the corresponding syn-cis-1,2,3,5,6,7,8,8a-octahydro-1,2-naphthalenedicarboxylic acid (II), which is converted by diazomethane into the syn-cis diester (III).

As in all other analogous cases that we have studied [1-3], the hydrogenation over a platinum catalyst of the compounds (I), (II), and (III) proceeds sterically in a strictly selective fashion with formation of only one of the possible isomers. Owing to the screening effect of the ortho carboxyls, which we proved for the cases of 1,2,3,5,6,7,8,8a-octahydro-1-naphthoic acid [3] and 4-methyl-4-cyclohexene-1,2-dicarboxylic acid [8], the addition of hydrogen to (I), (II), and (III) proceeds exclusively from the side opposite to the carboxyls, resulting in the formation of the saturated anhydride (IV), m.p. 76°, the acid (V), m.p. 212°, and the diester (VI), which have the cis-syn-cis configuration and belong to the cis-decahydronaphthalene series.

The liquid product of the diene synthesis, which did not crystallize after long standing and treatment with solvents, was readily hydrogenated over a platinum catalyst at room temperature with the absorption of one molecular equivalent of hydrogen, and a 30% yield was obtained of the individual saturated cis anhydride (VII), m.p. 128°, which differed from the cis-syn-cis anhydride (IV) and gave a new cis acid (VIII), m.p. 153°, when hydrolyzed. This fact, which definitely pointed to the presence of the isomeric anti-cis anhydride (X) in the liquid mixture of adducts, prompted us to study the thermal isomerization of the syn-cis anhydride (I) and the syn-cis acid (III), for it is known [8,9] that the thermal isomerization of syn-cis ortho-dicarboxylic acids readily results in their conversion into more stable isomers having the anti-cis configuration.

It was, in fact, found that the anhydride (I) and the acid (II), heated for one hour at 250° and then vacuum distilled, are isomerized in good yield to the liquid anti-cis anhydride (X), which is hydrolyzed by water to the anti-cis acid (XI), which can be converted by diazomethane into the anti-cis diester (XIII).

Like the Compounds (I), (II), and (III) of the syn-cis series, the anti-cis Compounds (X), (XI), and (XII) are also readily and sterically selectively hydrogenated over a platinum catalyst with formation of only one isomer in each case. Such selective hydrogenation, as in all the other analogous cases that we have studied, is due to the screening effect of carboxyl groups, as a result of which addition of hydrogen proceeds only from the side opposite to the carboxyls, with formation of the saturated anhydride (VII), acid (VIII), and diester (IX), which have a trans-anti-cis configuration and belong to the trans-decahydronaphthalene series. It was thus shown that, even under mild conditions, the condensation of 1-vinyl-1-cyclohexene with maleic anhydride results in the simultaneous formation of syn-cis and anti-cis anhydrides, (I) and (X), in the ratio of about 10 : 1.

The thermal isomerization of the syn-cis anhydride (I) into the anti-cis anhydride (X), and also the readiness with which the Compounds (X), (XI), and (XII) of the anti-cis series are hydrogenated, shows that the latter differ from the corresponding compounds of the syn-cis series, (I), (II), and (III), only in the disposition of the hydrogen at C-8a. An examination of molecular models fully confirms this inference and at the same time explains the steric selectivity of hydrogenation.

It follows from the general scheme of the diene synthesis that the addition of maleic anhydride to 1-vinyl-1-cyclohexene can proceed in two possible directions (a and b), of which a is predominant under mild conditions and gives an adduct of the syn-cis configuration (I). Condensation in the direction b, being energetically less favorable, goes with greater difficulty and gives a stable anhydride of the anti-cis configuration (X), which is epimeric to (I) with respect to the hydrogen at C-8a.

The anti-cis anhydride (X) has the energetically most favorable (e)-(e) disposition * of ortho-substituents and (e)-(p) disposition of meta-substituents, so that the anhydride (X) and other compounds of this series are thermally more stable than the syn-cis anhydride (I). The models show that the carboxyls have a screening effect in the isomeric anhydrides (I) and (X), and this results in sterically selective hydrogenation such that in the syn-cis anhydride (I) it must result in a cis-decahydronaphthalene system, and in the anti-cis anhydride (X) it must result in a trans-decahydronaphthalene system.

By further detailed investigations of the chemical transformations of these compounds, we completely confirmed these conclusions and rigorous proof was obtained of the spatial configurations - as epimers with respect to hydrogen at C-8a – of the syn-cis and anti-cis anhydrides (I) and (X).

EXPERIMENTAL **

Condensation of 1-Vinyl-1-cyclohexene with Maleic Anhydride

A solution of 98.5 g of freshly distilled maleic anhydride in 375 ml of absolute cryoscopic benzene containing a little pyrogallol (0.2-0.5 g) was placed in a three-necked flask fitted with mechanical stirrer, dropping funnel, thermometer, and calcium chloride tube. The flask was cooled to 2-3°, and the contents were stirred while 108 grams (1 mole) of 1-vinyl-1-cyclohexene (distilled over sodium; b.p. 142-144°; n_D^{20} 1.4960) was added over a period of 90 minutes. Stirring at this temperature was continued for 120 hours, and the benzene was then distilled off under reduced pressure (bath temperature not above 35°). The oily residue was left for two days at room temperature and was then cooled with ice for 2-3 hours. Oil was pressed from the crystals on the filter, and the crystals were then washed twice with 50-ml portions of a 1 : 3 mixture of diethyl ether and petroleum ether and then once with 50 ml of a 1 : 1 mixture of diethyl ether and petroleum ether. The product was 81.5 g of the syn-cis anhydride (I), m.p. 51-53°. The substance was purified by dissolving it in 100 ml of absolute ether, filtering off the polymer that separated, and diluting the solution with 150 ml of petroleum ether, when 66.5 g of pure syn-cis anhydride (I), m.p. 53-54°, was obtained [4]. Evaporation of the mother liquor to dryness and crystallization of the residue gave a further 8 g of pure anhydride (I). In all, therefore, 74.5 g (38%) of the anhydride was obtained.

The mother liquors were evaporated under reduced pressure, and the residual liquid was left at 0° for two days. The crystals that separated were pressed on the filter to remove oil and washed with a 1 : 2 mixture of diethyl ether and petroleum ether. The product was 36.7 g of a crystalline substance, m.p. 29-37°. Further evaporation of the mother liquor and cooling with ice and salt gave another 5.6 g of crystals, m.p. 33-42°. No more crystals were obtained when the residue was again cooled.

The low-melting crystalline product so obtained could not be purified from maleic anhydride, and it was hydrolyzed at the boil with water for 15 minutes. The polymer that separated from the solution was filtered off, 5 ml of acetone was added, and the mixture was left overnight. The substance that separated, amounting to 21 g, was the syn-cis-acid (II), m.p. 170-171°, and after crystallization from 20% aqueous acetone it had a constant melting point of 171-172° [4].

Found %: C 64.03, 64.05; H 7.18, 7.09. $C_{12}H_{16}O_4$. Calculated %: C 64.27; H 7.19.
Found %: M 221.7 (titration with NaOH). Calculated %: M 224.3.

The diphenacyl ester, prepared in the usual way, melted at 142-143° (from 80% alcohol), which corresponds to data in the literature [5].

The aqueous mother solution obtained after the separation of the syn-cis acid (II) was evaporated to dryness, and washing of the crystalline residue with benzene and then with ether yielded 7.3 g of maleic acid, m.p. 132-134°, undepressed by admixture of a known sample (131-133°). The total yield of the syn-cis adduct (I) calculated on the anhydride (I) was 53%.

* The symbol (e) denotes an equatorial disposition of a substituent, and the symbol (p) a polar disposition.
** All melting points are corrected.

The liquid product of the diene synthesis was twice distilled under reduced pressure and gave 29.5 g of a light-yellow viscous liquid, b.p. 169-170° (3 mm) and n_D^{20} 1.5214. This substance was dissolved in 60 ml of cryoscopic benzene and hydrogenated over platinum oxide, when 4670 ml (about 1.5 molecular equivalents) of hydrogen was absorbed. Solvent was distilled off, and the liquid residue was allowed to stand, when it partially crystallized. Washing of the hydrogenation product on the filter with a 1 : 2 mixture of benzene and petroleum ether gave 10.4 g of the trans-anti-cis anhydride (VII), m.p. 121-123°, which melted constantly at 127-128° after crystallization from a 1 : 1 mixture of benzene and petroleum ether (glistening scales).

Found %: C 69.34, 69.19; H 7.71, 7.59. $C_{12}H_{14}O_3$. Calculated %: C 69.21; H 7.74.

syn-cis Dicarboxylic Acid (II)

A mixture of 1.0 g of the syn-cis anhydride (I) and 5 ml of water was boiled for 15 minutes. Acetone (1 ml) was added to the warm solution, and when cold, the solution yielded 0.95 g of the syn-cis dicarboxylic acid (II), which after crystallization from 20% aqueous acetone melted at 171-172° and showed no melting point depression in admixture with the acid obtained previously (above).

In order to reconvert it into the syn-cis anhydride (I), the syn-cis acid (II) (0.35 g) was boiled for 15 minutes with 3.5 ml of acetic anhydride, which was then distilled off under reduced pressure. Crystallization of the residue from a mixture of diethyl ether and petroleum ether gave 0.15 g of the anhydride (I), m.p. 51-52°, which was found to be identical with the product described above. When the syn-cis acid (II) was boiled with acetyl chloride, an oily chlorine-containing product was obtained.

syn-cis Diester (III)

A suspension of 8.5 g of the syn-cis acid (II) in ether was treated with excess of ethereal diazomethane. Ether was distilled off, and vacuum distillation of the residue gave 8.7 g of syn-cis diester (III), b.p. 126-127° (2 mm); n_D^{20} 1.5000; d_4^{20} 1.1419; found MR 65.0; calculated MR 65.29.

Found %: C 66.70, 66.74; H 8.08, 7.98. $C_{14}H_{20}O_4$. Calculated %: C 66.65; H 7.99.

cis-syn-cis Anhydride (IV)

The syn-cis anhydride (I) (10 g) was dissolved in cryoscopic benzene (100 ml) and hydrogenated over 0.1 g of platinum oxide. One molecular equivalent of hydrogen (1100 ml at 0° and 760 mm) was absorbed. Solvent was distilled off under reduced pressure, and the liquid residue rapidly crystallized when treated with petroleum ether. Recrystallization from 100 ml of a 1 : 2 mixture of diethyl ether and petroleum ether gave 8.2 g of the cis-syn-cis anhydride (IV), m.p. 72-74°. A further 1.3 g of the same saturated anhydride, m.p. 72-74°, was isolated after two crystallizations from the mother liquor. After further recrystallization the substance melted at 75-76°.

Found %: C 69.42, 69.24; H 7.83, 7.89. $C_{12}H_{14}O_3$. Calculated %: C 69.21; H 7.74.
The other possible isomer was not isolated.

cis-syn-cis Dicarboxylic Acid (V)

a) A mixture of 4.2 g of the cis-syn-cis anhydride (IV) and 35 ml of 5% aqueous caustic soda was boiled for 15 minutes, filtered, and acidified with hydrochloric acid. A substance (4.3 g) of m.p. 200-203° was obtained. Crystallization from 80% aqueous acetone gave pure cis-syn-cis dicarboxylic acid (V), melting constantly at 211-212°. When (V) was heated with acetyl chloride, (IV) was obtained in high yield.

Found %: C 63.58, 63.72; H 7.98, 7.86. $C_{12}H_{16}O_4$. Calculated %: C 63.68; H 8.02.

b) The syn-cis acid (II) (12.0 g) was dissolved in absolute methanol and hydrogenated in presence of 0.2 g platinum oxide. Hydrogenation was very rapid, and in one hour one molecular equivalent of hydrogen (1200 ml) was absorbed. Catalyst was filtered off, methanol was distilled off under reduced pressure, and the crystalline residue was washed on the filter with 50% acetone. An almost quantitative yield (11.3 g) was obtained of the cis-syn-cis dicarboxylic acid (V), m.p. 207-210°. After crystallization from 80% acetone it melted at 211-212°, and there was no depression in a mixture melting point test with the sample obtained in the preceding experiment. No other crystalline substance could be isolated from the mother liquor.

cis-syn-cis Diester (VI)

a) A suspension of 5 g of the cis-syn-cis dicarboxylic acid (V) in ether was treated with excess of ethereal diazomethane. Ether was distilled off, and vacuum distillation of the residue gave 5.1 g of the cis-syn-cis diester (VI), b.p. 130-131° (2 mm), n_D^{20} 1.4902; d_4^{20} 1.1229; found MR 65.76, calculated MR 65.48.

Found %: C 66.0, 65.96; H 8.85, 8.68. $C_{14}H_{22}O_4$. Calculated %: C 66.12; H 8.72.

b) The syn-cis diester (III) (5.5 g) was dissolved in methanol and hydrogenated over platinum oxide. One molecular equivalent of hydrogen (490 ml) was absorbed. Methanol was distilled off, and vacuum distillation of the residue gave 5.3 g of the above-described cis-syn-cis diester (VI), b.p. 130-131° (2 mm) and n_D^{20} 1.4908.

anti-cis Anhydride (X)

a) The syn-cis anhydride (I) (5.0 g) was heated at 245-255° in a current of nitrogen for 45 minutes, and the reaction product was vacuum distilled (25 mm) at a bath temperature of 220-230°. Redistillation gave 3.3 g (66%) of pure anti-cis anhydride (X) in the form of a thick yellowish oil, b.p. 177-178° (8 mm) and n_D^{20} 1.5224.

Found %: C 69.60, 69.70; H 8.83, 8.82. $C_{12}H_{16}O_3$. Calculated %: C 69.88; H 6.84.

b) The syn-cis acid (II) (9.0 g) was heated in a current of nitrogen at 245-250° for 50 minutes. Vacuum distillation gave 6.7 g of the above-described anti-cis anhydride (X), b.p. 185-187° (11 mm) and n_D^{25} 1.5230.

Hydrogenation of the anti-cis Anhydride (X)

The anti-cis anhydride (X) (2.0 g) was dissolved in cryoscopic benzene (20 ml) and hydrogenated over a platinum catalyst. One molecular equivalent of hydrogen (220 ml) was absorbed. Benzene was distilled off, and the treatment of the residue with petroleum ether gave 1.75 g of the trans-anti-cis anhydride (VII), m.p. 123-124°. Crystallization from ether gave an anhydride of constant melting point (126-127°), which was found to be identical with the substance isolated directly from the liquid product of the diene synthesis.

anti-cis Dicarboxylic Acid (XI)

A mixture of 20.3 g of the liquid anti-cis anhydride (X) and 100 ml of water was boiled until complete solution occurred and was then boiled further for 15 minutes. As the solution cooled, acetone was added (about 20 ml in all) so that the oil that tended to separate was maintained in solution. The mixture was set aside at room temperature for three days. The crystals that separated were filtered off. The product was 11.5 g of (XI); after being vacuum dried at 80° and crystallized from 10% aqueous acetone, it had constant m.p. 154-155°. Evaporation of the mother liquor gave a further 1.5 g of (XI). Found %: C 64.53, 64.43; H 7.29, 7.34. $C_{12}H_{18}O_4$. Calculated %: C 64.27; H 7.19. The dibenacyl ester melted after crystallization from ethanol at 119-120°. Found %: C 73.23, 73.01; H 6.14, 6.09. $C_{32}H_{34}O_6$. Calculated %: C 73.02; H 6.13.

anti-cis Diester (XII)

A suspension of 3.75 g of the anti-cis acid (XI) in ether was treated with ethereal diazomethane. Solvent was distilled off, and vacuum distillation of the residue gave 3.8 g of the anti-cis diester (XII), b.p. 133-134° (3 mm), n_D^{20} 1.4970, d_4^{20} 1.1233; found MR 65.14; calculated MR 65.29.

Found %: C 66.65, 66.63; H 8.06; 7.89. $C_{14}H_{22}O_4$. Calculated %: C 66.65; H 7.99.

trans-anti-cis Dicarboxylic Acid (VIII)

a) A mixture of 8.0 g of the trans-anti-cis anhydride (VII) and 50 ml of 5% aqueous caustic soda was boiled for ten minutes. The solution was filtered and acidified with hydrochloric acid. The oil that separated rapidly solidified. The product was 8.3 g of the trans-anti-cis dicarboxylic acid, m.p. 152-153°. Recrystallization from a mixture of water with a little acetone did not affect the melting point.

Found %: C 63.64, 63.54; H 7.96, 7.76. $C_{12}H_{18}O_4$. Calculated %: C 63.68; H 8.02.

The acid (VIII) so obtained showed a large depression in melting point in admixture with the anti-cis dicarboxylic acid (XI). Boiling of the trans-anti-cis acid (VIII) with acetyl chloride resulted in a quantitative yield of the original trans-anti-cis anhydride (VII).

b) The anti-cis dicarboxylic acid (XI) (5.0 g) was dissolved in 100 ml of absolute methanol and hydrogenated in presence of 0.1 g of platinum oxide. Hydrogenation was rapid, and one molecular equivalent of hydrogen (510 ml) was absorbed. Methanol was distilled off, and the oily residue crystallized when a little water was added. The product was 4.2 g of the trans-anti-cis dicarboxylic acid (VIII), m.p. 149-151°. After being crystallized from 20% aqueous acetone, the acid had m.p. 151-152°, undepressed by admixture of the sample obtained in the preceding experiment. No other crystalline product could be isolated from the mother liquors.

trans-anti-cis Diester (IX)

a) A suspension of 6.3 g of the trans-anti-cis dicarboxylic acid (VIII) in ether was treated with ethereal diazomethane. Distillation gave 5.6 g of the trans-anti-cis diester (IX), b.p. 122-123° (2 mm), n_D^{20} 1.4809, d_4^{20} 1.1051; found MR 65.47, calculated MR 65.48.

Found %: C 65.81, 65.82; H 8.67, 8.74. $C_{14}H_{22}O_4$. Calculated %: C 66.12; H 8.72.

b) The anti-cis diester (XI) (6.1 g) was dissolved in absolute methanol (40 ml) and hydrogenated over platinum oxide. One molecular proportion of hydrogen was absorbed. The catalyst was filtered off, methanol was distilled off, and the residue was vacuum distilled, when 5.5 g of the above described trans-anti-cis diester (IX), b.p. 121-122° (2 mm) and n_D^{20} 1.4810.

SUMMARY

1. A study was made of the diene condensation of 1-vinyl-1-cyclohexene with maleic anhydride. It gives the syn-cis and anti-cis anhydrides (I) and (X) in the proportions of 10 : 1. These isomers differ in the disposition of the hydrogen at C-8a.

2. The thermal transformation of the syn-cis anhydride (I) into the anti-cis anhydride (X) was effected, and the corresponding isomeric acids (II) and (XI) and isomeric esters (III) and (XII) were prepared.

3. It was shown that the hydrogenation of derivatives both of the syn-cis series (I, II, III) and also of the anti-cis series (X, XI, XII) proceeds in a sterically selective manner: hydrogen adds from the least screened side (opposite to the carboxyl groups) with formation of derivatives of the cis- and trans-decahydronaphthalene series respectively.

4. An examination of molecular models has enabled us to explain the spatial configurations of the adducts obtained, (I) and (X), and also the steric selectivity of the hydrogenation of these and other compounds obtained.

CATALYTIC HYDROCONDENSATION OF CARBON MONOXIDE WITH OLEFINS

COMMUNICATION 16. HYDROCONDENSATION OF CARBON MONOXIDE WITH 1-BUTENE

Ya. T. Eidus and R. I. Izmailov

In a previous investigation [1] it was shown that liquid hydrocarbons are obtained in yields of up to 540 ml/cu.m or 55.5 ml/liter·hour in the hydrocondensation of carbon monoxide with 2-butene at 190° under atmospheric pressure, the composition of the original gas mixture being 4-6% of carbon monoxide, 70-75% of 2-butene, and 21-26% of hydrogen. 2-Butene reacts to the extent of 47%, of which 5% is hydrogenated to butane. The liquid condensate, when freed from C_4 hydrocarbons, contains 37% of unsaturated hydrocarbons, and after being hydrogenated, 76% of it boils within the range 36-332°. The reaction product is composed mainly of normal aliphatic hydrocarbons in admixture with a small amount of only slightly ramified branched hydrocarbons, where there is probably only one methyl side group, this being on the second carbon atom of the chain. The results indicate that, in the hydrocondensation of carbon monoxide with 2-butene, most of the latter isomerizes into 1-butene, which then reacts with carbon monoxide and hydrogen with predominant formation of hydrocarbons of normal structure.

In view of these results it was of interest to investigate the hydrocondensation of carbon monoxide with 1-butene under similar conditions. We have previously reported [2] the results of an investigation of the hydrocondensation of carbon monoxide with the n-butene obtained by dehydration of 1-butanol over alumina; this consisted predominantly of 1-butene, but the relative amounts of the isomers were not determined exactly. In these experiments we used an equimolecular mixture of butene and hydrogen containing 4-6% of carbon monoxide. Yields of liquid hydrocarbons of up to 635 ml/cu.m or 55 ml/liter·hour were obtained. The debutanized liquid condensate boiled over the range 28-276°, contained 28% of olefins, and, when hydrogenated, was found to contain about 24% by volume of C_5 hydrocarbons (about one-half of it isopentane), 15% of C_6, 8% each of C_7 and C_8, and 9% of C_9. About 30-35% of the butene was hydrogenated to butane. As will be seen from the data cited, the butene:hydrogen ratios differed greatly in investigations [1] and [2]: in the first it was 1 : 1, and in the second 2.7-3 : 1. In an investigation of the effect of the concentration of carbon monoxide on the course of the hydrocondensation of carbon monoxide with butene [3], it was shown that reaction was most rapid when the carbon monoxide content of the original gas was 6-8%. At 15-20% CO the yield of heavy hydrocarbons increased rapidly and the process, unlike the similar process with ethylene, was greatly retarded. It is possible that this explains the results obtained in a study of the behavior of 1-butene and cis-2-butene [4] under the conditions of gasoline synthesis over a Co-Cu-ThO_2 catalyst at 190° when added to the extent of 1.6-2.3% to an original gas mixture of 1 CO : 1.7 H_2. It was found that only a small proportion of the butene was converted into high-boiling oxygen compounds. Most of it was found in the C_4 fraction of the synthesis products, and it had no effect on the yield and composition of the C_5 fraction. In these experiments [4], 58.5% of the added 2-butene remained unchanged, 29.1% was hydrogenated to butane, and 3.6% was isomerized to 1-butene; 6.4% of the added 1-butene remained unchanged, 40.0% was converted into butane, and 28.2% was isomerized to 2-butene.

The object of the present work was the investigation of the hydrocondensation of carbon monoxide with 1-butene and the effect of additions of 10-30% of 2-butene on the course of the reaction. It was shown previously [5] that, in presence of hydrogen but in absence of carbon monoxide, 1-butene is isomerized to 2-butene in presence of a hydrocondensation catalyst at 190°; the relative amounts of 1- and 2-butenes in the products was 1 : 1.1. It would be expected that, under the same conditions but in presence of carbon monoxide, 1-butene would be converted to a certain extent into 2-butene, and additions of the latter in amounts of 10-35% would have no effect on the course of the hydrocondensation of 1-butene with carbon monoxide.

EXPERIMENTAL

Preparation of 1-Butene and of Its Mixtures with 2-Butene

1-Butene and its mixtures with various amounts of 2-butene were prepared by the dehydration of 1-butanol [b.p. 116.5 - 117.0° (756 mm); n_D^{20} 1.3991; d_4^{20} 0.8098; found MR 22.13; calculated C_4H_9OH MR 22.20] under various conditions over alumina prepared in various ways, differing according to the proportion of admixed 2-butene required. The method of determining the composition of the C_4 fraction was described previously [5].

It must be pointed out that there are some extremely contradictory statements in the literature about the compositions of n-butene mixtures obtained by the dehydration of 1-butanol over alumina. This is to be attributed to imperfect methods of analysis [5] and to a lack of appreciation of the effect of differences in the composition and properties of the alumina preparations used [6,7].

The activity of the catalyst with respect to the displacement of the double bond is to be attributed not to the aluminum hydroxide itself, but to acidic impurities [8], and therefore, depending on the method of preparing the catalyst – in particular, on the temperature at which it is calcined before use ("acidic" impurities are decomposed during calcination) – and also on the reaction temperature and time of contact with the catalyst, the 2-butene content of the gas obtained may vary over a wide range and may attain 90%. Table 1 gives the compositions of the original gas mixtures used in the present investigation.

TABLE 1

Catalyst No.	Experiment No.	Duration of experiment (hours)	Space velocity ($hour^{-1}$)	Contraction (%)	Composition of original gas (% by volume)				Yield (ml/cu.m)			Yield of (H+L) (ml/liter-hour)
					1-Butene	2-Butene	H_2	CO	Heavy Oil (H)	Light Oil (L)	H + L	
77	306	4.8	101	50.7	72.7	0.0	22.7	4.6	410.9	410.9	821.8	83.0
77	307	7.5	102	44.2	64.8	7.2	23.6	4.4	349.9	393.0	742.3	75.5
77	308	7.0	102	41.6	64.4	7.2	23.7	4.7	429.9	350.4	780.3	79.5
77	309	7.0	98	39.0	67.7	6.7	19.6	6.0	365.8	365.8	731.6	71.4
77	310	7.0	100	51.0	62.4	10.6	22.6	4.4	404.8	571.4	976.2	97.6
77	311	23.5	104	46.0	61.9	10.5	22.1	5.5	243.5	526.0	769.5	80.5
78	312	19.0	101	48.4	64.4	10.9	20.6	4.1	384.3	522.1	906.4	92.3
79	313	21.5	103	44.3	60.9	10.3	23.5	5.3	177.0	685.6	862.6	89.3
80	314	13.0	100	47.0	45.8	24.7	24.5	5.0	475.0	500.0	975.0	100.0

For the preparation of the mixture used in Experiment 306, pure 1-butene was obtained by the method described previously [5]; it did not contain 2-butene or isobutene, and its vapor pressure at 0° (p_0) was 963 mm, which corresponds to 100% 1-butene. For Experiments 307, 308, and 309 we used a mixture of 90-91% of 1-butene and 9-10% of 2-butene (p_0 941-945 mm) obtained by the dehydration of 1-butanol over commercial alumina at 360-370° in a porcelain tube of internal diameter 20 mm, the space velocity of the 1-butanol being 6.7 $hour^{-1}$. For Experiments 310-313 we prepared a mixture of 85.5% of 1-butene and 14.5% of 2-butene (p_0 930 mm) by dehydration in the same tube at 400° at a space velocity of the alcohol of 4.1 $hour^{-1}$ over alumina prepared as follows: precipitation with caustic soda from aluminum nitrate solution, conversion into sodium aluminate, reprecipitation from this with ammonium chloride [9]. Before use in the reaction the catalyst was calcined in a stream of air at 450° for four hours. The butene mixture of highest 2-butene content was used for the preparation of the original gas mixture for Experiment 314; it contained 70% of 1-butene and 30% of 2-butene (p_0 893 mm), and was obtained by the dehydration of 1-butanol over commercial alumina at 400° in a porcelain tube of internal diameter 14 mm, the space velocity of the 1-butanol being 4.1 $hour^{-1}$.

Hydrocondensation of Carbon Monoxide with 1-Butene and with Its Mixtures with 2-Butene

Table 1 gives the results of experiments on the catalytic hydrocondensation of carbon monoxide with 1-butene and with butene mixtures containing 65-90% of 1-butene and 35-10% of 2-butene. These experiments were carried out in a flow system at 190° and atmospheric pressure. The apparatus and procedure were the same as those used previously [1]. The reactor was a glass tube, 12 mm in diameter. The catalysts used

ns, 77-80) were all of the same composition and were prepared in the same way. They were used in 30-ml portions and were regenerated after they had been in use for 15-20 hours. The original gas mixtures contained 46-53% of 1-butene, 0.0-25% of 2-butene, 20-24.5% of hydrogen, and 4-6% of carbon monoxide, and they were passed over the catalyst at a space velocity of about 100 hour $^{-1}$. As will be seen from Table 1, the yield of liquid hydrocarbons (calculated on $C_4H_8 + H_2 + CO$) was 730-975 ml/cu.m, or 70-100 ml per liter of catalyst per hour, the contraction in the original gas being 40-50%. The ratio of heavy oil to light was about unity after the catalyst had been in work for about ten hours, and it was 0.25-0.73 after about 20 hours.

These results show that, as was to be expected, addition of 2-butene to the original mixture and gradual increase in its content within the range indicated do not bring about any regular changes in the course of the hydrocondensation reaction between carbon monoxide and 1-butene. The somewhat higher yield of hydrocarbons, as expressed in ml/cu.m or ml/liter·hour, in Experiments 310-314 is associated with a relative increase in the yield of the light oil (mainly owing to the longer working period of the catalyst) with a consequent increase in the volume of condensate. In one series of experiments, the composition of the outgoing gas was investigated in detail and, on the basis of the data obtained on the composition of the original gas and its contraction, the extent to which components of the original gas mixture took part in the process was determined. By way of example, we will give the relevant data for Experiment 306, in which the hydrocondensation of carbon monoxide with 100% 1-butene was carried out. In this experiment we took 14.6 liters (STP) of a gas mixture of composition 72.7% of 1-butene, 22.7% of hydrogen, and 4.6% of carbon monoxide, and apart from liquid condensate we obtained 7.2 liters of gas, of which 2.9 liters was fractionally distilled, for the purpose of analysis, through a Podbielniak low-temperature column. The results of the fractionation are shown in Table 2 and Fig. 1; Fractions III and IV did not contain isobutene.

It was shown, on the basis of the data given in Tables 1 and 2, that hydrogen reacted to the extent of 55.3%, carbon monoxide to the extent of 52.2%, and 1-butene to the extent of 76.2%: 7.2% of the original 1-butene (9.4% of that which reacted) was hydrogenated to butane, 9.4% (12.4% of that which reacted) was isomerized into 2-butene, and 2.1% (2.8% of that which reacted) was converted into cracking products ($C_1 + C_2 + C_3$). It will be seen later that a certain amount of butenes and butane were dissolved in the liquid condensate, and when this is taken into consideration it is found that 1-butene reacted to the extent of 74.4%, 8.3% of the original amount (11.2% of that which reacted) was converted into butane, and 12.3% (16.5% of that which reacted) was converted into 2-butene.

Fig. 1. Fractionation curve for the gaseous reaction products of the hydrocondensation of carbon monoxide with 1-butene (Experiment 306).

Part of the combined liquid condensate from Experiments 306-313 (200 ml) was separated from reaction water, washed twice with 2% caustic soda solution and then with water until neutral, and sealed in an ampoule with anhydrous copper sulfate. After this dehydration treatment, the copper sulfate was filtered off, and the dry condensate was subjected to debutanization in a low-temperature column. A part of the condensate was distilled off below 19°, and this amounted to about 21% by volume of the whole, had p_0 814 mm, and consisted of 31.3% of 1-butene, 49.4% of 2-butene, and 19.3% of butane. After the debutanization, a C_5 fraction (6.3% by volume) was distilled from the condensate through the same column; it came over at 19.5-22° — most of it at 20° — and it had n_D^{20} 1.3639, d_4^{20} 0.6276, and bromine value 184.0, which corresponds to 80.5% of unsaturated hydrocarbons. According to its boiling point and constants (n^{20} and d_4^{20}), this fraction was a mixture of 3-methyl-1-butene (data in literature [10]: b.p. 20.06°, n^{20} 1.3643; d_4^{20} 0.6272) and 2-methylbutane, components which form an azeotrope of b.p. 20° [11]. After debutanization and removal of the C_5 fraction, the condensate had n_D^{20} 1.4190; d_4^{20} 0.7304, and bromine value 59, which corresponds to 52% of unsaturateds. A portion of the condensate (92 ml) was hydrogenated in presence of platinized charcoal to which some chloroplatinic acid had been added [12]. The dry hydrogenation product, which had n_D^{20} 1.4130; d_4^{20} 0.7300, and bromine value 3.3 was fractionated (72 ml was taken) through a 90-plate

TABLE 2

column, when 35.6% by volume came over below 131°. The fractionation curve is shown in Fig. 2. The residue from this distillation (b.p. above 131°) was distilled from a Favorsky flask. All of the fractions collected and their properties are given in Table 3.

Fig. 2. Fractionation curve for liquid reaction products.

From these results it will be seen that about 40% by volume of the condensate distilled in the range 29.5–160° and contained C_5, C_6, C_7, C_8, and C_9 hydrocarbons in the proportions of about 2.3 : 2.4 : 2.7 : 2.9 : 1.0 (the fraction of b.p. 19.5–22° separated from the condensate before its hydrogenation is included in the C_5 hydrocarbons). As will be seen from Table 3 and Fig. 2, the supplementary C_5 fraction (Fraction I, Table 3), the bulk of which boiled at 36° and had n_D^{20} 1.3568 and d_4^{20} 0.6222, was n-pentane (data from literature [10]: b.p. 36.07°; n_D^{20} 1.3576; d_4^{20} 0.6262), mixed with some 2-methylbutane (b.p. 27.85°; n_D^{20} 1.3537; d_4^{20} 0.6197 [10]). It may be assumed, therefore, that the n-C_5 : i-C_5 ratio in the condensate was about 1 : 4. Fraction III (Table 3) (b.p. 87–88°, n_D^{20} 1.3724; d_4^{20} 0.6538) corresponded most closely in properties to 2-methylpentane (b.p. 60.27°; n_D^{20} 1.3715; d_4^{20} 0.6532 [10]), but it appeared to contain a little n-hexane. Fraction IV (b.p. 68–69°, n_D^{20} 1.3743; d_4^{20} 0.6595) was n-hexane (b.p. 68.74°, n_D^{20} 1.3749; d_4^{20} 0.6594 [10]). The heptane fraction (Fraction VI), which boiled mainly within the limits 95–97° (Fig. 2) and had n_D^{20} 1.3867 and d_4^{20} 0.6830, consisted mainly of n-heptane (b.p. 98.43°, n_D^{20} 1.3877; d_4^{20} 0.6837 [10]); the somewhat low values of the constants must be attributed to some admixture with branched heptanes. Under the conditions of the hydrocondensation reaction, branched hydrocarbons formed will contain, in the main, only one side chain. Hence, for the identity of the admixed substance we can assume only 2-methylhexane, since of the heptane isomers having one methyl side group, only this has lower constants (n_D^{20} 1.3849, d_4^{20} 0.6786 [10]) than n-heptane. Fraction VIII (n_D^{20} 1.3972, d_4^{20} 0.7022) consisted mainly of n-octane (b.p. 125.67°; n_D^{20} 1.3974; d_4^{20} 0.7025 [10]).

When Fractions VIII, VI, and a mixture of Fractions III and IV were investigated by the Raman spectrum method*, only normal C_8, C_7, and C_6 paraffins were detected, characterized respectively by the following wave

Effect of the Concentration of Hydrogen in the Original Mixture on the Course of the Hydrocondensation of Carbon Monoxide with 1-Butene

Comparison of results obtained in this investigation with results obtained previously [2] enables us to draw some conclusions concerning the effect of the concentration of hydrogen in the original gas on the course of the hydrocondensation of carbon monoxide with 1-butene, for the remaining conditions are comparable. The relative amounts of 1-butene and hydrogen in the original gas were about 3.5 : 1 in the present investigation and 1 : 1 in the previous investigation [2]. This change in the ratio of two main components for an unchanged concentration of the third resulted in considerable changes in the course of the reaction as follows. As a result of the 3.5-fold increase in the 1-butene: hydrogen ratio, the total yield of liquid hydrocarbons increased by 50-100% (from 480-650 ml/cu.m or 35-55 ml/liter·hour to 730-975 ml/cu.m or 70-100 ml/liter·hour), the amount of 1-butene that reacted changed from 97% to 76%, the content of unsaturateds in the hydrocondensate rose from 28% to 52%, and the average molecular weight of the hydrocondensate increased. In the previous and present investigations the upper boiling limits of the hydrogenated liquid hydrocondensates were, respectively, 276° and 340°, the contents in these of the C_5 fractions were 24% and 8%, the contents of the C_6 fractions were 15% and 9%, and the yields of butane on the amount of 1-butene that reacted were 32% and 9.4%. As regards the structures of the reaction products, they were found to be the same in both cases, the products being mainly aliphatic hydrocarbons of normal structure, with the exception of the C_5 fractions, which contained isopentane. It is interesting to note that previously, in an investigation of the hydrocondensation of carbon monoxide with ethylene [13], we found that the optimum ratio of ethylene to hydrogen was 2.5-3.

SUMMARY

1. The catalytic hydrocondensation of carbon monoxide with 1-butene was investigated at 190° at

atmospheric pressure. The original gas mixture consisted of 4-6% of carbon monoxide, 70-75% of 1-butene, and 20-25% of hydrogen.

2. The yield of liquid condensate attained 975 ml/cu.m or 100 ml/liter·hour. 1-Butene reacted to the extent of 74.4%, and about 9.4% of the 1-butene that reacted was hydrogenated to butane and about 15% was isomerized into 2-butene.

3. The liquid condensate, after being freed from the C_4 fraction and isopentane, contained 52% of unsaturated hydrocarbons.

4. The presence of up to 25% of 2-butene in the original gas mixture had almost no effect on the yield of liquid condensate in the hydrocondensation of carbon monoxide with 1-butene.

5. After being hydrogenated, the reaction products consisted essentially of saturated normal hydrocarbons containing, apparently, a very small amount of hydrocarbons having one methyl side group on the second atom of the hydrocarbon chain.

THERMAL REACTIONS OF TETRACHLOROETHYLENE AT SUPERHIGH PRESSURES

M. G. Gonikberg, V. M. Zhulin, and V. P. Butuzov

There have been reports in the literature of two attempts to prepare polymers of tetrachloroethylene by the use of superhigh pressure in conjunction with high temperature. Korshak and Matveeva [1] reported that they did not succeed in effecting the polymerization of tetrachloroethylene under a pressure of 5000 atm and at a temperature of 200°; the paper gives no further details of the results of the investigation. In 1953, Klaasens and Gisolf [2] investigated the mass polymerization of some unsaturated compounds at pressures of up to 10,000 atm. The apparatus described by these authors enabled them to measure the temperature within the mass of compressed material in the pressure vessel; the material was heated electrically by means of a spiral element. The use of such a heating system naturally resulted in considerable overheating in the vicinity of the spiral. The authors reported that at 10,000 atm and 150° tetrachloroethylene is carbonized as a result of a very rapid "explosive" process.

Tetrachloroethylene is a thermally stable compound. Experiments on the decomposition of tetrachloroethylene by the heat from a platinum wire electrically heated to 700-850° [3] showed that in seven hours 25 g of tetrachloroethylene gave 0.5 g of hexachlorobenzene and a very small amount of hexachloroethane. In work on the pyrolysis and chlorinolysis of some unsaturated perchloro hydrocarbons [4] it was found that tetrachloroethylene, unlike hexachloropropene, did not undergo any change in 12-15 seconds at 500°. Under the same conditions in presence of chlorine, hexachloroethane was formed in a yield of about 9% by weight on the amount of tetrachloroethylene taken.

EXPERIMENTAL

The tetrachloroethylene used was distilled through a 20-plate column and was found to have the following constants: b.p. 120.2-120.5° (751 mm); n_D^{20} 1.5057; d_4^{20} 1.6231. The literature [5] gives: b.p. 121.0° (760 mm); Hj_{20} 1.50494*; d_4^{15} 1.63109; d_4^{20} 1.60640.

We investigated the thermal reactions of tetrachloroethylene at pressures of up to 30,000 atm and at temperatures of up to 350°. The very first experiments (25,000 atm, 350°) showed that, under these conditions, tetrachloroethylene is converted into a solid mass consisting largely of hexachloroethane. The experiments were carried out in a superhigh-pressure multiplier with double mechanical support. In this apparatus it was possible to create pressures in the solid and liquid phases of up to 35,000 kg/sq.cm and simultaneously heat substance to 500-550° [6,7]. A heating element was contained in the conical high-pressure vessel, and inside the element was a lead ampoule containing tetrachloroethylene. The pressure was measured potentiometrically by a manganin manometer placed in the lower, cold part of the bore of the high-pressure vessel. The temperature was measured also potentiometrically by a differential iron-nichrome thermocouple and a copper resistance thermometer. The hot junction of the thermocouple was in the pocket of the ampoule (see below); the cold junction was in the lower part of the bore of the pressure vessel (insulated from the heating element by mica strips) inside the resistance thermometer. A four-circuit lead was assembled in the pressure vessel, and connections could be made from the outside to the manganin manometer, the copper resistance thermometer, the heating element, and the thermocouple.

The tetrachloroethylene was contained in a lead ampoule, about 0.5 ml in capacity and having a pocket for the thermocouple in its wall; the ampoule was sealed with lead. The position of the thermocouple made it possible to guard against overheating, which was more difficult to detect when the thermocouple was in

* Calculated from data for 15°.

the stopper of the ampoule as in our previous investigation [8] on the polymerization of 2,3-dimethyl-2-butene under a pressure of 27,500 atm. The use of lead for the construction of the ampoule was determined by its high plasticity and ability to transmit the external pressure satisfactorily. At 20,000 atm the melting point of lead is raised to about 460°, so that it was possible to carry out our experiments at 350°.

We carried out experiments with tetrachloroethylene at 350° (23,000 atm and 2 hours), 316° (24,000 atm and 6 hours), and 300° (22,000 atm and 6 hours, and 10,500 atm and 3 hours). The amount of tetrachloroethylene taken was 0.5-0.8 g. We give a detailed account of the results of the experiments at 350° and 23,000 atm.

A dark-brown solid (0.71 g) was removed from the ampoule. Vacuum distillation (15-17 mm) enabled us to isolate:

a) hexachloroethane (0.31 g, i.e. 44%), m.p. 185.3° after vacuum sublimation (the literature [9] gives m.p. 186.8-187.4°);

Found %: C 9.96, 10.09, 10.06; Cl 89.78, 90.05, 89.98. C_2Cl_6. Calculated %: C 10.15; Cl 89.85.

b) hexachlorobenzene (0.07 g, i.e. 10%), which was recrystallized twice from a benzene-ethanol mixture and vacuum distilled, when it melted at 228° (the literature [9] gives m.p. 227°) and in admixture with known hexachlorobenzene had m.p. 227.6°.

Found %: C 25.18, 25.16; Cl 74.61, 74.76. C_6Cl_6. Calculated %: C 25.23; Cl 74.72.

The residue from the distillation, amounting to 0.09 g (13%), was a resinous substance.

Found %: C 26.32, 26.22; Cl 69.60, 69.62; ash 1.84, 1.40.

Considerable yields of hexachloroethane were obtained also in the experiments at 316° and 300° (40-50%); reaction products included also a small amount of a heavy liquid, which distilled from an Emich tube as a colorless liquid containing hexachloroethane.

We also carried out experiments on tetrachloroethylene in which 4% of benzoyl peroxide (150°; 30,000 atm; 7 hours) or 5.5% of tert-butyl peroxide (200°; 24,700 atm; 6 hours) was present. Neither polymerization products nor thermal-decomposition products were found, the tetrachloroethylene being recovered unchanged.

Hence, we did not succeed in polymerizing tetrachloroethylene under the stated conditions of superhigh pressure and high temperature, a fact that is undoubtedly to be associated with the presence of very considerable steric hindrance. Moreover, in our experiments we did not confirm the findings of Dutch investigators [2] concerning the occurrence of an "explosive" process which results in the carbonization of tetrachloroethylene at 150° and 10,000 atm. We consider that this discrepancy results from local overheating in the experiments of these authors and from poor heat transfer within the bulk of the material under conditions of rapid reaction.

At 300-350° in the pressure range studied (10,500-24,000 atm), tetrachloroethylene undergoes almost complete thermal transformation and it is not possible to determine the effect of pressure on the rate of the process. However, a subsequent investigation at lower pressures has shown that increase in pressure brings about a considerable increase in the rate of the thermal transformations of tetrachloroethylene.

The mechanic M. D. Pushkinsky took part in the work.

SUMMARY

1. The reactions of tetrachloroethylene at 10,000-30,000 atm and 150-350° were investigated in presence and absence of peroxides.

2. Under the conditions studied, tetrachloroethylene does not polymerize. In 2-6 hours at 300-350° it undergoes almost complete thermal transformation with formation of 40-50% of hexachloroethane and a smaller amount of hexachlorobenzene.

ESTERIFICATION IN PRESENCE OF BORIC ACID, AND THE SYNTHESIS OF BORIC ACID

V. K. Kuskov and V. A. Zhukova

Boric acid is an extremely weak acid. The available data [1,2] indicate that boric acid molecules combine together through hydrogen bonds, so that in structure boric acid is akin to macromolecular compounds. It may be supposed that it is for this reason that the elimination of a proton is difficult and that boric acid - like its dehydration products, "polyboric acids" - is such a very weak acid. It may be supposed also that, under conditions that prevent the association or polymerization of boric aicd or polyboric acids, more definite acidic properties will be found. It is well known that, in presence of monohydric alcohols (glycerol, mannitol), boric acid forms complex compounds that titrate to a phenolphthalein end point as if boric acid were a monobasic acid of medium strength [3]. Boric esters form complex compounds with sodium alkoxides of formula $Na^+[(AlkO)_4B]^-$; these have the properties of salts of a comparatively strong acid [4].

These observations permit us to suppose that, under certain conditions, boric acid (or diboric acid, tetraboric acid, or other dehydration products) will behave as a fairly strong acid. One criterion of the strength of an acid is its activity as a catalyst [5], particularly in esterification reactions. In the present investigation we have found that under conditions under which reaction water is removed - 160-200° - boric acid catalyzes the esterification of carboxylic acids, such as benzoic, phthalic, and adipic acids. For the esterifications we used water-immiscible alcohols, namely, butyl, isobutyl, and isopentyl alcohols. During the reaction the water was distilled over into a water-separation tube, i.e. the reaction was carried out in a Dean and Stark apparatus. The alcohol was added dropwise to the heated mixture of the carboxylic acid and boric acid, the rate of addition being such that the temperature was maintained at about 200°, and not below 160°. When the addition of the alcohol was too rapid, the boiling point of the reaction mixture fell and esterification stopped, as could be readily seen by observing the water-separation tube, in which water ceased to collect. Towards the end of the reaction the boiling point of the reaction mixture fell.

Replacement of boric acid by metaboric acid did not effect any improvement in the reaction. It was evident that, in the last stage of the reaction, boric acids were converted into boric esters; metaborates were not formed. No resinous products were formed in the esterification. It was possible to isolate the required ester by simple distillation of the reaction mixture, for no resinification occurred under these conditions; it was generally difficult, however, to separate this ester from the boric ester, owing to the closeness in boiling point. A wash with water, with weak sodium carbonate solution, and again with water readily removed the easily hydrolyzed boric ester together with any boric and carboxylic acids present. When, owing to the low boiling points of the components, it was impossible to heat the mixture to 160° -- and it is better to heat to 200° - no esterification occurred. For example, we were unable to prepare acetic and butyric esters in presence of boric acid.

We found that, in absence of boric acid, butyl alcohol was not esterified. The esterification of benzoic acid with isopentyl alcohol, which was described by Lacroix and Vigier [6], was only partial - more than one-third of the acid did not react, i.e. the results of these authors were not confirmed. It was further found that boric esters are not intermediaries in the esterification of carboxylic acids in presence of boric acid. When, in fact, boric acid was replaced by its ester, esterification was much slower and was incomplete; also, some trialkyl borate came over with the water and alcohol. This did not occur during esterification in presence of boric acid. It could not be considered also that reaction with dehydration products of boric acid resulted in the formation of a carboxylic anhydride or "mixed" anhydride, which then acylated the alcohol. In a control experiment we heated a mixture of benzoic and boric acids at 200-220° for four hours in the Dean and Stark apparatus. Owing to anhydrization of the boric acid, 0.5 mole of boric acid lost 6.5 ml (about 0.35 mole) of water. Distillation of the reaction mixture remaining in the flask gave benzoic acid, not benzoic anhydride. It is evident that no benzoic anhydride is formed under the conditions of the esterification reaction.

Finally, mixed anhydrides of boric acid and the carboxylic acid do not act as a catalyst in the esterification. This is demonstrated by the following experiment. It has been shown that, when phthalic anhydride is

heated with boric acid, a mixed anhydride "boron phthalate" is formed [7]. Reaction between phthalic anhydride and butyl alcohol in presence of boron phthalate did not proceed readily: monobutyl phthalate was obtained, but very little dibutyl phthalate. On the other hand, when phthalic anhydride was first heated with butyl alcohol, i.e. was converted into monobutyl phthalate, which is unable to form a compound with boric acid, its esterification to dibutyl phthalate in presence of boric acid was found to be quite possible.

By the same method, i.e. heating of the components with distillation of the water formed into a water-separation tube, boric esters were prepared in accordance with the equation:

$$3ROH + H_3BO_3 \rightarrow B(OR)_3 + 3H_2O.$$

Reaction proceeded satisfactorily at 80° and higher. Water was distilled off with the esterifying alcohol, or, when the latter was water-soluble, with specially added benzene, toluene, or xylene. Even tripropyl borate, for which the reaction temperature was 82°, was obtained in high yield. Tributyl borate was formed smoothly; in the distillation reaction water came over with excess of butyl alcohol at 113-125°, or at 80° when benzene was added to the reaction mixture. The synthesis of triisopropyl borate proceeded at 73° (boiling point of the mixture), but the boric acid did not react completely and the yield of ester was only 30%.

The procedure described is convenient as a preparative method. The following methods, which have been proposed previously for the preparation of boric esters, are less convenient and often give poor yields: reaction of alcohols with boric-acetic anhydride [7], boron trichloride [8], boryl sulfate [9], or boric anhydride [10]; esterification in presence of hydrochloric acid [11] or the method of preparing tributyl borate from boric acid and absolute butyl alcohol [12], more recently applied in the preparation of some other boric esters [13].

Our investigation showed that, even at about 80°, boric acid can be esterified and, contrary to statements in the literature [14], the presence of another mineral acid is not necessary. It cannot be supposed that boric acid acts simply as a dehydrating agent, first losing water with formation of metaboric acid or other anhydrization product and then combining with water formed during esterification, etc. The data in the literature [2] shows that boric acid does not lose water below 100°. We found experimentally that, when benzene was boiled over boric acid in a Dean and Stark apparatus (i.e. at 80°), no water came over, but, when butyl alcohol was added to the mixture, esterification very quickly began (at the same temperature of 80°) and reaction water distilled off. It is evident that, in an anhydrous medium at 80° and higher, boric acid is strong enough to catalyze the formation of boric esters. It is most probable that association of boric acid molecules does not occur under these conditions, so that it reacts as a comparatively strong acid. The esterification of carboxylic acids is similarly accelerated, but, as this reaction occurs at 160-200°, it is probable that in this case it is not orthoboric acid that takes part in the reaction, but its anhydrization products. Above 100°, boric acid loses water and is converted, according to available data [2], into pyroboric acid $H_2B_2O_4$, and further — above 140° — into tetraboric acid. It is evident that these are the acids that catalyze the esterification of carboxylic acids.

The electronic structure of boric acid is not inconsistent with these views. The boron atom of boric acid, being surrounded with a sextet of electrons, must have a tendency to confer acid properties. The anion of monomeric metaboric acid should be stabilized as a result of the symmetrically disposed oxygen atoms, as in the acetate and nitrate anions. This should favor the elimination of a proton. In an analogous way the anions of di- and tetra-boric acids may be stabilized.

EXPERIMENTAL

1. Synthesis of Carboxylic Esters

Synthesis of Butyl Benzoate. A mixture of 30.5 g (0.25 mole) of benzoic acid and 3.1 g (0.05 mole) of boric acid was heated to 200° in a three-necked flask fitted with thermometer, dropping funnel, and water-separation tube. The mixture was boiled while 37 g (0.5 mole) of butyl alcohol was added from the dropping funnel over a period of eight hours. About two-thirds of the alcohol was added at 200-205°, and the temperature in the flask then fell — finally to 155°. When water ceased to distil over, the mixture was boiled for a further 30 minutes and cooled. Cold water (25 ml) was added, and the mixture was shaken carefully. The mixture was extracted with 50 ml of benzene, and the water layer containing precipitated boric acid was removed. The benzene layer was washed with 5% sodium carbonate solution and with water, and was then dried with magnesium sulfate. Benzene was distilled off, and the butyl benzoate was distilled (b.p. 247-249°). The yield was 30 g (87.8%).

Synthesis of Dibutyl Phthalate. The same apparatus was used. A mixture of 30 g (0.2 mole) of phthalic anhydride and 25 g (0.33 mole) of butyl alcohol was heated at 200° for two hours. The mixture was cooled to

100°, and 2.5 g (0.04 mole) of boric acid was added. The mixture was then heated to 200° and boiled for 12 hours while 27 g (0.37 mole) of butyl alcohol was added dropwise. After two-thirds of the butyl alcohol had been added, the temperature gradually fell from 200° to 135°. It was then boiled for five hours (until distillation of water ceased completely). The further treatment was as in the preceding experiment. The yield of dibutyl phthalate, b.p. 179-182° (3 mm), was 44.6 g (80%).

Isobutyl benzoate, isopentyl benzoate, and dibutyl adipate were prepared similarly to butyl benzoate. The results are given in Table 1.

TABLE 1

No.	Ester prepared	Amount of boric acid (g)	Amount of alcohol (g)	Reaction temperature (°C)	Time (hours)	Yield of ester (g)	Yield of ester (%)
1	Butyl benzoate	30.5	37	200—130, at end 155	8	39	87.6
2	Isobutyl benzoate	30.5	37	Ditto	10	40	90
3	Isopentyl benzoate	30.5	60	"	5	40	83.3
4	Dibutyl adipate	14.6	37	200—140	10	22	85.3
5	Diburyl phthalate	30	52	200—135	14	44.6	80

2. Synthesis of Boric Esters

Triisopropyl Borate. A mixture of 15.5 g (0.25 mole) of boric acid and 10 ml of benzene was prepared in a flask fitted with dropping funnel, thermometer, water-separation tube, and reflux condenser. A mixture of 60 g (1 mole) of absolute isopropyl alcohol and 30 ml of benzene was placed in the dropping funnel. About one-third of this mixture was run into the flask, and the contents of the flask were boiled for eight hours (b.p. 71-73°). Boiling was then maintained for seven hours while the remainder of the mixture of isopropyl alcohol and benzene was added dropwise. A further 10 ml of benzene and 15 g (0.25 mole) of isopropyl alcohol was then added, and boiling was continued for three hours (73°), until water ceased to separate. The contents of the flask were distilled through a Vigreux column 12 cm in height, and the fraction boiling over 120° (upper limit nearly 150°) was collected. Redistillation of this fraction gave 7 g (30%) of triisopropyl borate, b.p. 125-135° (which corresponds to data in the literature [7]).

Tripropyl Borate. A mixture of 7.75 g (0.125 mole) of boric acid, 30 g (0.5 mole) of propyl alcohol, and 20 ml of benzene was boiled over a sand bath in a flask fitted with a 6-ml water-separation tube and reflux condenser until water ceased to distil off (about eight hours). The boiling point of the mixture was 83°. The further treatment was as for isopropyl borate. The fraction boiling above 160° was collected. Redistillation of this fraction gave 22.4 g (95%) of tripropyl borate, b.p. 177-179° (the literature [7] gives 177°).

A series of boric esters was prepared similarly. Their properties and details of the conditions of synthesis are given in Table 2.

In conclusion, the authors thank S. L. Volkovich for useful suggestions made during this investigation.

SUMMARY

1. It was shown that nonvolatile carboxylic acids can be esterified in presence of boric acids.

2. A method is proposed for the preparation of boric esters.

3. The reactions occuring were investigated experimentally, and theoretical views are advanced on their mechanism.

* Tris-2-chloroethyl borate has not been described in the literature. It is a colorless liquid which darkens in color when kept. It is rapidly hydrolysed by water with separation of boric acid.

Found %: B 4.43, 4.46; Cl 42.91, 42.69. $C_6H_{12}Cl_3O_3B$. Calculated %: B 4.34; Cl 42.82.

[Publisher's Note: Tris-2-chloroethyl borate is, in fact, described by Martin and Mako [8] and by Jones et al. (J. Chem. Soc. 1946, 824).]

BRIEF COMMUNICATIONS

BREAKDOWN OF THE FERROCENE NUCLEUS BY HYDROGENATION AND THE ACTION OF HALOGENS

A. N. Nesmeyanov, E. G. Perevalova, R. V. Golovnya, T. V. Nikitina, and N. A. Simukova

The study of the laws governing the replacement of the hydrogens of ferrocene (dicyclopentadienyliron) [1] and its derivatives demands the development of a method for proving the structures of di- and poly-substituted ferrocenes [2]. The method of confirmatory synthesis from the corresponding substituted cyclopentadienes, carried out by Pauson [3] for di- and poly-phenylferrocenes and 1,1'-bisdiphenylmethylferrocene, is of little value for this purpose, not only because of the poor accessibility of cyclopentadiene derivatives, but also because the method is applicable only to the preparation of derivatives with hydrocarbon substituents. The most suitable method for proving the structures of polysubstituted ferrocenes depends on the rupture of the iron-carbon bond with formation of cyclopentane derivatives, this being effected by, for example, hydrogenation or the action of halogens. Woodward and coworkers [4] showed that ferrocene is not hydrogenated over reduced platinum oxide under normal conditions. Fischer [5] did not succeed in hydrogenating ferrocene in presence of a nickel catalyst at 150° and 150 atm.

In the present investigation we effected the breakdown of ferrocene and some of its derivatives by the action of bromine and chlorine and by hydrogenation with hydrogen in presence of Raney nickel under severe conditions.

EXPERIMENTAL

Ferrocene (30 g) was hydrogenated in cyclohexane (60 ml) in presence of Raney nickel in a rotating 500-ml autoclave for five hours at 300° and a further four hours at 340°. The initial hydrogen pressure was 120 atm, and the working pressure was 280 atm. Distillation through a 35-plate column gave 4.1 g of cyclopentane, b.p. 47-49° (745 mm), n_D^{20} 1.4060, and d_4^{20} 0.7440, and 3 g of a mixture of b.p. 36-47° (745 mm) and n_D^{20} 1.4040, which, judging from its refractive index, consisted of cyclopentane and 5% of n-pentane [6]. For cyclopentane the literature [6] gives b.p. 48.7-48.8° (742.6 mm), n_D^{20} 1.4060, and d_4^{20} 0.7450. Some ferrocene (16.2 g) was recovered unchanged. The total yield of cyclopentane was 7 g (67% on the amount of ferrocene that reacted).

The yield of n-pentane was increased to 23% on the total amount of cyclopentane when freshly prepared Raney nickel was used. Reduction of the working pressure to 180 atm also increased the yield of n-pentane (to 7% of the total amount of cyclopentane), which is in accord with the results of Kazansky and Terentyeva [7], who showed that with increase in the pressure of hydrogen there was a rise in the temperature at which scission of the cyclopentane ring occurred in presence of a platinum or nickel catalyst.

Diacetylferrocene (28 g) was hydrogenated in alcohol (60 ml). The initial hydrogen pressure was 95 atm, and the working pressure was 240 atm. Heating was for one hour at 100°, two hours at 300°, and five hours at 345°. The products isolated were 9.2 g (53%) of ethylcyclopentane (distilled through a 35-plate column), b.p. 101.3-102.3°, n_D^{20} 1.4202, and d_4^{20} 0.7856, and 3.6 g (15% on the diacetylferrocene taken) of diethylferrocene [8]. For ethylcyclopentane the literature gives b.p. 100.5-101.5° (740 mm); n_D^{20} 1.4202; d_4^{20} 0.7654 [9]; b.p. 101-102° (747 mm) n_D^{20} 1.4200; d_4^{20} 0.7682 [10].

Ferrocenedicarboxylic acid was hydrogenated in the form of a solution of its sodium salt (4.3 g) in water (50 ml) for one hour at 180° and 2.5 hours at 265°. The initial hydrogen pressure was 122 atm, and the working pressure was 280 atm. The produce isolated was 2 g (65%) of cyclopentanecarboxylic acid, identified by

its p-bromophenacyl ester, which melted, both alone and in admixture with an authentic sample, at 75-76°.

When ferrocenedicarboxylic acid was hydrogenated in cyclohexane (five hours at 265° and 200 atm), 37% of cyclopentane and a little ferrocene was obtained. Hydrogenation in alcoholic solution (30 g in 100 ml) resulted in the formation of cyclopentanecarboxylic acid (3.5 g, i.e. 14%) and its ethyl ester (5.2 g, i.e. 17%), b.p. 168.5-170°, n_D^{20} 1.4362, and d_4^{20} 0.9504. For ethyl cyclopentanecarboxylate the literature [11] gives: b.p. 171.9° (737 mm); 89.3° (45 mm); n_D^{20} 1.4360, d_4^{20} 0.9523.

Bis-p-nitrophenylferrocene (12 g) was hydrogenated in cyclohexane (130 ml) for one hour at 142°, three hours at 195°, one hour at 250°, and three hours at 326°. The initial hydrogen pressure was 120 atm, and the working pressure was 280 atm (if the autoclave was heated rapidly, there was an explosion). The product isolated was 1.3 g (15.3%) of cyclopentylcyclohexane, b.p. 75-76° (6 mm), n_D^{21} 1.4750 and d_4^{21} 0.8818. For cyclopentylcyclohexane the literature gives: b.p. 214°; 225-227°, n_D^{21} 1.4728, 1.4767; d_4^{21} 0.8780, 0.8813 [12,13].

Apart from cyclopentylcyclohexane, an appreciable amount of light-brown resin was formed; this substance was insoluble in water and in ether, but soluble in chloroform; it contained nitrogen and iron and rapidly underwent change in the air. The yield of cyclopentylcyclohexane could not be increased, and resin formation could not be reduced, by more prolonged hydrogenation (there are references in the literature to difficulties met in the hydrogenation of aromatic amines in presence of Raney nickel [14]).

Thus, the formation of ethylcyclopentane, cyclopentanecarboxylic acid, and cyclopentylcyclohexane by the hydrogenation of diacetylferrocene, sodium ferrocenedicarboxylate, and bis-p-nitrophenylferrocene, respectively, provides the first chemical proof that in these compounds the substituents are in different rings of the ferrocene nucleus.

We effected the breakdown of the ferrocene nucleus also by means of bromine and chlorine. We have previously reported that treatment of ferrocene with bromine in boiling carbon tetrachloride gives pentabromocyclopentane [15]. When ferrocene (1 mole) was treated with bromine (6.5 moles) in boiling carbon tetrachloride, a 70% yield was obtained of pentabromocyclopentane, m.p. 103-104° (crystallized from alcohol and carbon tetrachloride). When the amount of bromine or the duration of heating was increased, the yield of pentabromocyclopentane was increased to 80-82%, but a mixture of stereoisomers, m.p. 83-101°, was formed.

Found %: C 13.39, 13.30; H 1.09, 1.08; Br 85.75 85.52. $C_5H_5Br_5$. Calculated %: C 12.92; H 1.08; Br 85.96.

Breakdown of the ferrocene nucleus can be effected also by means of chlorine. Chlorine was passed at room temperature into a solution of ferrocene (1.86 g) in carbon tetrachloride (40 ml) for two hours, and pentachlorocyclopentane was obtained in 62% yield on the amount of ferrocene that reacted (3% of ferrocene remained in the form of a cation). It was found that the yield of pentachlorocyclopentane was raised to 90% by gradually adding a solution of 3.72 g of ferrocene in carbon tetrachloride (20 ml) to an ice-cold saturated solution of chlorine in carbon tetrachloride (80 ml) and then passing chlorine at 0° for two hours. Pentachlorocyclopentane crystallizes from 70% alcohol and can be readily sublimed in a vacuum; m.p. 38-39°.

Found %: C 24.72, 24.66; H 2.17, 2.20. $C_5H_5Cl_5$. Calculated %: C 24.76; H 2.08.

Ferrocene is stable to the action of iodine. After a solution of ferrocene and iodine in acetic acid had been boiled for one hour, the ferrocene was recovered unchanged (the ferrocene-iodine complex was reduced with sodium thiosulfate).

The bromine method of breaking down the ferrocene nucleus was applied to ferrocenecarboxylic and ferrocenedicarboxylic acids. Treatment of ferrocenecarboxylic acid with bromine (boiling for one hour in carbon tetrachloride) resulted in its complete breakdown with formation of a mixture of pentabromocyclopentane isomers, m.p. 80-100°, in 44% yield (an isomer of m.p. 103-104° was isolated after one chromatographic treatment on silica gel) and also a bromine-containing carboxylic acid which decomposed when heated to 90° with gas evolution and blackening. This substance was readily soluble in ether, alcohol, and benzene, but insoluble in petroleum ether; its structure was not established.

Found %: C 25.80, 25.80; H 1.98, 2.15; Br 62.81, 62.96.

When ferrocenedicarboxylic acid was broken down with bromine, only the above-described bromine-containing carboxylic acid was isolated. No pentabromocyclopentane could be detected, even when the reaction product was subjected to chromatographic separation.

Thus, the results of the breakdown of ferrocenedicarboxylic acid with bromine confirm the conclusion drawn from the hydrogenation experiments, namely, that the carboxy groups are in different rings.

One of us, in collaboration with N. A. Volkenau, has effected the breakdown of ethylferrocene with bromine, and pentabromocyclopentane, m.p. 103-104°, was isolated from the products. Breakdown of the ferrocene nucleus with bromine can be applied in the proof of the presence of an unsubstituted ring in a ferrocene dreivative. This method, unlike the hydrogenation method, does not require large amounts of material, since pentabromocyclopentane can readily be isolated chromatographically.

SUMMARY

1. It was shown that ferrocene and its derivatives are broken down with formation of cyclopentane and its derivatives when treated with bromine and chlorine, and also with hydrogen under severe conditions in presence of Raney nickel.

2. It was proved by hydrogenation that the substituents in diacetylferrocene, ferrocenedicarboxylic acid, and bis-p-nitrophenylferrocene are in different rings.

PREPARATION OF BICYCLO[2.2.1]HEPTA-2,5-DIENE BY THE CONDENSATION OF CYCLOPENTADIENE WITH ACETYLENE

A. F. Plate and M. A. Pryanishnikova

Much interest has been shown recently in aldrin, a new, highly effective preparation for the combating of agricultural pests, notable for its high toxicity to insects and its harmlessness to plants.

Aldrin (I) (1,2,3,4,10,10-hexachloro-1,4,4a,5,8,8a-hexahydro-1,4,5,8-dimethanonaphthalene) can be prepared by the condensation of hexachlorocyclopentadiene with bicyclo[2.2.1]hepta-2,5-diene [1]:

(I)

Bicyclo[2.2.1]hepta-2,5-diene has been prepared in 25% yield by the elimination of hydrogen chloride from 5-chlorobicyclo[2.2.1]hept-2-ene and the elimination of chlorine from 5,6-dichlorobicyclo[2.2.1]hept-2-ene [2]. Also, its preparation by the condensation of acetylene with cyclopentadiene in 32% yield has been described in a patent [3].

In view of the importance of aldrin, in 1955 we carried out experiments on the condensation of cyclopentadiene with acetylene under pressure at various temperatures in an autoclave:

At 290-320° a 40-45% yield of bicyclo[2.2.1]hepta-2,5 diene was obtained. In work at the Ya. V. Samsolov Scientific Institute for Fertilizers and Insectofungicides, aldrin was synthesized from our preparation by condensing it with hexachlorocyclopentadiene [4].

EXPERIMENTAL

Experiments on the preparation of bicyclo[2.2.1]hepta-2,5-diene were carried out in a one-liter rotating steel autoclave placed in an electrically heated furnace. Cyclopentadiene (20 g) and isopentane (20 ml) were loaded into the autoclave, which was then closed. Acetylene was passed in up to a pressure of 9-10 atm, and the autoclave was heated to the required temperature, which was maintained for 5-60 minutes. The maximum pressure attained was not greater than 30 atm. When the autoclave was cool, it was unloaded and the reaction mixture was fractionated. The bicyclo[2.2.1]hepta-2,5-diene then obtained had the following properties: b.p. 89.5-90.5°; n_D^{20} 1.4693, d_4^{20} 0.9056. The literature gives: b.p. 89-89.5°; n_D^{20} 1.4670; d_4^{20} 0.8992 [2]; b.p. 83-86° (620-635 mm); n_D^{20} 1.4685-1.4720; d_{20} 0.8770-0.9100 [3].

The dependence of the yield of bicyclo[2.2.1]hepta-2,5-diene on the reaction temperature and the duration of heating is shown in the diagram. It will be seen that, when heating is for 30 minutes, the diene synthesis between cyclopentadiene and acetylene does not go below 230°. With rise in temperature the yield of

bicyclo[2.2.1]hepta-2,5-diene gradually increases and attains a maximum of 40% at 295-305°. With further rise in temperature the yield of the desired product falls rapidly as a result of the resinification of the reaction products.

Relation between the yield of bicyclo[2.2.1]hepta-2,5-diene and the temperature: _____ duration of heating 30 minutes; _____ duration of heating 5 minutes.

However, when the heating is for a shorter time the optimum temperature for the reaction appears to be higher. Thus, reaction at 320° for five minutes resulted in a 45% yield of bicyclo[2.2.1]-hepta-2,5-diene. The investigation is continuing.

SUMMARY

The condensation of cyclopentadiene with acetylene under pressure gave a 40-45% yield of bicyclo[2.2.1]hepta-2,5-diene, the starting material for the synthesis of the insecticide aldrin.

SOME PECULIAR FEATURES OF THE POLYMERIZATION OF ANHYDRIDES OF α-CARBOXYAMINO ACIDS

K. T. Poroshin

Much attention hasbeen devoted recently to the synthesis of polyanhydro-α-amino acids and the study of their properties, for these compounds are to a certain extent analogous to the simplest proteins and to certain antibiotics and hormones. Apart from the polycondensation of esters of α-amino acids, considerable progress has been made in the investigation of the polymerization of anhydrides of α-carboxyamino acids [1]. For a long time many investigators [2] adopted the view that the mechanism of the polymerization Reaction (1) consisted in the initiation and propagation of this reaction and that the polypeptides formed cannot react among themselves after the whole of the α-carboxyamino acid anhydride has been used up:

$$X(COCHRNH)_n + \text{(NCA)} \rightarrow X(COCHRNH)_{n+1} + CO_2, \qquad (1)$$

in which X = OH, R_2N, OR (initiators).

Water, amines, and alcohols can serve as initiators. When water is used as an initiator, the polyanhydro-α-amino acids obtained by the polymerization of α-carboxyamino acid anhydrides should contain equal numbers of carboxyls and terminal amino groups. However, it was shown by Sela and Berger [3] and by Sluyterman and Labrieyre [4] that the carboxyl content of the polyanhydro-α-amino acid is higher than that indicated by Equation 1.

Sela and Berger [3] suggested that, in addition to the main Reaction (1), the Process (2) may occur, i.e. the amino group of the peptide may react with the second carbonyl group of the α-carboxyamino acid anhydride with formation of a compound with a free carboxyl group:

$$OH(COCHRNH)_nH + \text{(NCA)} \rightarrow OH(COCHRNH)_nCONHCHRCOOH \qquad (2)$$

Hence, if Reaction (2) occurs, "urea-peptides" may be formed, and these may yield the hydantoin of the amino acid or of the peptide, e.g.

Wessely and Mayer [5], and also Granacher and Wolf [6] isolated the corresponding hydantoins from polypeptides obtained from anhydrides of α-carboxyamino acids.

Substantial proof of the possibility of a reaction of Type (2) is provided by the investigations of Berger, Sela, and Katchalski [7] and of Farthing [8], who showed that an anhydride of an α-carboxyamino acid can react with sodium methoxide in presence of methanol with formation of both the sodium salt of methyl 2-(carboxyamino) alkanoate (main reaction) and also the sodium salt of 2-(methyoxycarbonylamino)alkanoic acid, i.e.

In this connection the work of Frenkel, Neufeld, and Katchalski [9] is deserving of attention.

A method that we have developed [10] made it possible to determine the amount of 2,5-piperazinediones in the polycondensation products of glycine and DL-alanine esters. Applying this method, we determined the amounts of piperazinediones in the products of the polymerization of the anhydrides of N-carboxyglycine and N-carboxy-DL-alanine, and also in the products of the copolymerization of these anhydrides.

It must be pointed out that Sluyterman and Labrieyre [4] isolated about 2% of piperazinediones from polyglycine obtained by solution polymerization of the anhydride of N-carboxyglycine, this being effected by extraction with a mixture of hot water and alcohol. On the basis of this fact— and also of our own results, which confirm the presence of piperazinediones in the products of the polymerization of anhydrides of α-carboxyamino acids — it may be assumed that, in addition to the main reaction of linear-polymer formation and the reaction in which "hydantoin-peptides" are formed, a process occurs in which piperazinediones are formed. In view of these considerations, the polymerization reaction of α-carboxyamino acid anhydrides can be considered to occur by the following mechanism:

We must point out that, under certain conditions of temperature, the possibility cannot be excluded of the formation of piperazinediones directly from dipeptides[11].

EXPERIMENTAL

The anhydrides of N-carboxyglycine and N-carboxy-DL-alanine were prepared from the benzyloxycarbonyl derivatives of the amino acids. N-(Benzyloxycarbonyl) glycine was prepared by the gradual addition (over a period of 10-15 minutes) of 21 g of benzyl chloroformate and 25 ml of 4 N NaOH to a solution of 7.5 g of glycine in 50 ml of 2 N NaOH. Reaction proceeded in the cold for 30-40 minutes. The solution was washed twice with ether, and the aqueous solution was then acidified to Congo red with concentrated sulfuric acid. The precipitated crystals of N-(benzyloxycarbonyl)glycine were washed with water. Recrystallization was not generally necessary, satisfactory analytical results being obtained on the original product:

Found %: C 57.42; H 5.37; N 6.64. $C_{10}H_{11}O_4N$. Calculated %: C 57.39; H 5.30; N 6.70.

The molecular weight of the N-(benzyloxycarbonyl)glycine was 209.1, and it melted at 120°.

N-(Benzyloxycarbonyl)-DL-alanine was prepared by the same method. Benzyl chloroformate (24 g) and 4 N NaOH (25 ml) were added in portions to a solution of 8.9 g of DL-alanine in 50 ml of 2 N NaOH. After the first crystallization the compound melted at 114° and had a molecular weight of 223.1. The elementary analysis was as follows:

Found %: C 59.20; H 5.85; N 6.32. $C_{11}H_{13}O_4N$. Calculated %: C 59.16; H 5.87; N 6.28.

The anhydrides of N-carboxyglycine and N-carboxy-DL-alanine were prepared as follows: the benzyloxycarbonyl derivatives of the amino acids were converted into acid chlorides by treatment with phosphorus pentachloride in ether; benzyl chloride was then eliminated. The anhydrides so formed were crystallized. For the anhydride of N-carboxyglycine:

Found %: C 35.75; H 3.01; N 13.8. $C_3H_2O_3N$. Calculated %: C 35.6; H 2.9; N 13.8.

For the anhydride of N-carboxy-DL-alanine:

Found %: C 41.9; H 4.55; N 12.35. $C_4H_5O_3N$. Calculated %: C 41.7; H 4.3; N 12.2.

The anhydrides of α-carboxyamino acids were polymerized in the mass at reduced pressure (10-12 mm). In all cases water was used as initiator. When the polymerization was complete, the polyanhydro-α-amino-acid (polyglycine, poly-DL-alanine, or the copolymer obtained from a 1 : 1 mixture of the anhydrides of the N-carboxy derivatives of the two amino acids – was carefully washed with absolute ether and subjected to analysis for piperazinedione content by the method that we have developed [10]. The results of the investigation are given in the table, which gives the polymerization conditions (temperature and time), the degree of polymerization n, and the piperazinedione contents of the polyanhydro-α-amino acids obtained.

Name of the polyanhydro-α-amino-acid	Polymerization conditions		n	Piperazinedione content (%)
	Temperature (°C)	Time (hours)		
Polyglycine	100	3	6	13,03
	165	2	10	9,25
	160	2	45	5,39
Poly-DL-alanine	150	2	12	18,38
	100	2,5	14	5,02
	100	4	20	2,34
Glycine-DL-alanine copolymer	105	5	10	6,48
	95	4	34	1,65
	160	2	58	0,37

SUMMARY

1. Polymerization reactions were carried out with anhydrides of N-carboxyglycine and N-carboxy-DL--alanine, and the 2,5-piperazinediones present in the polymerization products were determined quantitatively.

2. A hypothesis is advanced concerning the mechanism of the polymerization reaction of anhydrides of α-carboxyamino acids; it accounts for the formation of 2,5-piperazinediones.

DI-2-THIENYLMETHANOL

Ya. L. Goldfarb and M. L. Kirmalova

As is well known, in the course of its development the chemistry of thiophene has in many respects repeated the chemistry of benzene; this applies both to the substances synthesized and to the methods of synthesis. It is not clear, therefore, why the thiophene analog of such a simple and accessible compound as benzhydrol has not been described (we have been unable to find reports of this substance in the available literature). It is possible that the labile character of di-2-thienylmethanol (I) (see below) is in part responsible for this situation; in this respect it is similar to tri-2-thienylmethanol, which has been isolated only in the form of salts [1], and differs from the comparatively stable alkyl(and aryl)thienylmethanols.

As a part of our laboratory's program of work on the synthesis of di-2-thienylmethane derivatives, we attempted to prepare di-2-thienylmethanol by the usual organomagnesium synthesis, as described for α-methyl-2-thiophenemethanol [2] and α-phenyl-2-thiophenemethanol [3]. Under these conditions, however, reaction was accompanied by considerable resinification, and only the ether (II) was isolated in very small amount. We succeeded in obtaining the alcohol itself by modifying the conditions somewhat, namely, carrying out the synthesis in an atomsphere of nitrogen and decomposing the organomagnesium complex not with acid, but – as is quite customary – with ammonium chloride solution. When the alcohol (I) is heated in a water bath for five minutes in presence of traces of acid, it is converted into the ether (II), the reaction being accompanied by considerable resinification. Work on the properties and reactions of di-2-thienylmethanol is continuing..

(I) (II)

EXPERIMENTAL

Preparation of the ether (II). An ethereal solution of 2-thienylmagnesium bromide prepared from 8.2 g of 2-bromothiophene and 1.2 g of magnesium was added dropwise to a stirred ice-cold solution of 5.6 g of 2-thiophenecarboxaldehyde in 10 ml of dry ether. The yellow precipitate that formed was decomposed under ice cooling with 14 ml of dilute (1 : 1) hydrochloric acid. The dark-colored ethereal solution was separated, washed with sodium bisulfite solution and with water, and dried with magnesium sulfate. After removal of ether a dark-colored crystallizing oil remained. The substance was washed with alcohol and dissolved in hot ligroin. The solution was cooled and gave 1.4 g of a crystalline precipitate, m.p. 79°. After being recrystallized from ligroin and alcohol, the ether melted at 81.5-82.5°. It darkened in color when kept in the cold.

Found %: C 57.85, 57.69; H 3.81, 3.79. $C_{18}H_{14}OS_4$. Calculated %: C 57.72; H 3.77.

Preparation of di-2-thienylmethanol (I). A solution of 8.4 g of 2-thiophenecarboxaldehyde in 20 ml of ether was added with cooling (0-5°) to an ethereal solution of 2-thienylmagnesium bromide prepared from 12.8 g of 2-bromothiophene and 1.9 g of magnesium. The reaction was carried out in an atmosphere of nitrogen. When the addition was complete, stirring was continued for 20 minutes. The precipitate that formed was

decomposed under cooling with 40 ml of concentrated ammonium chloride solution. The ether layer was separated and dried with magnesium sulfate. After evaporation of ether, 12.3 g of a light-colored oil remained, and this crystallized when cooled. A small portion of the crystals was pressed off on a porous tile and recrystallized twice from ligroin: m.p. 56-57°. Di-2-thienylmethanol becomes yellow when kept in the cold.

Found %: C 55.44, 55.35; H 4.06, 3.99. $C_9H_8OS_2$. Calculated %: C 55.07; H 4.11.

SUMMARY

The syntheses are described of the previously unknown di-2-thienylmethanol and bis(di-2-thienylmethyl) ether.

OPENING OF THE TETRAHYDROFURAN RING UNDER THE ACTION OF ALUMINUM HALIDES

N. I. Shuikin and I. F. Belsky

Investigations by various authors have shown that that the tetrahydrofuran ring can be opened under the action of hydrogen halides with formation of the corresponding aliphatic halogen compounds. For example, Froebe and Hochstatter [1] obtained 1,4-dichloropentane by heating tetrahydro-2-methylfuran with concentrated hydrochloric acid in a sealed tube at 60° for four hours.

Starr and Hixon [2] showed that reaction of tetrahydrofuran with dry hydrogen chloride resulted in the formation of 4-chloro-1-butanol in 56% yield. This result was confirmed by Fried and Kleen [3], who studied the action of dry hydrogen halides on tetrahydrofuran and tetrahydro-2,5-dimethylfuran and found that the tendency for the rings of these compounds to open diminishes progressively as we pass from HI to HBr and HCl. The action of dry hydrogen iodide and hydrogen bromide on tetrahydrofuran gave, respectively, 1,4-diiodobutane and 1,4-dibromobutane in yields of 75% and 60%. Reaction of the same hydrogen halides with tetrahydro-2,5-dimethylfuran gave 2,5-diiodo- and 2,5-dibromohexanes. Dry hydrogen chloride did not react at all with tetrahydro-2,5-dimethylfuran, but it reacted with tetrahydrofuran with opening of the ring and formation of 4-chloro-1-butanol, in agreement with the results of Starr and Hixon. In the same investigation, Fried and Kleen showed that, in presence of anhydrous zinc chloride, tetrahydrofuran reacted with dry hydrogen chloride with formation of 1,4-dichlorobutane in 56% yield, but tetrahydro-2,5-dimethylfuran gave 2,5-dichlorohexane in a yield of only 8%. French Patent 864759 [4] reports the preparation of 1,5-dihalobutanes in high yields (up to 95%) by the treatment of tetrahydrofuran with hydrogen halides in presence of sulfuric acid or other dehydration catalysts. Cloke and Ayers [5] showed that phosphorus tribromide, like hydrogen bromide, has a splitting effect on the tetrahydrofuran ring: reaction of phosphorus tribromide with tetrahydrofuran results in the formation of 1,4-dibromobutane in 53% yield.

In our investigation we have studied the action of anhydrous aluminum halides ($AlCl_3$ and $AlBr_3$) on tetrahydrofuran and tetrahydro-2-methylfuran. We have showed that under the action of these salts the tetrahydrofuran ring is opened with formation of dihalo paraffins. Tetrahydrofuran and aluminum chloride gave 1,4-dichlorobutane, and with aluminum chloride and bromide tetrahydro-2-methylfuran gave 1,4-dichloro- and 1,4-dibromo-pentanes, respectively.

(X is Cl or Br)

EXPERIMENTAL

Tetrahydrofuran and tetrahydro-2-methylfuran were prepared by the hydrogenation of furan and 2-methylfuran, respectively, over Raney nickel at 125°. They were isolated from the reaction products by fractionation through a 30-plate column. The tetrahydrofuran had b.p. 65-66° (755 mm), d_4^{20} 0.8886, and n_D^{20} 1.4078. The tetrahydro-2-methylfuran had b.p. 79-79.2° (750 mm), d_4^{20} 0.8582, and n_D^{20} 1.4060.

Experiments on the reactions of tetrahydrofuran and tetrahydro-2-methylfuran under the action of aluminum halides were carried out as follows. One molecular proportion of the tetrahydrofuran was introduced into an ice-cooled flask fitted with mechanical stirrer. Not less than two-thirds of a molecular proportion of anhydrous aluminum halide was then added in small portions under constant stirring. Reaction was vigorous and exothermic. After the whole of the aluminum halide had been added, the reaction mixture was stirred for one hour at room temperature and then for 2-3 hours in a water bath. Toward the end of the reaction the mixture became thick and black. The reaction products were extracted with ether, and the ether extract was washed with water and dried with calcium chloride. It was then vacuum fractionated. From the products formed by reaction between tetrahydrofuran and aluminum chloride, we isolated 1,4-dichlorobutane in 32% yield; it had the following properties: b.p. 81-83° (10 mm) d_4^{20} 1.1101; n_D^{20} 1.4590; found MR 30.80, calculated ($C_4H_8Cl_2$)MR 30.41.

Scission of tetrahydro-2-methylfuran by aluminum chloride and bromide under the same conditions gave 1,4-dichloro- and 1,4-dibromo-pentanes respectively. 1,4-Dichloropentane, obtained in 58% yield, had the following properties; b.p. 53-54° (4 mm); 104-105° (115 mm); 162-164° (750 mm); d_4^{20} 1.0731; n_D^{20} 1.4510, found MR 35.39, calculated ($C_5H_{10}Cl_2$)MR 35.02. 1,4-Dibromopentane (67% yield) had the following properties: b.p. 66-67° (6 mm); d_4^{20} 1.6871; n_D^{20} 1.5094; found MR 40.73; calculated ($C_5H_{10}Br_2$)MR 40.82.

Apart from these compounds, reaction of tetrahydrofuran and of tetrahydro-2-methylfuran with aluminum chloride and with aluminum bromide gave some high-boiling halogen-containing substances. For example, from the products of reaction between tetrahydro-2-methylfuran and aluminum chloride we isolated a fraction having the following properties: b.p. 124-127° (10 mm), d_4^{20} 1.0253; n_D^{20} 1.4647; found MR 58.85; calculated ($C_{10}H_{20}Cl_2$)MR 58.12. This fraction appeared to consist essentially of dichlorodecane.

SUMMARY

1. It was shown that the tetrahydrofuran ring is opened under the action of aluminum chloride or bromide with formation of dihalo paraffins.

2. It was found that reaction of tetrahydrofuran with aluminum chloride gives 1,4-dichlorobutane in 32% yield, and reaction of tetrahydro-2-methylfuran with aluminum chloride and with aluminum bromide gives, respectively, 1,4-dichloropentane in 58% yield and 1,4-dibromopentane in 67% yield.

CURRENT EVENTS

ANNUAL MEETING OF THE DIVISION OF CHEMICAL SCIENCES OF THE ACADEMY OF SCIENCES OF THE U S S R

The Annual Meeting of the Division of Chemical Sciences of the Academy of Sciences of the USSR was held on January 31 and February 1, 1956. The Academician-Secetary of the Division of Chemical Sciences, M. M. Dubinin, presented his report on the scientific activities of institutes of the Division during 1955 and the applications made of the Division's work in the national economy.

At the beginning of his address, Academician M. M. Dubinin pointed out that the Annual Meeting was taking place during an important period for the country, on the eve of the Twentieth Congress of the Communist Party of the Soviet Union and soon after the publication of the draft of the Directive of the Congress on the Sixth Five-year Plan for the Development of the National Economy of the USSR (1956-1960). The draft of this directive, stated Academician Dubinin, refers to the world-wide development of science and the extension of theoretical investigations into all branches of knowledge. It is proposed to direct the efforts of scientists and the use of the material resources of scientific institutes onto work mainly concerned with problems of great importance for the national economy. M. M. Dubinin enumerated the problems which came within the responsibility of the Division of Chemical Sciences. In 1955 the activities of the newly created scientific councils and commissions on various problems developed greatly, particularly with respect to the organization of conferences on individual scientific subjects and the examination of matters relating to the organization of scientific work.

Passing to the activities of institutes of the Division during 1955, Academician M. M. Dubinin stated that in the N. S. Kurnakov Institute of General and Inorganic Chemistry work had carried on along lines traditional for that institute. As a result of an investigation on the complex compounds of bi- and quadri-valent platinum, new data had been obtained for the quantitative characterization of the trans effect. With the laws of the trans effect as guide, about forty complex compounds of platinum, palladium, rhodium, iridium, ruthenium, and silver were synthesized. The results of these investigations are of great importance for the preparation of these elements in the pure state. Physicochemical investigations on the simple and complex compounds of germanium, zirconium, hafnium, titanium, neodymium and samarium, tantalum, indium, gallium, thallium, and rhenium have enabled the conditions under which they react with salts, oxides, acids, etc. to be determined. New data have been obtained which are of importance for the preparation of rare elements from Soviet raw materials. The speaker referred also to the work of the institute on natural salts and synthetic inorganic compounds.

Refering to the work of V. G. Khlopin Radium Institute, Academician Dubinin stated that, in development of the fundamental ideas of V. G. Khlopin, investigations have been carried out on the distribution of various new radioactive elements between solids and liquids, and also between two liquid phases. A study was made of the behavior of transuranic elements when precipitated by means of lanthanum potassium double sulfate, and also of the mechanism by which they were entrained. The state of radioactive elements in extremely dilute solutions was studied. Closely agreeing results were obtained by various methods for the uranium contents of stone and iron meteorites; the comparative migration of thodium isotopes from uraninites was studied. The thorough investigation of radioactive methods for the determination of geological age and the improvement of their accuracy was continued.

The interaction of 400-700 Mev particles with complex nuclei was investigated by the method of thick-layer photographic plates. New data were obtained on the mechanism of fission processes at high energies. Progress was made in investigations on nuclear spectroscopy. With the aid of γ-spectrometers of high resolving power constructed at the Institute, the γ-spectra of individual isotopes of lanthanum, gold, iridium,

europium, arsenic, ruthenium, and antimony were investigated, and this made it possible greatly to increase the accuracy of the schemes of energy levels for these elements.

Passing to the activities of the V. I. Vernadsky Institute of Geological and Analytical Chemistry, Academician Dubinin referred to the completion of extensive investigations on the radiochemistry of the products of nuclear reactions occurring the bombardment of uranium, thorium, bismuth, and copper with high-energy particles. A study was made of the yields of fission products and the positions of the elements in the periodic system, the identities of the particles formed by radioactive decay, and the energies of these particles. New b-active isotopes were discovered, and some new a-radiators were found among the rare earths. The progress of work on the geochemistry of isotopes has enabled estimates to be made of the age of Ukrainian precambrian rocks by a comparative method based on determinations of uranium-lead, strontium-rubidium, and argon-potassium ratios. Investigations on the geochemistry of lead enabled several questions concerning the ore-formation process to be resolved.

Investigations of great importance were carried out on the chemistry of the rare elements. For example, a complete scheme for the separation and isolation of all fifteen rare-earth elements was worked out experimentally. Work on the separation of zirconium and hafnium was completed and brought into practical application. Spectrum, x-ray spectrum, and radioactivity methods were developed for the determination of extremely small amounts of rare elements in pure niobium, tantalum, zirconium, tungsten, molybdenum, and other metals. The x-ray-spectrum investigations were completed by the development of a theory of the fine structure of solids.

The report referred also to work of the institute on biogeochemistry. This established the causes of deleterious effects on animals and plants in some districts of the country due to insufficiency or excess of copper, molybdenum, lead, strontium, cobalt, and other elements.

As Academician Dubinin stated, the activities of the Institute of Silicate Chemistry have developed in various directions: heterogeneous equilibria and phase transformations in silicate systems had been studied, and work had been carried out on the hydrothermal synthesis of calcium hydrosilicates and on the study of hydrogen bonding in these by the method of infrared spectroscopy. The polymorphous transformations of silica were studied by methods of adiabatic calorimetry and thermography. Investigations were carried out for industry on organosilicon coatings, on ceramics, on the introduction into industry of new progressive technology in the polishing of glass, and on other subjects.

In its connection with hydroconstruction, the work of the Hydrochemical Institute is of great importance for the national economy. Academician Dubinin referred to the study of the hydrochemical regime in the Volga immediately before the flooding of the Kuibyshev and Gorky reservoirs, the prognosis of the mineralization and change in chemical composition of the waters of Lake Balkhash that would result from the projected hydrotechnical construction in that region, and other laboratory and field work of the institute.

The Institute of Physical Chemistry is notable for the great variety of the work which it carries out. In his report, M. M. Dubinin referred to some of the most important of these lines of work. In the field of electrochemistry and chemical sources of current, a new method was developed for the investigation of the mechanism of the separation of molecular hydrogen in the electrolysis process, and it was shown for the first time that atomic hydrogen has an oxidizing function and passes into molecular hydrogen at the electrode at high overvoltages as a result of simultaneous combination with a hydrogen ion and an electron. With the aid of labeled atoms, new data were obtained concerning the mechanism of the electrodeposition of chromium. By the same method, the transfer of silver and antimony from the lattice of the positive plate of an accumulator to the negative plate was studied. The effect of organic substances on the self-discharge of a zinc electrode was studied. Among investigations on the corrosion of metals, the speaker referred to work on the principles underlying a new method for the electrochemical protection of stainless steels by means of anodic polarization, to investigations on the mechanism of the corrosion of metals in soils (which showed the dependence of the rate of corrosion on the salinity and moistness of the soils), and to various other investigations.

In the same institute, said M. M. Dubinin, 1955 saw the completion of work on the mechanism of the effect of an active medium on creep and fatigue in metals and its publication as a monograph. A physicochemical investigation was carried out also into the fine vibrational grinding of cements, and this has provided a basis for a new technology of building materials. In connection with the study of aerosols, a convenient continous method has been devised for measuring critical supersaturations at condensation nuclei, and a simple continuous counter has been designed for these nuclei.

In the catalysis field, several investigations have been completed on the electronic theory of catalysis on semiconductors, the modifying effect of nonmetals in the catalytic preparation of ethylene oxide has been confirmed, and it has been shown that the selectivity and activity of catalysts can be raised. The classification of catalytic processes according to the nature of the primary act has been improved, and a theory for the selection of catalysts of the acid-base type has been developed.

In 1955 the work of the Institute of Chemical Physics was centered on the kinetics and mechanisms of chemical reactions. The concept of macroscopic stages in chemical processes and the special part played by the initial period was developed and provided with experimental support. The results of this work give reason to suppose that the solution of the problem of directing a chemical process is associated with action directed onto the macroscopic stages.

Experimental investigation has established the main features of mechanism of the action of aprotonic acids in acid-catalyzed reactions. It was shown for the first time that aprotonic acids of the boron trifluoride type act like protonic acids: they form complexes with various substances, and the products are powerful protonic acids.

Academician Dubinin then passed to work on organic chemistry and discussed the investigations carried out at the Institute of Heteroorganic Compounds. In this institute, work has continued on the chemistry of organometallic compounds, and of ferrocene in particular. A large number of ferrocene derivatives have been prepared, and the effect of substituents on the activity of the cyclopentadiene rings of the ferrocene molecule has been determined. In the organophosphorus field, the theory of tautomerism has been examined in the light of the tautomeric equilibrium of lactim-lactams, dialkyl hydrogen phosphorothioates, etc. Many compounds having insecticidal action have been synthesized. In the organosilicon field, a beginning has been made in the development of methods of synthesizing organic polymers containing a chain of silicon and aluminum atoms linked through oxygen atoms.

An extensive investigation of the telomerization of ethylene with carbon tetrachloride and with chloroform has enabled the conditions to be found under which the higher tetrachloroalkanes (odd members of the series containing up to 51 carbon atoms in the molecule) could be prepared at a comparatively low pressure. For the first time, the effect of pressure and of the relative amounts of the reactants on the yield of practically important telomerization products has been determined. Methods for the synthesis of various carboxylic acids, amino acids, amino alcohols, etc. have been devised.

In the field of macromolecular compounds, a number of theoretical problems on the effect of the structures of the original reactants on the properties of the resulting polymers have been solved. Many new polymers have been synthesized from various dicarboxylic acids and various bifunctional compounds. These include polymers containing silicon, sulfur, and phosphorus. The properties of the polymers obtained have been studied.

Referring to the work of the N. D. Zelinsky Institute of Organic Chemistry, the speaker pointed out the substantial progress in investigations associated with the development of the theory of chemical structure and the extension of theoretical and experimental investigations on heterogeneous catalysis. New regularities have been discovered in the structural and spatial directivity of the diene synthesis. Hydration, cyclization, isomerization, and oxidation reactions have been studied, and their mechanisms have been established with the aid of labeled atoms. Methods have been developed for the building up of carbon chains of the isoprenoid type from acetylenic alcohols. These make it possible to effect the complete synthesis of some important natural substances. Work has been completed on the development of new methods of synthesis of the new sedative isopromedol and on the clinical testing of this substance.

The multiplet theory of catalysis has been developed further, particularly the aspects of energetic correspondence and quasiheterogeneous surfaces. With the aid of the kinetic method, an extensive investigation has been made in order to determine the bonding energy between the reacting molecules and the catalyst. For the first time in heterogeneous catalysis it has been proved experimentally that the hydrocondensation of carbon monoxide with olefins proceeds by a chain mechanism.

The work of the Institute of Macromolecular Compounds has centered mainly around the problem of establishing the relationship of the chemical structures of the reactants and the polymerization conditions to the structure and properties of the polymers. A theory has been advanced which provides a semiquantitative explanation of the phenomena occurring when high polymers pass into the vitreous state and when they are annealed. The theory has enabled a relationship to be established between the vitrification temperature and the characteristics of the substance. New data have been obtained concerning the activity of the double bonds

of vinyl compounds in reactions with free radicals. Investigations on ion exchange have been completed, and principles that can form the basis of a theory of chromatography and the exchange of large ions have been laid down.

Investigations of vinyl compounds have enabled new transparent polymeric compositions to be developed and the future course of work on such polymers to be planned. Work on the synthesis of macromolecular compounds having new or specific properties has resulted in the development of polymers which are now to be produced on a larger scale in conjunction with industrial organizations.

After his review of the activities of the institutes of the Division of Chemical Sciences, Academician Dubinin reported that in 1955 there were seven sessions of the Division at which one general progress report and thirty-two scientific papers were read and discussed. Work on the July Session on the Peaceful Uses of Atomic Energy, the preparation of reports for the Geneva conference, and the organization of the chemical section of the Exhibition on the Peaceful Uses of Atomic Energy all occupied important places among the activities of the Division.

The speaker referred to the considerable changes that had occurred in the publishing activities of the Division. Three new journals had been brought into being: The Journal of Inorganic Chemistry, The Journal of Scientific and Applied Photography and Cinematography, and Geochemistry. Moreover, the sizes of several other journals had been increased.

Academician M. M. Dubinin noted with satisfaction the considerable strengthening of scientific ties with foreign scientists. An agreement had been reached with the chemical societies of Britain and France concerning the exchange of scientific papers for publication in the journals of each country. This form of close collaboration and mutual exchange of information, stated the speaker, will a find a wide basis for development in the future, both here and abroad.

There were more than twenty participants in the discussion on M. M. Dubinin's report.

Academician S. I. Volfkovich drew attention to the need for the publication of more books on methods more encyclopedias, and more reference books; these must be written by suitable teams of authors. S. Z. Roginsky, Corr. Member Acad. Sci. USSR, expressed the opinion that it is essential to proceed vigorously in the further extension of the material basis of work on the problem of catalysis. Academician Rebinder pointed out the importance of rapid publication of comments on completed scientific investigations of theoretical importance or of importance to the national economy. S. N. Danilov, Corr. Member Acad. Sci. USSR, referred to the necessity of extending the laboratories of the Division and equipping them fully.

N. A. Bakh, Doctor Chem. Sci., discussed the desirability of re-examining the system of training scientific staffs with the object of ensuring that the institutes will be better provided with creative workers. I. P. Alimarin, Corr. Member Acad. Sci. USSR, pointed out the importance of the better coordination of scientific investigations; he referred, in particular, to the field of analytical chemistry. Moreover, better technical equipment with modern apparatus was necessary, particularly for the outlying scientific establishments. Academician I. L. Knunyants made an appeal for the intensification of scientific investigation into the chemistry of proteins. He made some remarks on individual papers on proteins that have been published in recent years, and he discussed also some problems of scientific organization. Academician A. N. Frumkin criticized the work of the Journal of Physical Chemistry and pointed out the necessity of strengthening international relations, particularly with respect to the problem of electrochemical kinetics. Ya. K. Syrkin, Corr. Member Acad. Sci. USSR, referred to the inadequate development of investigations on the theory of chemical structure, and he emphasized the significance of the investigations of the Kazan scientists Zavoisky and Kozyrev on paramagnetic resonance.

I. M. Lepeshkov, Doctor Chem. Sci., emphasized the importance of developing investigations on inorganic chemistry and the necessity of extending the material basis for these investigations. Academician V. A. Kargin pointed out the importance of research leading to the development of new directions in chemical science. Academician A. P. Vinogradov drew attention to the useful purpose that would be served by a new publication or new sections in existing journals having the object of systematically acquainting workers in particular branches of science with the investigations of others in that field. In A. P. Vinogradov's opinion, this procedure would provide the best means of effecting the satisfactory coordination of scientific investigations.

On questions relating to the organization of scientific work, contributions to the discussion were made by M. I. Nikitin, Corr. Member Acad. Sci. USSR; Academician N. N. Semenov; O. A. Alekin, Corr. Member Acad. Sci. USSR; V. M. Vdovenko, Doctor Chem. Sci.; N. A. Toropov, Doctor Chem. Sci.; N. I. Shulkin, Corr. Member Acad. Sci. USSR, and others.

In some concluding remarks, Academician M. M. Dubinin referred to some criticisms sent to the Bureau of the Division; these criticisms were justified and were of importance, and he suggested that members of the Bureau should study them carefully and take them into account in their further work.

At the final session of the Annual Meeting of the Division of Chemical Sciences, the participants listened with interest to a paper by Academician V. N. Kondratyev on "Lines of Progress in the Theory of the Chemical Process".

The paper was followed by a discussion.

SALUTATIONS

IVAN LYUDVIGOVICH KNUNYANTS

Dear Ivan Lyudvigovich:

The Division of Chemical Sciences of the Academy of Sciences of the USSR and the Editorial Board of the Bulletin of the Academy of Sciences of the USSR, Division of Chemical Sciences, warmly congratulate you on the attainment of the age of fifty.

It is with great satisfaction that we note your varied scientific activities in the chemistry of heterocyclic and natural substances, macromolecular compounds, and fluorine.

May you make further creative progress in your scientific work.

Division of Chemical Sciences,
Academy of Sciences of the USSR

Editorial Board of the Bulletin of the Academy of
Sciences of the USSR, Division of Chemical Sciences

IVAN NIKOLAEVICH NAZAROV

Dear Ivan Nikolaevich:

The Division of Chemical Sciences of the Academy of Sciences of the USSR and the Editorial Board of the Bulletin of the Academy of Sciences of the USSR, Division of Chemical Sciences, warmly greet and congratulate you on the occasion of your fiftieth birthday.

Your fruitful scientific activity over many years in many fields of organic chemistry is well known to chemists everywhere.

Accept our best wishes for your health and further success in your creative work in the service of our Fatherland.

Division of Chemical Sciences,
Academy of Sciences of the USSR

Editorial Board of the Bulletin of the Academy of
Sciences of the USSR, Division of Chemical Sciences

COLLOIDAL PROPERTIES OF POLONIUM •

I. E. Starik, N. I. Alekseenko, and N. G. Rozovskaya

The question of the state in which extremely minute amounts of a substance are present in a solution is a fundamental and highly controversial problem in radiochemistry. For various reasons, great experimental difficulties were met in the solution of this problem, and as a result there are now two directly opposed points of view on the matter. According to one of these, radioactive elements in microconcentrations are able to form colloidal solutions, in spite of the fact that the solubility product is not attained. The possibility of the formation of colloidal solutions is associated by some authors with specific properties of the radioactive elements [1]. According to the second point of view, the radioactive elements are present in the ionic state under these conditions, but they are absorbed by colloids present in the solution and therefore behave like colloids [2].

There are three main causes for the difficulty met in the solution of this problem.

1. No methods exist which will unequivocally resolve the question of the nature of radiocolloids. It is not a matter of increasing the sensitivity of existing methods of colloid chemistry, but of the difficulty in principle of finding a method that would give an answer to the question. Actually, workers on this problem, from Paneth onward, used all of the existing methods in order to determine whether the radio-elements investigated were colloidal, and it appeared that, in view of the proofs they obtained by many methods of the colloidal nature of these elements, there could be no doubt about the solution of the problem. However, as Zsigmondy correctly pointed out, a study of the colloidal behavior of these elements by the usual methods does not enable us to decide whether they themselves are true colloids, or whether they are adsorbed by extraneous colloids that are always present in solutions.

2. It is wrong to pose this question of the colloidal nature of radio-elements in solutions in its general form, for such a question must depend for its solution on the chemical nature of the elements and on the conditions under which they are studied.

3. Substantial difficulties arise from the absence of data on the solubilities of compounds of the radio-elements investigated and from the complications met in the determination of such solubilities, for at such low

Fig. 1. Relation of deposition of polonium on copper to the concentration of polonium at pH: 1) 1; 2) 4; 3) 13.

Fig. 2. Relation of deposition of polonium on copper to the concentration of polonium at pH: 1) 6; 2) 7; 3) 8; 4) 9.

• Paper read at a general meeting of the Division of Chemical Sciences of the Academy of Sciences of the USSR on October 27, 1955.

concentrations adsorption and other processes make this determination very difficult. Moreover, the results of solubility determinations depend greatly on the assumption made regarding the degree of hydrolysis or ionization.

In the period of more than forty years that has elapsed since the investigations of Paneth [3] and Godlewski [4], many attempts have been made to solve this problem and to extend these investigations to all artificial radio-elements, but even now the question of the existence of radio-elements as true colloids still remains a controversial one. We shall not discuss the history of this problem, but it may be noted that a large number of investigators took part in these investigations [3-14]. It must be emphasized that the most important investigations were those of Paneth, Hahn, Haissensky, and Chamie.

It appeared to us that the solution of the question of principle involved in this problem – the possibility of the existence of true colloids in very dilute solutions – could be most conveniently attempted for the case of polonium, although work with this element is made very difficult by the existence of a large number of valency states, the complexities met in the determination of these, and the amphoteric character of the element. As one of us has shown previously [15], this question can be solved by the application of only one method – the indirect method of adsorption. It was shown that adsorption of polonium by negatively charged surfaces – such as glass, and also colloids – is at a minimum in neutral and weakly alkaline media, i.e. in those media in which its colloidal properties are at a maximum. If polonium exhibits colloidal properties because it is adsorbed on extraneous colloidal particles, then it would be expected that its colloidal properties would be most marked in an acid medium, and not in the neutral and alkaline media in which it is actually observed.

The proposed method appears to give an unequivocal answer to the question, but some investigators still do not reject the adsorption theory of the nature of radiocolloids. We therefore considered it necessary to use several methods, the results of which, taken together, would provide a more unequivocal solution of the question and would give a clearer picture of the state of polonium in various media. We used the following methods: 1) electrochemical deposition on metals; 2) adsorption and desorption of polonium at a glass surface; 3) centrifugation; 4) ultrafiltration; 5) radiography. With the object of resolving the question of the polydispersity of polonium solutions, each polonium solution was investigated three times by each of these methods.

Let us pass now to an examination of the results of the study of the electrochemical deposition of polonium on copper in solutions varying in pH and concentration. It may be expected that appreciable deposition of polonium on copper will occur in those media in which the polonium is mainly in the ionic state; in those media in which the polonium is hydrolyzed and forms colloidal solutions, the effective concentration of polonium ions will be much less and the amount of polonium deposited on copper should also be appreciably less. The following conclusions can be made from an examination of the curves in Figures 1 and 2. For each value of the pH, the relation between the amount of polonium deposited and its concentration in the solution has its own characteristic features. At pH 1 we find that the percentage of the polonium deposited increases with increase in concentration, which is in accord with the view that the polonium is in the ionic state. At pH 4 the percentage deposition again increases, but the process is somewhat distorted as a result of appreciable adsorption on impurities present in the solution. At pH 6 and 7 there is at first a similar rise in the percentage deposition of polonium, which must be explained by the presence of polonium in an ionic, nonhydrolyzed state. It is evident, however, that with increase in the polonium concentration hydrolysis begins to have an effect, which becomes greater at pH 7.2, since the sharper fall in the percentage deposition of polonium occurs at this pH. Above a concentration of $1.77 \cdot 10^{-10}$ mole/liter, the percentage deposition of polonium at pH 7.2 remains constant. At pH 8 and 9 the percentage deposition of polonium on copper is independent of the polonium concentration and is represented by a straight line (Fig. 2).

Fig. 3. Relation of the deposition of polonium on copper to pH at polonium concentrations of: 1) 10^{-9} mole/liter; 2) 10^{-10} mole/liter; 3) 10^{-12} mole/liter.

It is natural to suppose that, in these media at all of the concentrations investigated, polonium forms insoluble compounds. Confirmation of the presence of insoluble compounds in these media is provided by the

fact that the percentage of the polonium separated is identical in three successive depositions from the same solution (Table 1). Actually, if in the first deposition of polonium on copper a definite though very small amount of polonium ions is deposited and in the course of the day that passes between two successive depositions the ions are replaced by partial dissolution of the solid phase and reestablishment of equilibrium, then the effective concentration of ions will attain its previous value.

It is of interest to note also that, as can be seen from Fig. 3, the pH at which the sharp reduction in the deposition of polonium occurs depends on its concentration:

Conc. Po	pH	$L_{Po(OH)_4}$
$5{,}2\cdot10^{-12}$	7,6	$1{,}3\cdot10^{-57}$
$1{,}8\cdot10^{-10}$	7,2	$6{,}8\cdot10^{-58}$
$1{,}7\cdot10^{-9}$	6,9	$7{,}1\cdot10^{-58}$

On the basis of these results an idea can be obtained of the solubility of the hydrolysis products and the solubility product of the postulated hydrolysis product can be estimated. Hence, a study of electrochemical deposition enables us to characterize the various states of polonium in various media.

TABLE 1

Deposition of Polonium on Copper

pH	Concentration of polonium in the solution (mole/liter)	Polonium deposited (%)		
		First deposition	Second deposition	Third deposition
1.2	$5.22\cdot10^{-12}$	23	24	18
4.2	$5.22\cdot10^{-12}$	23	7.3	2.9
5.8	$3.82\cdot10^{-12}$	26.5	10.0	8.4
7.2	$3.82\cdot10^{-12}$	27	15.7	8.9
8.0	$5.22\cdot10^{-12}$	5.3	5.6	4.6
9.3	$5.22\cdot10^{-12}$	3.9	5.0	10.0
13	$5.22\cdot10^{-12}$	10,7	4.8	4.1
1.2	$1.49\cdot10^{-10}$	33	35	51
4.2	$1.77\cdot10^{-10}$	28	6.1	2.9
6.6	$1.40\cdot10^{-10}$	16	8.0	5.1
7.1	$1.77\cdot10^{-10}$	5.3	7.2	5.7
8.0	$1.77\cdot10^{-10}$	5.1	2.8	3.4
9.0	$1.77\cdot10^{-10}$	3.0	2.0	3.1
13	$1.77\cdot10^{-10}$	6,0	6.5	4.8
1.1	$1.09\cdot10^{-9}$	37	40	54
4.2	$1.18\cdot10^{-9}$	17	6.6	3.6
5.8	$1.73\cdot10^{-9}$	9.1	2.8	1.9
6.6	$1.09\cdot10^{-9}$	11,0	4.7	4.5
6.9	$1.73\cdot10^{-9}$	6.0	5.2	2.3
8.1	$1.18\cdot10^{-9}$	2.4	0.6	0.8
9.1	$1.18\cdot10^{-9}$	0.5	0.3	0.2
13	$0.77\cdot10^{-9}$	5.0	5.0	8.2

Let us now pass to a comparison of these results with those obtained by other methods. Adsorption experiments were carried out with glasses of various compositions, including quartz glass. It must be pointed out that the limits of reproducibility in these experiments were about 15%. The adsorption of polonium on different kinds of glass (Table 2) followed a different course in each separate case, but it was established quite firmly that in all cases adsorption was at a minimum in a neutral medium.

Special attention was paid to a more detailed study of the relation between adsorption on one kind of glass and the concentration of polonium in the original solution. It is quite obvious that, if polonium forms true colloids subject to the mass-action law, then this factor is very important. As can be seen from Fig. 4, at a polonium concentration of 10^{-10} mole/liter, the adsorption maximum lies in the pH range 4.2-6 and the minimum in the range 8-9.

The explanation of the existence of a maximum may be that with rise in pH from 1 to 4 the hydrogen ion concentration falls and creates favorable conditions for considerable adsorption of polonium ions. However, with further rise in pH the degree of adsorption falls, probably as a result of the occurrence of hydrolysis of polonium compounds. It is interesting that at pH 7.2 the degree of adsorption is fairly high, even when the polonium concentration is 10^{-10} mole/liter, a concentration at which – as we have seen from the electrochemical experiments – insoluble compounds are formed. The probable explanation is that in this medium colloidal polonium particles are still positively charged and are therefore adsorbed to a fair extent by the negatively charged glass. At a pH of about 8, however, the charge of the colloidal particles changes in sign, so that adsorption by the glass stops. At pH 8-9 adsorption is at a minimum, which may be explained by the formation of insoluble compounds and a considerable reduction of the ionic component.

The existence of an equilibrium between the soluble and insoluble parts is indicated by the absence of any difference in the degree of adsorption in repeated operations at pH 8-9 (Table 3). It is true that the degree of adsorption varies little in three successive experiments at pH 1, but in this case there is no reason to doubt

Fig. 4. Dependence of the adsorption of polonium on glass on pH at a polonium concentration of 10^{-10} mole/liter.

Fig. 5. Dependence of the adsorption of polonium on glass on the polonium concentration at pH: 1) 4; 2) 1; 3) 13.

Fig. 6. Dependence of the adsorption of polonium on glass on the polonium concentration at pH: 1) 6; 2) 7; 3) 8; 4) 9.

that the polonium is in the ionic state and, moreover, at such low pH its tendency to be adsorbed is low so that the concentration of the solution after the adsorption experiment is very little different from the concentration after a day has elapsed; each successive adsorption, therefore, is carried out under almost identical conditions, and the degree of adsorption will remain constant. At all other values of pH the extent of the second adsorption is less, probably as a result of the adsorption of polonium ions on impurities present in the solution and the competition between the two adsorption processes. At a concentration of the order of $8 \cdot 10^{-10}$ mole/liter, the degree of adsorption is considerably lower than at lower polonium concentrations, but the absolute amounts of adsorbed polonium at concentrations of $1.8 \cdot 10^{-10}$ and $8 \cdot 10^{-10}$ mole/liter are almost identical. These results indicate that adsorption of polonium on the glass surface is nearing its saturation point. The amount of adsorbed polonium is $5 \cdot 10^{-14}$ g-atom/sq. cm.

Let us now examine the relation of the adsorption of polonium at various values of pH to the polonium concentration (Figures 5 and 6). In the pH range 1-4 polonium is mainly in the ionic, nonhydrolyzed state, and the degree of adsorption falls with rise in the polonium concentration, thus indicating the gradual saturation of the surface of the adsorbent. In the region of pH 6 and 7 polonium is probably in the hydrolyzed state to an appreciable extent, and at first the degree of adsorption increases with increase in the polonium concentration; it quickly attains saturation, however, and it then falls. In the pH range 8-13 the degree of adsorption is low and changes very little with change in the polonium concentration. The general character of the variation of the adsorption is similar to that represented by the curves for pH 6 and 7, although the degree of adsorption is considerably less in the pH range 8-13. In this respect the curves are very similar to those for the electrochemical deposition of polonium on copper and indicate the existence of an ionic component in equilibrium

TABLE 2

Degree of Adsorption (%) of Polonium by Glasses Differing in Composition

Medium / Kind of glass	0.1*N* HNO_3	0.01*N* HNO_3	Neutral	0.001*N* NaOH	0.1*N* NaOH
Quartz glass	2.7	—	0.2	—	0.6
L-36	1.3	2.4	0.6	1.6	2.8
No. 23	1.1	1.7	0.4	0.8	0.9
L-100	0.8	1.8	0.3	—	—
31-4	0.7	1.4	0.6	1.3	1.2

with insoluble polonium compounds. We see, therefore, that the results on the adsorption of polonium by glass are in full agreement with the results on the electrochemical deposition of polonium on copper.

The results obtained on the desorption of polonium from glasses of various compositions completely confirm the views derived from the study of adsorption with respect to the state of the polonium in the different media. By way of example we give curves for the desorption of polonium by means of 1 N HNO_3 from L-36

TABLE 3

Adsorption of Polonium by Glass

pH	Concentration of polonium in the solution (mole/liter)	Degree of adsorption (%)		
		First experiment	Second experiment	Third experiment
1.2	$8.29 \cdot 10^{-12}$	2.2	1.8	1.3
4.2	$8.29 \cdot 10^{-12}$	6.6	2.9	3.2
5.8	$8.29 \cdot 10^{-12}$	7.0	1.0	0.8
7.2	$5.22 \cdot 10^{-12}$	6.2	2.7	1.9
8.0	$5.22 \cdot 10^{-12}$	4.9	3.1	2.4

6.1	$7.73 \cdot 10^{-10}$	2.2	2.6	2.6
7.1	$7.73 \cdot 10^{-10}$	1.6	1.5	1.5
8.1	$8.85 \cdot 10^{-10}$	1.6	0.6	0.6
9.1	$8.85 \cdot 10^{-10}$	0.5	0.6	0.5
13	$8.85 \cdot 10^{-10}$	0.3	0.2	0.2

(Pyrex type) glass and from quartz glass (Figures 7 and 8). The preliminary adsorption was from solutions of polonium in water and in 0.1 N HNO_3. Degree of desorption (%) is plotted as ordinate and time (hours) as abscissa. The results show that there is a great difference in the desorbing effect of 1 N HNO_3 according as the adsorption of the polonium is from distilled water or from 0.1 N HNO_3; this is most readily explained by a difference in the state of the polonium. According to our views, in distilled water polonium is mainly in the colloidal form and in 0.1 N HNO_3 it is mainly in the ionic form, so that it may be expected that a difference

Fig. 7. Dependence of the desorption of polonium from glass L-36 by means of 1 N HNO_3 on the conditions of adsorption:
1) from water; 2) from 0.1 N NaOH; 3) from 0.1 N HNO_3.

Fig. 8. Dependence of the desorption of polonium from quartz glass by means of 1 N HNO_3 on the conditions of adsorption:
1) from water; 2) from 0.1 N NaOH; 3) from 0.1 N HNO_3.

will be found in the desorption, colloidal particles being less firmly bound to the sorbent surface than multivalent cations are. The experiments confirmed this view. Also, the difference in the character of the desorption kinetics in these two cases should be noted: this again supports the views that we have expressed. The difference in character between the curves for the desorption of polonium adsorbed from water and from 0.1 N HNO_3 may be associated also with the diffusion of polonium ions into glass from a medium of 0.1 N HNO_3.

The results we obtained on centrifugation and ultrafiltration again confirmed the above-stated views on the state of polonium in various media. The centrifugation results provide a criterion of the degree of dispersity of the particles. The use of our usual centrifuges permits the precipitation of particles of about 10 μ in radius, i.e. the fraction of the polonium which is associated with coarsely dispersed particles is centrifuged out. In centrifugation experiments adsorption occurs on impurities present in the solution and on the walls of the centrifuge tubes, so that the results are of poor reproducibility and are semiquantitative in character. The results showed that the centrifugation affected only coarsely dispersed particles carrying adsorbed radio-element, for the centrifugation maximum corresponds to the adsorption maximum for polonium (Fig. 9); in those media in which polonium exhibits mainly colloidal properties, the amount of polonium centrifuged out – as also the degree of adsorption – tends to zero. The centrifugation results confirm that at pH 8-10 polonium forms mainly insoluble compounds.

The ultrafiltration results, like the centrifugation results, provide a criterion of the dispersity of the particles. In our preliminary experiments we used industrial ultrafilters having a mean pore diameter of 300 mμ, so that they could retain only coarsely dispersed particles. The results obtained by the ultrafiltration method showed (Fig. 10) that in this case the maximum retention of polonium by the ultrafilters coincided with the maximum tendency for polonium to be adsorbed. The retention of polonium was at a minimum in those media in which polonium is present in the colloidal form. The ultrafiltration experiments, therefore, are in full accord with the results obtained by other methods.

In conclusion, we shall discuss briefly the radiographic method, which finds extensive application in the study of the state of radio-elements in solution. The radiographic method was first applied to solutions by Chamie [16] in 1927. The method consists essentially in the application of a drop of the solution of radio-elements either directly to the surface of a photographic plate, or to a piece of mica placed in contact with the photographic emulsion, or to vaseline smeared on the plate to protect it from the chemical action of the solution. Chamie's photographs indicated a nonhomogeneous distribution of activity and the presence of groups of atoms. The author calculated that each such group contained 10^6-10^8 polonium atoms, so that such a group could not consist only of polonium atoms and must be an adsorption complex. In Chamie's opinion, such groups exist in the solution itself and are not formed when the solution comes into contact with the surface. The results of further investigations by the radiographic method – by Herzfinkel and Jedrzejowski [11], Hahn [8], Werner [7], and Blau and Rona [12] – confirmed Chamie's views and lent them precision.

Fig. 9. Relation between the precipitation of polonium by the centrifugation method and the pH for a polonium concentration of 10^{-12} mole/liter.

Fig. 10. The ultrafiltration of polonium from solutions of various pH at a polonium concentration of 10^{-9} mole/liter.

Radiography as applied to solutions is generally regarded as a method of studying what is happening in the solution, and the possible adsorption of radio-elements by the mica, vaseline, paraffin, or photographic emulsion to which the solutions of the radio-elements are applied is not taken into account.

Shortly after the appearance of Chamie's first papers, one of us, in collaboration with Diezenrot-Mysovskaya [17], showed experimentally that it is the polonium adsorbed on the mica applied to the photographic plate that is effective in the radiography, the image formed being characteristic only of the adsorption of polonium by mica. In the present investigation we made a detailed study of the distribution of polonium in photographic emulsions impregnated with polonium solutions differing in concentration and pH, and we compared this distribution with that of polonium on a mica or glass surface. We found that, in all cases, the distribution of polonium was similar in character: the radiographs showed a nonhomogeneous distribution of activity and the presence of aggregates of active atoms. A quantitative investigation of the absorption of polonium by the photographic emulsion as a function of pH and a comparison of this process with the adsorption of polonium on mica and on glass under similar conditions showed that the processes were undoubtedly similar and were similarly affected by pH changes. These results enable us to assert that radiographs obtained in these ways give us a picture only of the adsorption of the radio-element at the surface in contact with the solution, the aggregates of active atoms observed on the radiographs being adsorptional formations. The radiographic method, therefore, is applicable to the study of the state of radio-elements in solution only as a method for the study of adsorption in general. Thus, radiography gives results in accord with other methods, but permits us to study only adsorption phenomena at the surface of contact with the solution, and not the state of the radio-elements in the solution itself.

We consider that the results obtained by the use of various methods of investigation — 1) adsorption by glass, 2) desorption from glass, 3) electrochemical deposition on copper, 4) centrifugation, 5) ultrafiltration, 6) the use of all of the methods at various polonium concentrations, 7) the performance of three successive experiments on a given solution, 8) radiography — enables us not only to give an unequivocal answer to the question of the existence of polonium in the true colloidal state, but also to define more precisely the conditions under which polonium occurs in the various conditions.

The study of the electrochemical deposition of polonium enabled us to calculate approximate values of the solubilities of polonium compounds. These values, of course, are not very accurate, but they undoubtedly give an idea of their order of magnitude and enable us to explain the formation of colloids of the radio-elements on the basis of our usual concepts. In the formation of radio-colloids, therefore, there is nothing specific that must be associated with their radioactive nature, and all the results obtained can be applied to the usual elements.

We are applying these methods also to other elements: uranium, ruthenium, radium, etc. We consider that the systematic study that we have now begun with the aid of these methods with the object of determining the behavior of radio-elements in the low-concentration range will enable us to obtain more accurate knowledge of the properties and peculiarities in behavior of micro-quantities of these elements.

CONCENTRATION LIMITS FOR FLAME PROPAGATION IN MIXTURES OF HYDROGEN AND OXIDES OF NITROGEN

E. A. Blyumberg, A. N. Pomansky, and N. M. Emanuel

It has been long known that hydrogen is able to form explosive mixtures not only with molecular oxygen, but also with chemical compounds containing oxygen in the bound state. The system of this kind that is most frequently encountered is H_2–N_2O [1, 2, 3]. There are some investigations also on the explosive character of H_2–NO mixtures [4, 5, 6]. There are no data in the literature on the explosion of H_2–NO_2 mixtures; the displacement of the ignition field due to additions of NO_2 to hydrogen-air mixtures at low pressures has been determined [7], and rates of flame propagation and flame temperatures were recently determined for mixtures of hydrogen with NO and NO_2 [8].

The paper [1] gives data on the limits of flame propagation in mixtures of hydrogen and nitrous oxide spark-ignited in closed steel tubes 1.6 cm in diameter. Under these conditions, flame is propagated in mixtures containing not less than 5% of hydrogen (lower limit) and not more than 75% of hydrogen (upper limit). Data are given also on the narrowing of the flame-propagation field in presence of nitrogen, argon, helium, and carbon dioxide. The inhibiting effect of these additives on flame propagation in H_2–N_2O mixtures diminshes along the series He > CO_2 > N_2 > Ar. In a later investigation [2], a more accurate value was obtained for the upper limit for flame propagation in H_2 + N_2O mixtures, but the value of 83.9% given by these authors is nevertheless somewhat less than the value obtained in the present investigation. In the investigation [3] on the limits for flame propagation in hydrogen-air mixtures, the displacement of the limits when oxygen was replaced by nitrous oxide was also determined. There was some change in the lower limit, and the upper limit was lowered to a greater extent than would be expected from the amounts of oxygen in N_2O and O_2 molecules.

Although it has been known since, at the latest, 1887 [5] that hydrogen forms explosive mixtures with nitric oxide, the concentration limits for flame propagation in such mixtures were determined much later [6] (lower limit 13.5% H_2; upper limit 49.4% H_2). When the H_2–NO mixture was diluted with 10% on its volume of nitrogen, the limits for flame propagation were narrowed (lower limit 14.3%; upper limit 37.0%). These experiments were carried out in an explosion buret, diameter 1.5 cm and length 30 cm, provided with a platinum spark gap for the ignition of the mixture (the power of the spark is not given in the paper).

As will be seen from this short review, the papers cited contain mainly fragmental information on the explosive character of mixtures of hydrogen with N_2O and NO. The concentration limits given in these papers are generally low in comparison with those observed in our investigations. This fact is probably associated with the use by these authors of explosion vessels of small diameter and of insufficiently powerful sources for the ignition of the flammable mixture. Moreover, the study devoted to the effect of inert diluents on the flame-propagation field is quite inadequate. It was of interest to obtain complete information in a single investigation on the flame-propagation fields in mixtures of hydrogen with oxides of nitrogen and inert diluents.

EXPERIMENTAL

Experimental Procedure

As is well known, the values of the concentration limits for flame propagation depend on the dimensions of the vessel, the powerfulness of the ignition source, the temperature and pressure of the mixture, the presence of various additives in the mixture, the conditions of mixing the mixture, the ability of the mixture to propagate a cool flame, etc. The experimental procedure must be selected, therefore, with due regard to the effects of these factors.

The concentration limits are widened as we pass from narrow tubes to wider ones, but it is known that for vessels of diameter greater than 5 cm the dimensions cease to have any effect on the values of the limits. In the present investigation we used explosion flasks 8 cm in diameter, so that the effect of this factor on the values of the limits was excluded. With rise in temperature the concentration limits are widened. Increase in pressure greatly raises the upper limit, but has only a small effect on the lower limit. Reduction of the pressure to below atmospheric results in a closer approach of the upper and lower limits for flame propagation. In our investigation we did not examine the effects of pressure and temperature on the concentration limits; all experiments were carried out at a pressure of 750 mm and a temperature of 20° with spark ignition of the mixture.

The ability of the spark to ignite the mixture is determined not only by the composition of the mixture, but also by the characteristics of the source of ignition. At concentrations in the vicinity of the two limits a more powerful spark is necessary for the ignition of the mixture than at concentrations within the explosion range. A weak spark may not ignite a mixture which will burn when a more powerful spark is applied. Hence, in the determination of the concentration limits, it is always necessary to make sure that the spark used is sufficiently powerful. It must be pointed out that the actual energy yielded by a spark is always less than that calculated from the electrical characteristics of the system: Zeldovich and Simonov [9] showed that the efficiency of a spark is not generally more than a few percent.

In order to confirm that our spark had sufficient, or even more than sufficient, energy, we carried out experiments on the limits of flame propagation in a mixture of hydrogen and air with sparks having half and double the energy of the spark that it was proposed to use. These experiments showed that the values of the limits did not vary over this range of energy. Further confirmation of the adequacy of our spark is provided by the close agreement between our results on the limits of flame propagation in hydrogen-air mixtures and similar results obtained in the investigation [3], in which the mixtures were ignited with an open flame.

The apparatus in which flame-propagation limits were determined is shown diagrammatically in Fig. 1. The explosion flask 1, which is provided with a ground-on cap 6 for the reduction of the pressure to atmospheric and the preservation of the flask, is fixed in a wooden box 2, one side of which has been replaced by a thick sheet of Plexiglas so that visual observation of the explosion can be made. Molybdenum electrodes are fused in so as to form a gap in the center of the flask at which the spark ignition of the mixture is effected. The flask is connected through a tap to a vacuum apparatus which enables the flask to be emptied and filled. The mixture of hydrogen and nitrogen oxide was prepared directly in the explosion flask. The flask 1 was first evacuated, some hydrogen was passed in from a cylinder, and then the nitrogen oxide (N_2O and NO from gas holders; NO_2 from the tube 4). The partial pressure of each component was measured with a mercury manometer. The mixture was ignited 5-6 minutes after mixing, this period being adequate to ensure that a uniform mixture was obtained. The spark used for the ignition of the mixture was obtained from a high-tension unit, which is shown diagrammatically in Fig. 1 together with the vacuum part of the apparatus. The high tension (up to 7.5 kV) is obtained from the step-up transformer 7, the output of which is rectified by the kenotron KR-110 8 and passed to the 2-microfarad condenser 9. The cathode of the kenotron is fed from the step-down transformer 10, which has a rheostat in the primary circuit. The condenser is charged, and the operation of the switch 11 will then connect the condenser to the electrodes in the explosion flask (spark gap 2 mm), and the spark discharge of the condenser will occur. The powerfulness of the spark was varied in the experiments by varying the p.d. applied to the primary of the step-up transformer and to the kenotron, and also by varying the length of the spark gap.

The hydrogen used was the commercial gas from a cylinder. Nitrous oxide was prepared by the thermal decomposition of ammonium nitrate, and it was purified from NO and collected over saturated brine, in which N_2O is almost insoluble. Nitric oxide was prepared by the action of hydrochloric acid on sodium nitrate solution in presence of ferric chloride and was also kept in a gas holder over brine. Nitrogen dioxide was prepared from nitric oxide and oxygen. The reaction was carried out in the vacuum part of the apparatus shown in Fig. 1. Nitric oxide was mixed with excess of oxygen in the evacuated glass flasks 3, and the resulting equilibrium mixture of nitrogen dioxide and dinitrogen tetroxide ($2NO_2 \rightleftharpoons N_2O_4$) was pumped off through the trap 5, which was cooled with liquid air; all oxygen was then removed from the system. The mixture was then thawed and was kept as a liquid in the tube 4, which has a ground joint and is connected to the apparatus through a tap.

At room temperature we are dealing with the equilibrium mixture $2NO_2 \rightleftharpoons N_2O_4$ which contains an appreciable amount of N_2O_4. In preparing the mixtures, we always took the measured manometric pressures of the equilibrium mixture as our basis, but in calculating the actual amount of oxygen taking part in the reaction, we made a correction for the equilibrium between nitrogen dioxide and dinitrogen tetroxide, taking into account the vari-

ation of the equilibrium constant with temperature and pressure. Table 1 gives the result of such a calculation for our experimental conditions [T = 20°, p_{total} = 750 mm, the partial pressure of the equilibrium mixture $2NO_2 = N_2O_4$ varied from 75 mm (0.098 atm) to 675 mm (0.88 atm)].

Diagram of apparatus: 1) explosion flask; 2) wooden box with screen; 3) flasks for the preparation of NO_2; 4) tube for keeping NO_2; 5) trap for reaction products; 6) ground-on cap for reducing pressure after the explosion; 7) step-up transformer; 8) kenotron KR-110; 9) 2-microfarad condenser; 10) step-down transformer; 11) switch.

Experimental Results

Flame-propagation field for H_2—N_2O mixtures. The experimental results on the concentration limits for flame propagation in mixtures of hydrogen and nitrous oxide with and without the addition of an inert diluent (nitrogen) are presented in Fig. 2 in triangular coordinates. Concentrations are expressed as percentages, and can be determined in the usual way for any point on the diagram. The blank circles indicate explosive mixtures, and the black circles indicate mixtures in which no explosion occurred. The flame-propagation field is the area bounded by the horizontal axis and by the curve drawn so as to lie between the rings and the black circles.

It will be seen from Fig. 2 that, in absence of nitrogen, mixtures of hydrogen and nitrous oxide are explosive for a wide range of compositions: from 5.0% to 86.0% N_2O. As the mixture is diluted with nitrogen, the flame-propagation field becomes narrower, and the propagation limits continue to become closer together until, at 75% of nitrogen, flame propagation no longer occurs, irrespective of the relative amounts of hydrogen and nitrous oxide in the mixture. It should be noted that all mixtures containing less then 5% or more than 86% of hydrogen are nonexplosive, irrespective of the relative amounts of the other components (nitrogen and nitrous oxide).

In $H_2 + N_2O$ mixtures diluted with air (Fig. 3), flame propagation again does not occur in mixtures containing less than 5% hydrogen. The upper limit falls somewhat and approximates to 74% of hydrogen, i.e. to the value of the limit for a mixture of hydrogen and air. Fig. 4 shows the flame-propagation fields for mixtures of hydrogen with oxygen and nitrogen, which we determined for comparison. Comparison between Figures 2 and 4 shows that the flame-propagation field for mixtures of hydrogen and nitrous oxide is somewhat narrower than that for mixtures of hydrogen and oxygen, though the difference is not great. The lower limits do not differ appreciably, the main difference being in the upper limits.

Figure 2. Flame-propagation field for $H_2 + N_2O + N_2$: o) explosive mixtures; •) no explosion occurs (the points are distinguished in the same way in Figures 3-8).

Figure 3. Flame-propagation field in $H_2 + N_2O$ mixtures diluted with air.

Figure 4. Flame-propagation field in $H_2 + O_2 + N_2$ mixtures.

Figure 5. Flame-propagation field in $H_2 + NO + N_2$ mixtures.

Flame-propagation field for H_2—NO mixtures. In Fig. 5 the experimental results on the concentration limits of flame propagation in $H_2 + NO$ mixtures are shown in the same triangular coordinates. The minimum hydrogen concentration at which flame propagation is possible is 11.4% (lower limit), and the maximum concentration is 60% (upper limit).

Dilution with nitrogen narrows the field of explosive compositions, and already at 40% of nitrogen no flame propagation can be observed. Here, therefore, we have an appreciably narrower flame-propagation field than in the case of mixtures of hydrogen with nitrous oxide and oxygen.

Flame-propagation field for H_2—NO_2 mixtures. The experimental results on the concentration limits for flame propagation in $H_2 + NO_2$ mixtures are given in Fig. 6. From right to left along the horizontal axis of this graph, the percentage content of the equilibrium mixture $2NO_2 \rightleftharpoons N_2O_4$ in the final mixture is plotted. By the use of Table 1 it is easy to determine the N_2O_4/NO_2 ratio in the various mixtures with hydrogen. In $H_2 + (2NO_2 \rightleftharpoons N_2O_4)$ mixtures the flame-propagation field is displaced toward higher hydrogen concentrations, the lower concentration limit being 25% of hydrogen, which is considerably higher than for other nitrogen oxides.

Figure 6. Flame-propagation field in $H_2 + (2NO_2 \rightleftharpoons N_2O_4) + N_2$ mixtures.

The values of the concentration limits for flame propagation in mixtures of hydrogen with nitrogen oxides, air, and oxygen, as determined in the present investigation, are collected in Table 2. In the last column of Table 2 we give the amounts of nitrogen that must be present so that flame propagation will not occur in the mixtures, irrespective of the relative amounts of hydrogen and oxidant. A comparison of our results enables us to conclude that hydrogen-oxygen mixtures are the most favorable for flame propagation, and then follow mixtures of hydrogen with N_2O, NO_2, and NO. The amount of nitrogen necessary for the complete passivation of the mixture falls in the same order.

We studied also flame propagation in mixtures in which the oxidizing agent was not an individual nitrogen oxide, but a mixture of oxides. In this series of experiments the ternary mixtures $H_2 + NO + N_2O$ and $H_2 + NO + NO_2$ were studied, and the content of each individual nitrogen oxide was varied from zero to the concentration corresponding to the lower hydrogen concentration limit for flame propagation in a mixture of hydrogen with this oxide. In the case of mixtures with NO_2, the equilibrium mixture $2NO_2 \rightleftharpoons N_2O_4$ was taken, as before. The results of these experiments are shown in the form of triangular graphs in Figures 7 and 8.

TABLE 1

Compositions of Mixtures of Hydrogen with N_2O_4 and NO_2 for Various Partial Pressures of the Equilibrium Mixture at 20°

Content of equilibrium mixture $2NO_2 \rightleftharpoons N_2O_4$ in final mixture (%)	Partial pressure of equilibrium mixture $2NO_2 \rightleftharpoons N_2O_4$ (atm)	Degree of dissociation (%)	Composition of mixture (%)		
			NO_2	N_2O_4	H_2
10.0	0.098	44.9	6.2	3.8	90.0
20.0	0.200	33.4	10.0	10.0	80.0
30.0	0.294	27.8	12.4	17.6	70.0
40.0	0.39	24.3	15.7	24.3	60.0
50.0	0.49	21.9	17.9	32.1	50.0
60.0	0.59	20.0	20.0	40.0	40.0
70.0	0.69	18.7	21.9	48.1	30.0
80.0	0.78	17.5	23.8	56.2	20.0
90.0	0.88	16.5	25.5	64.5	10.0

Note. The expression for the equilibrium constant is taken from [10]:

$$\log K = -\frac{2692}{T} + 1.75 \log T + 0.00484\,T - 7.144 \cdot 10^{-6} \cdot T^2 + 3.062$$

$$\alpha = \sqrt{\frac{1}{1+\frac{4P}{K}}} \qquad [NO_2] = \frac{2\alpha}{1+\alpha}$$

TABLE 2

Concentration Limits for Flame Propagation

Mixture	Amount of H_2 in limiting mixture (%)		Amount of nitrogen necessary for complete passivation of the mixture
	Lower limit	Upper limit	
H_2+N_2O	5.0	86.0	75.0
H_2+NO	11.4	60.0	40.0
$H_2+(2NO_2 \rightleftarrows N_2O_4)$	24.0	87.6	60.0
H_2+ air	4.0	74.0	62.0
H_2+O_2	4.0	96.0	82.0

Figure 7. Flame-propagation field for $H_2 + NO + N_2O$ mixtures.

Figure 8. Flame-propagation field for $H_2 + NO + NO_2$ mixtures.

As will be seen from Fig. 7, $H_2 + NO + N_2O$ mixtures are explosive over a very wide field of compositions. As in the case of nitrous oxide, absence of flame propagation is found only in mixtures containing less than 5% and more than 86% of hydrogen. When additions of N_2O are made to mixtures of hydrogen and NO, the flame-propagation field is greatly extended, and already at 15% N_2O the mixture behaves as $H_2 + N_2O$, rather than H_2 + NO.

The flame-propagation field for $H_2 + NO + NO_2$ mixtures is shown in Fig. 8. The overall effect of the introduction of NO_2 into an $H_2 + NO$ mixture is to extend the flame-propagation field fairly considerably; although the lower limit is raised as the NO_2 content of the mixture increases, this is more than counterbalanced by the rise in the upper concentration limit.

If we consider $H_2 + N_2O$ and $H_2 + NO_2$ as our basic mixtures, then on the basis of Figures 7 and 8 we may state that dilution of these mixtures with nitric oxide results in a narrowing of the flame-propagation field in accordance with the closer concentration limits for the $H_2 + NO$ mixtures.

SUMMARY

The concentration limits were determined for flame propagation in mixtures of hydrogen with nitrogen oxides (N_2O, NO_2, NO) and an inert diluent (nitrogen), the components being taken in various proportions.

PHASE DIAGRAM OF THE BINARY SYSTEM TITANIUM-ALUMINUM

I. I. Kornilov, E. N. Pylaeva, and M. A. Volkova

The phase diagram of the system titanium-aluminum has been investigated by various workers [1-4]. In early investigations [1] alloys of the binary system containing 0-37% of titanium were studied, and there were indications of the existence of the compound $TiAl_3$ (62.7% Al) in the system. The compound $TiAl_3$ melts incongruently and forms a eutectic with aluminum at 0.03% Ti. In later investigations [2-4] titanium-rich alloys of the system were studied. It was shown that, apart from the compound $TiAl_3$, there is an intermediate γ-phase based on the compound TiAl (36.02% Al). This phase is formed by peritectic reaction and has a tetragonal face-centered lattice. In the phase diagrams given in the papers published, liquidus curves and peritectic-equilibrium curves are represented by broken lines.

EXPERIMENTAL

Preparation of Alloys. In the present investigation alloys of the binary system titanium-aluminum containing up to 70% Al were studied by the following methods: thermal analysis, microstructure determination, hardness determination, x-ray structure analysis, heat-stability determination. The alloys were prepared from titanium of 99.5% purity and aluminum of 99.99% purity. Alloys containing up to 37.5% Al were prepared by powder-metallurgy methods, and were then melted in a vacuum induction furnace. The remaining alloys, which contained up to 70% Al, were prepared by the fusion of the pure metals. The change in weight of the samples was checked by weighing them before and after fusion; it was generally less than 0.5% of the weight of the sample.

Thermal Analysis. In studying the fusion diagram with a Kurnakov pyrometer, we recorded cooling curves for alloys containing 20-70% Al. The weight of each sample was 30-40 g. The fusion was carried out in an induction furnace in a current of pure argon. Titanium-rich alloys were melted in thorium dioxide crucibles, and the remainder in corundum crucibles coated with zirconium dioxide. Temperatures were measured with a thermocouple of platinum and platinum-rhodium. For the determination of the crystallization temperatures of alloys containing 97.5%, 95%, and 90% of titanium, a tantalum-tungsten thermocouple was used. The thermal-analysis results are given in Table 1. Figure 1 shows the phase diagram of the binary system titanium-aluminum, constructed on the basis of the experimental results. Three branches of the liquidus curve are shown; these correspond respectively to crystallization of the β solid solution based on titanium, the γ solid solution based on the compound TiAl, and the compound $TiAl_3$. Liquidus branches intersect at temperatures of 1510° and 1400°, corresponding to the peritectic equilibria:

1. β + melt $\rightleftharpoons$ γ at 1510°
2. γ + melt $\rightleftharpoons$ $TiAl_3$ at 1400°

At 600° on the aluminum-rich side of the system eutectic equilibrium occurs with a eutectic point corresponding to 0.03% Ti [1]. Aluminum raises the temperature for the polymorphous transformation of titanium. In order to determine the temperature for the transformation of the α-modification into the β-modification, a differential recording was made with a Kurnakov pyrometer for pure titanium and an alloy containing 2.5% Al in an atmosphere of argon. The following temperatures were found for the beginning of the conversion of the α-phase into the β-phase: for pure titanium 870°, and for the 2.5% Al alloy 930° – values that are in accord with data in the literature.

TABLE 1

Results of Thermal Analysis

Figure 1. Phase diagram of the binary system titanium-aluminum (fusion diagram plotted from the authors' data).

Microstructure. Microstructure investigations were carried out on cast samples and on samples quenched from various temperatures. The alloys were sealed in silica ampoules under vacuum and subjected to the following thermal treatment:

1) Homogenizational annealing at 1200° for 48 hours and at 1100° for 500 hours, followed by slow cooling in the furnace; or 2) quenching in water after a period of 48 hours at 1200°, or 100 hours at 1000°, or of 200 hours at 800°, or of 330 hours at 700°.

In the thermal treatment, these long periods at constant temperature were essential because a state of equilibrium is attained very slowly in these alloys. Sections were etched with a reagent of the following composition: 1 part of hydrofluoric acid, 1 part of glycerol, and 1 part of nitric acid. Samples having the structure of the α solid solution were etched with sulfuric acid (1 : 1) heated to about 90°. The microstructural analysis of the alloys confirms the thermal-analysis results.

In systems ranging from pure titanium to an alloy containing 37.5% Al, the phase that first crystallizes from the melt is the β-phase, a solid solution based on β-titanium and having a body-centered cubic lattice. The microstructure of alloys with primary separation of the β-phase in the cast state has the form of long thin plates (Fig. 2).

Alloys quenched from 1200° are shown in Figures 3 and 4. The sample containing 7.5% Al has a disintegrated β-phase, this condition being the result of the instability of this phase under the conditions of quenching. The structure of an alloy in the (α + β) region is shown in Fig. 3 (15% Al): the α-phase is present as light-colored grains, and the disintegrated β-phase as fine needle-shaped segregations. Alloys containing 17.5-25% Al and quenched from 1200° have the polyhedral structure of the α solid solution (Fig. 4). Samples of alloys of the binary system titanium-aluminum quenched from 800° and containing 0-20% Al have the structure of the α solid solution (Fig. 5). An alloy containing 22.5% Al and quenched from 800° shows disintegrated grains of α solid solution and the separation of the γ-phase as a result of the reduction of the solubility of aluminum in titanium with lowering of temperature (Fig. 6). At 1510° a peritectic reaction occurs in the system between crystals of β-phase containing 29.5% Al and melt containing 37.5% Al with formation of the γ solid solution based on the compound TiAl.

Fig. 7 shows the structure of the cast alloy containing 30% Al; it consists of primary crystals of disintegrated β solid solution, which are surrounded by γ-phase in the form of streaks. The 35% Al alloy contains residues of undissolved α'-phase and also γ-phase that has separated as a result of the peritectic reaction; this has the form of grains, which appear darkly colored in the photograph (Fig. 8). At a temperature of about 1300° (determined by the method of quenching samples from temperatures above and below this), a peritectoid reaction occurs in the system. Peritectoid transformation is undergone by alloys containing 26-35% Al. In the case of the 28% Al alloy we may follow the course of the peritectoid reaction. Fig. 9 shows a cast sample of the 28% Al alloy from the (β + γ) region, and Fig. 10 shows the same sample quenched from 800°. It can be seen from Fig. 10 that the alloy underwent transformation while in the solid state; the (α + γ) phase is present.

A similar structure is possessed by all alloys containing 27.5-35% Al and quenched from temperatures below the temperature of the peritectoid transformation. Alloys in the γ-phase region have a characteristic microstructure, which is shown in Fig. 11 (it consists of grains of γ solid solution). In the range of 60-65% Al a second peritectic reaction occurs at 1400° between the melt and solid γ-phase with formation of the compound $TiAl_3$. The microstructure of an alloy from the two-phase region (γ + $TiAl_3$) is shown in Fig. 12; it consists of grains of γ solid solution and needle-shaped segregations of the compound $TiAl_3$ (the latter is brittle in the pure state). Fig. 13 shows the microstructure of a sample containing 70% Al: the eutectic and the primary plates of the compound $TiAl_3$ can be seen.

Hardness of the Binary Alloys. Samples of alloys submitted to various thermal treatments were tested for hardness in a Vickers apparatus by means of a diamond pyramid under a load of 10 kg. Alloys containing 60% or more of aluminum were tested for hardness in the cast state. The results obtained are given in Table 2 and represented graphically in Fig. 14. The curves show that, as the solubility limit of aluminum in titanium is approached, the hardness of the alloy rapidly increases. The increase in hardness continues up to the (α + γ) two-phase boundary. Beyond the solubility limit of the solid solution the hardness diminishes, and in the region of the compound TiAl it has a minimum value. In the single-phase region of the γ solid solution, the hardness varies according to a curve that is turned with its convex side upwards; in the two-phase region (γ + $TiAl_3$) it rises slightly up to the composition of the compound $TiAl_3$. From the composition corresponding to the compound $TiAl_3$ the hardness falls sharply down to the value for pure aluminum. The hardness curve in the region of alloy compositions that have been studied inadequately is represented by a broken line.

X-Ray Structure Investigation. The structures of the alloys were investigated by the x-ray method in the Department of Aviation Materials of the Zhukovsky Air Force Engineering Academy in collaboration with A. Ya. Snetkov. The powders for investigation were obtained by grinding samples that had been given prolonged annealing at 800°. The experimental samples were prepared from the powders by cold hammering and further annealing in sealed silica tubes at 800° for 24 hours. The measurements were made in a Debye camera (d = 57.4 mm), and also in a Sachs camera for reflection pictures. Iron radiation was used in the Debye camera, and from the photographs obtained the phase composition and type of crystal structure were determined by the asymmetry method. Copper radiation was used in the Sachs camera, and from the photographs obtained the parameters a and c of the lattice of the α solid solution were determined.

Figure 14. Graph showing the relation between Vickers hardness of alloys of the binary system titanium-aluminum and composition: •) queriched from 800°; x) quenched from 1200°; o) cast.

x-Ray photographs of alloys containing 0-28% Al taken in the Debye camera had one system of lines corresponding to a close-packed hexagonal lattice (phase α). The x-ray photograph of the 28% Al alloy showed the existence of two phases, one having a hexagonal lattice (α) with close packing, and the other a tetragonal face-centered lattice (γ).

x-Ray photographs of alloys containing 32.5-50% Al showed lines corresponding solely to one tetragonal lattice (phase γ). A summary of lattice-parameter measurements for the α-phase is given in Table 3.

Figure 15 gives a graphical representation of the effect of the aluminum content on the parameters of the close-packed hexagonal lattice. As the aluminum content of the alloy increases, the lattice constants a and c of the α solid solution diminish greatly and the ratio c/a increases (Fig. 15). When the saturation limit of the solid solution is reached, the lattice parameters a and c remain constant. Near the solubility limit the curves for the relation between the lattice parameters of the α solid solution and the aluminum concentration become less steep, but their slopes are greater than those found in the investigation of Bumps, Kessler, and Hansen [3]. Unlike these authors, we determined the limiting aluminum concentration in the α aluminum-titanium solid solution by the x-ray method (21.6% Al at 800°).

Investigation of Heat Stability. We are the first to investigate the heat stability of alloys of the titanium-aluminum system; we used the centrifugal method [5] at 550° under a stress of 15 kg/sq.mm. The aluminum contents of the alloys investigated varied from zero to 27.5%. The deformation time at 550° was 250 hours, and then 50 hours was given at 600° under the same stress. The bending deformations of the binary alloys under the action of a centrifugal force are given as a function of aluminum content in Table 4 and Figures 16 and 17. As a measure of heat stability we took the linear bending displacement in millimeters, considered as a function of time, and also the time for the attainment of a given linear displacement (2 and 4 mm) as a function of the aluminum content of the alloy. Investigation showed that, under these test conditions, the heat stability of the alloys increases as the aluminum content of the α-titanium solid solution increases. It is characteristic here that the heat-stability of the alloys increases up to 20-21% Al, i.e. up to the aluminum concentration corresponding to the solubility

Figure 15. The effect of aluminum on the parameters of the hexagonal lattice of the α-phase in the system Ti—Al.

Figure 16. Heat-stability of the binary system titanium-aluminum as a function of the aluminum content (0, 5, 7.5%) at σ = 15 kg/sq.mm.

Figure 17. Heat-stability of the binary system titanium-aluminum as a function of the aluminum content (0, 10, 20, 12.5%) at σ = 15 kg/sq.mm.

Figure 18. Phase diagram and composition-property diagrams of the system titanium-aluminum.

limit in α-titanium. Alloys of the two-phase region (α + γ) containing 22.5% and 27.5% Al were found to be less heat-stable than alloys containing 15-21% Al. Figure 18 shows the solubility diagram for aluminum in titanium in juxtaposition with diagrams for crystalline-lattice parameters and for time of attainment of bending displacements of 2 mm and 4 mm in the heat-stability test.

It will be seen from Fig. 18 that, for moderate test temperatures, there is a definite relationship, which has been observed in some other metal systems [6-10], between heat-stability, chemical composition, and structure of alloys of the binary system titanium-aluminum. Alloys lying in the region of solid solutions at the limit of saturation have higher heat-stability than pure titanium or unsaturated solid solutions based on tita-

nium. Maximum heat stability is possessed by alloys having compositions in the vicinity of the saturation boundary of the solid solutions.

SUMMARY

1. The phase diagram of the binary system Ti—Al was studied by the following methods: thermal analysis, microstructure analysis, x-ray structure analysis, hardness determination, and heat-stability determination.

2. The following transformations occur in the Ti—Al system:

a) peritectic reaction β + melt ⇌ γ at 1520° between 29.5% and 37.5% Al; b) peritectic reaction γ + melt ⇌ $TiAl_3$ at 1400° between 60% and 64% Al; c) peritectoid reaction β + γ ⇌ α at 1300° between 28% and 35% Al; d) temperature for the conversion of α-phase into β-phase rises from 870° at 0% Al to 1300° at 27.5% Al.

3. At 1200° the solubility of aluminum in titanium is 26%, and at 800° it is 21.6%.

4. Aluminum reduces the parameters of the lattice of the α solid solution: a - from 2.95 to 2.881 kX; c - from 4.716 to 4.646 kX; and the ratio c/a rises almost linearly from 1.598 to 1.613.

5. The hardness of titanium-aluminum alloys increases as the amount of aluminum dissolved in the α-phase of titanium increases. The hardness of alloys lying in the γ-phase region is considerably lower than the hardness of alloys lying in the region of α solid solution.

6. Investigation by the centrifugal method of the heat stability of alloys of the binary system at 550° and σ = 15 kg/sq.mm showed that the heat stability of alloys depends on their compositions and structures.

7. As the concentration of aluminum in the α-titanium solid solution increases, the heat stability of the alloy increases.

8. Maximum heat stability is possessed by alloys in the vicinity of the limit of solubility of aluminum in titanium. Alloys of the (α + γ) two-phase region have low heat stability, as compared with alloys in the region of solid solutions.

EFFECT OF TEMPERATURE ON THE DIFFUSION CURRENT AND THE THICKNESS OF THE DIFFUSION LAYER

V. V. Gerasimov and I. L. Rozenfeld

Diffusion is the controlling factor in many corrosion processes associated with depolarization by oxygen. Several studies of the mechanism of the reduction of oxygen have appeared [1-4], but the effect of temperature has not been investigated. It was considered to be of interest to investigate the temperature dependence of the limiting diffusion current and the thickness of the diffusion layer. The theory of the transfer of a substance in a stirred solution, as developed by Levich [5], enables us to calculate the thickness of the diffusion layer (δ) and the limiting diffusion current (I_d).

$$\delta = 1{,}63 \cdot D^{\frac{1}{3}} \nu^{\frac{1}{6}} \omega^{-\frac{1}{2}}; \quad (1)$$

$$I_d = 0{,}617\, nFD^{\frac{2}{3}} \nu^{-\frac{1}{6}} \omega^{\frac{1}{2}} c, \quad (2)$$

in which D is the diffusion coefficient, ν is the kinematic viscosity of the solution, ω is angular velocity, c is the concentration of the diffusing substance, n is the number of electrons taking part in the reaction, and F is the faraday number.

In the present investigation we studied the effect of temperature on δ and I_d. Measurements were carried out with a rotating copper electrode in a solution containing $FeCl_3$ (0.005 N) and HCl (0.1 N) and with a rotating amalgamated copper electrode in N NaCl. In all the experiments the rate of stirring was 1500 r.p.m. The measurements were carried out by the method developed by Kabanov and Siver [6].

EXPERIMENTAL

In the region of oxygen depolarization, the cathodic polarization curves obtained at an amalgamated copper electrode in N NaCl (Fig. 1) have two inflections. The first inflection corresponds to the reaction of hydrogen peroxide formation:

$$O_2 + 2H_2O + 2e \longrightarrow H_2O_2 + 2OH^-; \quad (3)$$

and the second inflection corresponds to the ionization of oxygen to hydroxyl ions:

$$O_2 + 2H_2O + 4e \longrightarrow 4OH^-. \quad (4)$$

The potentials at which the inflections corresponding to Reactions (3) and (4) occur on the polarization curves are in close accord with the values obtained by Tomashov [2] and Kolthoff and Miller [7].

Tables 1 and 2 give values of I_d and δ, as calculated from Formulas (1) and (2) and as determined experimentally. Values of ν were taken from tables [8], and the oxygen concentration from data in the literature [8, 9]. The diffusion coefficient of ferric chloride at 20° was calculated from the experimentally determined value of I_d by means of Equation 2; for other temperatures it was calculated from Torre's data [10]. The diffusion coefficient of oxygen was calculated from the equation:

$$D = \frac{kT}{6\pi r}, \tag{5}$$

in which k is Boltzmann's constant, T is the absolute temperature, and r is the radius of the diffusing molecule. The value of r was determined from the value of D_{O_2} at 18° by means of Equation 5. The value of D_{O_2} was obtained by extrapolation of Landolt's data [3]. The experimental values of δ were obtained with the aid of the equation:

$$\delta_{expt} = \frac{nFCD}{I_{d_{expt}}}. \tag{6}$$

TABLE 1

Effect of Temperature on the Thickness of the Diffusion Layer at a Rotating Copper Electrode (1500 r.p.m.) in a Solution of $FeCl_3$ (0.005 N) and HCl (0.1 N)

Temperature (°C)	D (x 10^{-5} cm^2/sec)	ν (x 10^{-2} poise)	Calculated values		Experimental values	
			I_d (ma/sq.cm)	δ (x 10^{-3} cm)	I_d (ma/sq.cm)	δ (x 10^{-3} cm)
20	0.51	1.05	6.8	1.06	6.80	1.06
40	0.72	0.656	9.9	1.08	10.0	1.07

80	1.35	0.356	16.7	1.18	17.0	1.16
30	0.623					

Figure 1. Cathodic polarization curves for a rotating amalgamated electrode in N NaCl (1500 r.p.m.): 1) 95°; 2) 80°; 3) 50°; 4) 20°.

It follows from Tables 1 and 2 that the calculated values of δ and I_d are in close agreement with the experimental values. In solutions containing $FeCl_3$ (0.005 N) and HCl (0.1 N), the depolarizer concentration is constant and I_d increases almost linearly with temperature. In N NaCl the oxygen concentration falls with rise in temperature and I_d passes through a maximum. The thickness of the diffusion layer increases with temperature. Analysis of Equation 1 shows that δ is more greatly dependent on the diffusion coefficient than on the viscosity (the power index of D is 1/3, whereas that of viscosity is 1/6). The diffusion coefficient increases with rise in temperature, and, for constant stirring conditions, the thickness of the diffusion layer also increases:

$$\frac{\delta_{80}}{\delta_{20}} = \frac{1.62\omega^{-\frac{1}{2}} D_{80}^{\frac{1}{3}} \nu_{80}^{\frac{1}{6}}}{1.62\omega^{-\frac{1}{2}} D_{20}^{\frac{1}{3}} \nu_{20}^{\frac{1}{6}}} =$$

$$= \left(\frac{D_{80}}{D_{20}}\right)^{\frac{1}{3}} \left(\frac{\nu_{80}}{\nu_{20}}\right)^{\frac{1}{6}} = 1.4 \cdot 0.79 = 1.1. \tag{7}$$

The ratio of the experimentally determined values of δ_{80} and δ_{20} is 1.095.

TABLE 3

Values of n at Different Temperatures (1500 r.p.m.)

Temperature (°C)	Copper: I_d (ma/sq.cm)	Copper: n	Iron: I_d (ma/sq.cm)	Iron: n
20	0.8	3.15	0.64	2.53
50	0.89	3.17	0.77	2.65
80	0.74	2.45	0.65	2.15
95	0.5	2.23	0.50	2.23

Investigation of the kinetics of the cathodic process shows that at rotating copper and iron electrodes in N NaCl the values of I_d (Table 3) are lower at all temperatures than the values calculated and obtained experimentally at an amalgamated electrode for the reduction of oxygen according to Equation 4 (n = 4), and are greater than for values calculated for Equation 3; this can be seen from an examination of Table 2. This indicates that, under the given conditions, reduction of oxygen at copper and iron goes partly according to Equation 3, with formation of hydrogen peroxide, and partly according to Equation 4. A similar phenomenon was noted by Kabanov and Siver [6].

The view that the reduction in the value of the limiting diffusion current at copper and iron in N NaCl (as compared with I_d for n = 4) is the result of the screening of part of the surface by oxide films must be rejected on account of the following considerations. The equilibrium potential for the cathodic reduction reactions of Cu_2O, CuO, and $Cu(OH)_2$ in a neutral medium is 0.053-0.19 v [2]. It follows from Fig. 2 that a copper electrode is polarized to potentials that are more negative then 0.1 v. At these potentials the oxides and hydroxides of copper must be reduced. The coincidence between the forward and reverse courses of the cathodic polarization curves for copper (Fig. 2) confirms this view. The behavior of iron is similar (Fig. 3). Tomashov [2] also has noted that at potentials of from −1.0 to −1.2 v oxides on copper and iron are reduced.

At present no theory exists that will enable us to calculate δ in an unstirred electrolyte. Table 4 gives the values of δ calculated by means of Equation 6 from values of I_d measured experimentally at platinum in a solution containing $FeCl_3$ (0.0047 N) and HCl (0.1 N) and at copper and iron in N NaCl in an open system and in a closed system (in which the oxygen concentration does not change with temperature). Table 4 shows that, as the temperature rises, δ diminishes from, on the average, 0.05 cm at 20° to 0.025 cm at 95°. It follows from Fig. 4 that, as a first approximation, we can assume a linear relationship between log δ and 1/T:

$$\log \delta = 1.11 + \frac{476}{T}, \quad (8)$$

Figure 2. Cathodic polarization curves for copper in N NaCl at 1500 r.p.m.: o) forward course; x) reverse course.

Figure 3. Cathodic polarization curves for iron in N NaCl at 1500 r.p.m.: o) forward course; x) reverse course.

Figure 4. Temperature dependence of the thickness of the diffusion layer in unstirred electrolytes, from Equation 8 and from experimental data: o) copper in N NaCl (open system); Δ) copper in N NaCl (closed system); x) iron in NaCl (open system).

As the temperature rises in an unstirred electrolyte, the value of δ is affected by two opposing factors: 1) as a result of changes in the diffusion coefficient and viscosity δ tends to increase; 2) as a result of the increased mixing resulting from convection δ tends to diminish. The second is the deciding factor. The extent of convectional mixing at a given temperature is not strictly constant and, in each individual case, will depend on the conditions of thermostating, the form and dimensions of the vessel and sample, the rate at which the electrolyte evaporates, etc. As a result, the values of δ are not strictly reproducible, and there are therefore considerable discrepancies between the results of different investigators [2, 11-13].

SUMMARY

1. An investigation was made of the effect of temperature on the limiting diffusion current and the thickness of the diffusion layer at copper, iron, and amalgamated copper electrodes in stirred and unstirred solutions of sodium chloride and ferric chloride.

2. In unstirred electrolytes at constant oxygen concentration the limiting diffusion current increases with temperature. When the concentration of oxygen changes as a result of reduction of solubility with rise in temperature, the limiting current attains its maximum value at 80° and then falls.

TABLE 4

Effect of Temperature on the Thickness of the Diffusion Layer in Unstirred Electrolytes

Temperature (°C)	Platinum in $FeCl_3$ (0.0047 N) + HCl (0.1 N)		N NaCl							
			Copper				Iron			
			Open System		Closed System		Open System		Closed System	
	I_d (ma/cm²)	δ (cm)	I_d (ma/cm²)	δ (cm)	I_d (ma/cm²)	δ (cm)	I_d (ma/cm²)	δ (cm)	I_d (ma/cm²)	δ (cm)
20	0,145	0,047	0,023	0,056	0,023	0,056	0,02	0,052	0,02	0,052
30	0,209	0,042								
40	0,275	0,0365								
50	0,35	0,034	0,040	0,042	0,055	0,046	0,035	0,041	0,045	0,048
80	0,61	0,028	0,055	0,028	0,105	0,029	0,048	0,028	0,081	0,036
95			0,043	0,0256	0,145	0,026	0,042	0,0256	0,110	0,033

3. In a stirred electrolyte the thickness of the diffusion layer increases with rise in temperature. In unstirred electrolytes δ diminishes with rise in temperature as a result of increased convectional mixing.

4. At iron and copper in N NaCl oxygen is reduced partly to hydrogen peroxide and partly to hydroxyl ions.

EFFECT OF STEAM AND COMPRESSION TREATMENTS ON THE MACROSTRUCTURE AND CATALYTIC ACTIVITY OF ALUMINA

I. E. Neimark, L. Kh. Freidlin, A. I. Rastrenenko, and N. V. Borunova

Difficultly reducible metal oxides are often used as catalysts and also as carriers of catalysts, their function then being to increase the catalyst surface and preserve the catalyst from recrystallization at high temperatures. The causes of the aging of metal oxides have not yet received adequate study. The question of the effect of steam on aging processes in metal oxides is particularly deserving of attention, for water is liberated when the hydroxide of a metal is converted into the oxide, and it is very frequently found as a foreign substance in chemical reactions.

Ormont [1] states that aging processes, which he denotes conventionally by $[S] \rightarrow [S]_n$, proceed with reduction in free energy in all temperature ranges, and foreign substances may either accelerate or retard aging. Maslyansky and Shenderovich [2] found that reduction under pressure of molybdenum trioxide with hydrogen containing 2% of water vapor gave completely inactive brown dioxide. Bohm [3], Fricke and Severin [4], and Weitbrecht and Fricke [5] carried out x-ray and electron microscope studies of changes in the structure of alumina and clays resulting from the action of steam.

In the present investigation the effect of steam on the macrostructure of alumina was studied by adsorption and catalysis methods. The results of this study show that treatment of alumina with steam at 350° results in far-reaching changes in its macrostructure. It is probable that in the course of this treatment the micellar aggregates forming the skeleton of the gel become coarser, the fine pores disappear, and the predominant radius of the intermediate pores increases. It was found that, after the steam treatment, the specific surface of the alumina was reduced from 355 to 125 sq.m/g. In absence of steam, a reduction in the specific surface of alumina of this magnitude is attained only by ignition at temperatures of about 1000° [6]. It was found that, at the same time, there was a reduction in the catalytic activity of the alumina in dehydration reactions. It is probable that the deactivation of alumina is due to its recrystallization in presence of steam at high temperatures and pressures.

It is important to note, therefore, that in processes carried out under pressure in presence of steam the structures of oxide catalysts and carriers may undergo considerable change. Treatment with steam may serve as a method for controlling the porosity properties of oxide catalysts and carriers.

Recrystallized coarse-pore oxide catalysts will probably be of low activity in reactions at relatively low temperatures, but they may be more active in reactions at high temperatures, the rates of which are often limited by diffusion processes. It is natural to suppose that the low specific surface of natural silicates, as compared with artificially prepared silicates, is to be associated with prolonged periods in contact with steam under the pressures existing in rocks.

We also studied the effect of compression at 20,000 atm on the macrostructure of alumina. The results of this study indicate that compression destroys the intermediate pores of alumina and reduces its specific catalytic activity.

Figure 1. Sorption isotherms for methyl alcohol vapor on alumina samples:
1) Untreated original sample; 2) sample treated with steam; 3) sample compressed at 20,000 atm.
The lowest curve is the benzene isotherm for the sample treated with steam. Desorption points are denoted by short lines.

Figure 2. Curves for the distribution of the volume of intermediate pores of alumina samples with respect to effective pore radius:
1) Untreated original sample; 2) sample treated with steam; 3) sample compressed at 20,000 atm.

EXPERIMENTAL

Change in the Macrostructure of Alumina During Treatment with Steam

Alumina powder was heated at 350° in steam at 100 atm in an autoclave for five hours, and it was then formed into 3 x 3 mm grains. In order to establish the structural characteristics of the treated and untreated alumina samples, determinations were made of their apparent densities, their static activities with respect to benzene and methyl alcohol, and their sorption and desorption isotherms for benzene and methyl alcohol vapors, which were determined with the aid of a quartz spring balance in a vacuum apparatus.

Figure 1 shows isotherms for the sorption and desorption of methyl alcohol vapor on samples of alumina, namely, a sample that was not treated with steam (1) and a sample that was treated with steam (2); for the second sample the benzene isotherm is also shown. Adsorption is expressed in millimoles per gram. Fig. 2 shows the calculated curves for the distribution of volume of pores with respect to effective pore radius.

The table gives structural characteristics of the alumina samples investigated, namely, apparent density δ, total volume of pores V_{Σ}, calculated from the difference between the apparent and true densities, volume V_s of liquid benzene and methyl alcohol sorbed from the saturated vapors, and values of the radii corresponding to the maxima on the curves for the distribution of the volume of pores with respect to effective pore radius. The specific surface was calculated from the adsorption isotherm expressed in the linear coordinates of the BET (Brunauer, Emmett, and Teller) equation and also from the value of the adsorption at $p/p_s = 0.1$ by Kiselev's method. The specific surface values given in the table have been averaged; it is these values that were used in the calculations.

TABLE

Structural Characteristics of Alumina Samples (True Density = 3.02 g/cc)

Sample	Apparent Density δ (g/cc)	Total pore Volume V_Σ (cc/g)	Sorption from saturated vapors at 20° V_s (cc/g)		Specific surface (sq.m/g)	Predominant radius or intermediate pores r(A)
			for CH_3OH	for C_6H_6		
1-original, untreated	0.89	0.79	0.50	0.54	355	30
2-treated with steam	0.91	0.77	0.42	0.41	125	90
3-compressed at 20,000 atm	2.20	0.12	0.12	0.12	280	10

It will be seen from the table and figures that the steam treatment brought about a great change in the structure of the alumina: the specific surface was reduced almost to one-third of its original value, and the predominant pore radius increased from 30 to 90 A. On the original sample (Isotherm 1) sorption proceeded both by adsorption in micropores of small radius (less than 10 A), and also by capillary condensation in intermediate pores at comparatively high relative pressures; on the steam-treated sample (Isotherm 2) absorption of methyl alcohol vapor proceeded mainly by capillary condensation (pores for which $\bar{r}$ was about 90 A).

Variation of the Acitivity of Alumina in the Dehydration of Formic Acid

A study was made of the activity of alumina for the dehydration of 85% formic acid passed at a space velocity of 1.5 $hour^{-1}$. The degree of conversion of the acid was determined from the yield of gas from 1 ml of acid. It will be seen from Fig. 3 that steam treatment of the alumina greatly reduced its activity. The reaction temperature had to be raised to almost 100° in order to effect the same degree of decomposition as that obtained over an untreated sample. This lowering of activity is in accord with the great reduction in the specific surface of the alumina brought about by steam treatment.

Figure 4 gives the specific catalytic activities of samples of alumina for this reaction, as calculated for 1 sq. m of surface. This figure shows that their specific activities differ insignificantly below 300°. Above 300°, the activity of the untreated sample remains almost unchanged, but that of the steam-treated sample rises sharply. It is clear that these differences in behavior between the two samples of alumina are associated with difference in macrostructure. Under the action of steam the predominant radius of intermediate pores was tripled, so that the surface of the sample became more accessible and more completely utilized in the reaction.

Variation of the Activity of Alumina in the Dehydration of Ethyl and Isopropyl Alcohols

In presence of the alumina that was not treated with steam, ethyl alcohol was already dehydrated at a measurable rate at 270°. At 310° 93.3% conversion was attained (space velocity 0.12 $hour^{-1}$). When ethyl alcohol was passed over a sample of the same alumina that had been pretreated with steam, no dehydration occurred, even at 400-425°. Steam treatment of the alumina reduced its activity also for the dehydration of isopropyl alcohol (Fig. 5).

Figure 3. Catalytic decomposition of formic acid over samples of alumina: 1) Original; 2) pretreated with steam; 3) compressed at 20,000 atm.

Figure 4. Catalytic activity of alumina samples in the decomposition of formic acid, calculated for 1 sq. m of surface: 1) Original sample; 2) sample pretreated with steam; 3) sample compressed at 20,000 atm.

Figure 5. Catalytic dehydration of isopropyl alcohol in presence of samples of alumina: 1) Untreated; 2) pretreated with steam.

Effect of Compression on the Macrostructure and Catalytic Activity of Alumina

Alumina was compressed at 20,000 atm in the special pressure multiplier described previously [7]. The structural characteristics of the compressed sample are given in the table and represented in Figures 1 and 2 (Curves 3). It will be seen from the table and Figures 1 and 2 that, in the compression process, the apparent density of the alumina was increased by a factor of almost 2.5 and the volume of intermediate pores was reduced by a factor of five, this being indicated by the reduction in the size of the hysteresis loop (Fig. 1). The specific surface was reduced from 355 to 280 sq.m/g, and the effective pore radius from 30 to 10 A. Hence, under mechanical treatment it is mainly the intermediate pores that are broken down. These results are in accord with our previous results on the change in the macrostructure of silica gel when subjected to high pressure [8].

Figure 3 shows that both catalysts (compressed and uncompressed alumina) have almost the same activity for the dehydration of formic acid, as calculated for unit volume; their specific activities, calculated for 1 sq. m of surface, differ inappreciably at low temperature. At higher temperatures compressed alumina is appreciably

less active than uncompressed (Fig. 4). It is obvious that these differences in activity are associated with differences in the character of the porosity of the catalysts. In the compressed sample the porous structure is based mainly on micropores (r less than 10 A), and intermediate pores, having been destroyed under the superhigh pressure, are almost absent, as can be seen by comparing ordinates on the curves showing the relation between $\frac{\Delta W}{\Delta r}$ and r. The insufficiency of the number of intermediate pores results in diffusional retardation of reaction.

Figure 6. Sorption isotherms for methyl alcohol vapor on samples of alumina, calculated for unit surface (1 sq.m):
o) Original; Δ) steam-treated; □) compressed.

The identity in nature of the activities of the adsorbing surfaces of uncompressed, compressed, and steam-treated alumina is indicated by the coincidence of the absolute adsorption isotherms for methyl alcohol vapor, as calculated for unit surface of the adsorbent (Fig. 6).

SUMMARY

1. The effects of treatment with steam and of compression at 20,000 atm on the macrostructure and catalytic activity of alumina were investigated.

2. It was shown that steam treatment resulted in reduction of the catalytic activity of alumina, great reduction of its specific surface, almost complete disappearance of the micropores, and increase of the volume of intermediate pores. Steam treatment can be used as a method for the control of the porous character of oxide catalysts.

3. Compression results in increase of the apparent density of alumina: the intermediate pores are destroyed, and this causes lowering of the specific catalytic activity of alumina at high temperatures; the reaction is then subject to diffusional retardation.

TRIALKYL PHOSPHORIMIDATES

TRIALKYL PHENYLPHOSPHORIMIDATES

M. I. Kabachnik and V. A. Gilyarov

In a previous paper [1], which was devoted to the synthesis and the investigation of the properties of dialkyl phenylphosphoramidates, we described the alkylation of the sodium derivative of a dialkyl phenylphosphoramidate with an alkyl halide, which resulted in the formation of a P-alkyl-N-phenylphosphonimidic ester:

A substance of the same structure was synthesized also by the action of phenyl azide on an alkylphosphonous ester:

The products were the first P-alkylphosphonimidic acid derivatives to be prepared. The corresponding trialkyl phosphorimidates (I) are the nitrogen analogs of trialkyl phosphates (II) and trialkyl phosphorothionates (III):

Whereas the last two classes of substances have been known for a long time and have been thoroughly studied, trialkyl phosphorimidates have not been described previously.

Organic derivatives of quinquevalent phosphorus containing the grouping P=N were described by Staudinger and coworkers [2], who prepared them by the action of phenyl azide on trialkylphosphines:

Horner and Gross [3] recently studied this reaction in detail and applied it to various azides. However, apart from our synthesis referred to above, Staudinger's reaction has been applied to phosphines, and not to esters of tervalent phosphorus acids. Accordingly, the imides obtained are P,P,P-triarylphosphine imides (IV), the nitrogen analogs of triarylphosphine oxides (V) and sulfides (VI):

As Staudinger and coworkers showed, phosphine amides have many very interesting properties. Even more interesting properties are to be expected from imido derivatives of phosphoric and phosphonic esters of type (I), which contain the $p\pi$-conjugated system of bonds $R-O-\underset{\underset{|}{}}{P}=N-$. Substances of a closely related type were systematically investigated by Kirsanov and coworkers [4]. By reaction of phosphorus pentachloride with amides of carboxylic or sulfonic acids they obtained N-acyl-P,P,P-trichlorophosphine imides:

$$Ac{\cdot}NH_2 + PCl_5 = 2HCl + Ac{\cdot}N{=}PCl_3$$

which were converted into various derivatives by the action of alcohols and other reagents. However, Kirsanov's compounds contained an acyl group on nitrogen, i. e., were the mixed imides of two acids, namely, phosphoric acid and a carboxylic or sulfonic acid. It would appear that the preparation of substances of type (I) by Kirsanov's method is impossible.

TABLE

No.	Formula of substance	B.p. in °C (p in mm)	n_D^{20}	d_4^{20}
1	$(CH_3O)_3P{=}NC_6H_5$	44-45 ($2\cdot10^{-4}$)	1.5232	1.1713
2	$(C_2H_5O)_3P{=}NC_6H_5$	118-119 (1.5)	1.5022	1.0743
3	$(C_3H_7O)_3P{=}NC_6H_5$	122 (1)	1.4920	1.0297
4	$(i\text{-}C_3H_7O)_3P{=}NC_6H_5$	49-50 ($2\cdot10^{-4}$)	1.4880	1.0116
5	$(C_4H_9O)_3P{=}NC_6H_5$	144-145 (1)	1.4885	1.0036
		91-92 (1)	1.5030	1.1233
6	$(C_2H_5O)_2P(O)N(CH_3)C_6H_5$	99 (1.5)	1.5030	1.1237
7	$(C_2H_5O)_2P(O)N(C_2H_5)C_6H_5$	91 (0.5)	1.4972	1.0917
8	$(C_2H_5O)_2P(O)N(COCH_3)C_6H_5$	84-84.5 (0.01)	1.5038	1.1670

We investigated the reaction of phenyl azide with trialkyl phosphites and found it proceeded smoothly with formation of trialkyl phenylphosphorimidates in good yield:

$$(RO)_3P + C_6H_5N_3 \rightarrow (RO)_3P{=}NC_6H_5 + N_2.$$

Constants of the substances obtained (Nos. 1-5) are given in the table*.

Esters of quinquevalent phosphorus acids (trialkyl phosphates, dialkyl phenylphosphoramidates), as also dialkyl hydrogen phosphites and O,O-dialkyl hydrogen phosphorothioites, the tautomeric equilibrium of which is greatly displaced in the direction of the quinquevalent phosphorus form [5], do not react with phenyl azide. We

* It must be mentioned that, in the case of triisopropyl phosphite, it is necessary to distill the reaction products in a high vacuum. Otherwise, the main reaction product is diisopropyl phenylphosphoramidate, formed, probably, by the pyrolysis of triisopropyl phenylphosphorimidate:

$$(i\text{-}C_3H_7O)_3P{=}NC_6H_5 \rightarrow C_3H_6 + (i\text{-}C_3H_7O)_2P(O)NHC_6H_5.$$

therefore consider that reaction with phenyl azide can be regarded as characteristic of tervalent phosphorus compounds. Like the well known Arbuzov rearrangement [5], addition of sulfur [6], and addition of a cuprous halide [5], reaction with phenyl azide may be useful for the investigation of the structures of certain organophosphorus compounds.

An investigation of the properties of trialkyl phenylphosphorimidates gave interesting results. In some reactions they behave like Staudinger's phosphine imides: thus, when treated with carbon disulfide they exchange the phenylimido group for a sulfur atom, and phenyl isothiocyanate is formed simultaneously:

$$(RO)_3P{=}NC_6H_5 + CS_2 \rightarrow (RO)_3P{=}S + C_6H_5N{=}C{=}S.$$

In some reactions, however, not only the P=N linkage has a specific effect on the course of the process, but also the presence of alkoxy groups attached to phosphorus. Thus, it was found that the product of the hydrolysis of triethyl phenylphosphorimidate was not triethyl phosphate, as might be expected on analogy with the reaction of phosphine imides:

$$Ar_3P{=}NC_6H_5 + H_2O \rightarrow Ar_3PO + C_6H_5NH_2,$$

but diethyl phenylphosphoramidate:

An analogous result was obtained in reactions with anhydrous hydrogen chloride and with benzoic acid in an inert medium:

Investigation of the alkylation of triethyl phenylphosphorimidate with methyl iodide showed that this reaction proceeds in a way that is to a certain extent analogous to that of the alkylation of trialkyl phosphorothionates. As is well known, trialkyl phosphorothionates undergo the Pishchimuka rearrangement [7] with alkyl halides with formation of phosphorothiolic esters:

$$(RO)_3PS + R'I \rightarrow (RO)_2PO(SR') + RI.$$

Correspondingly, triethyl phenylphosphorimidate reacts with alkyl halides with formation of diethyl alkylphenylphosphoramidates:

We proved the structure of the rearrangement product obtained by the action of methyl iodide by confirmatory synthesis from diethyl phosphorochloridate and N-methylaniline:

Reaction with acetyl chloride is analogous to the methylation reaction, the acetyl derivative of the phenylphosphoramidic ester being formed:

The structure of the product was proved by the formation of acetanilide by hydrolysis:

It may be considered that the reactions of trialkyl phenylphosphorimidates with water, with hydrogen chloride, and with benzoic acid are extremely similar in type. In all three cases the action of the reagent is directed to the 1,4-positions of the $\sigma\pi$-conjugated system R—O—P=N—, and reaction proceeds with transfer of reaction center. For the hydrolysis reaction, which proceeds in a conducting medium, a scheme that is usual for reactions of this kind may be proposed:

However, for the action of hydrogen chloride in an isooctane medium or of benzoic acid in a xylene medium, reaction with formation of a six-membered transition complex cannot be excluded:

Alkylation and acylation reactions can be represented similarly:

Unlike these reactions, the reaction of carbon disulfide proceeds only at the P=N bond and is therefore directed to the 1,2-positions:

EXPERIMENTAL

Preparation of Trialkyl Phenylphosphorimidates

An ether solution of phenyl azide was added dropwise to a stirred ether solution of the trialkyl phosphite, the reaction mixture being cooled with ice. Evolution of nitrogen was observed 3-5 minutes after the addition was begun. The mixture was set aside for 30 minutes at room temperature, ether was distilled off, and the residue was vacuum distilled.

Trimethyl phenylphosphorimidate. This was prepared from 8.7 g (0.07 mole) of trimethyl phosphite in 25 ml of ether and 10.7 g (0.09 mole) of phenyl azide in 7 ml of ether. Two distillations in high vacuum gave 12.0 g (80.0%) of trimethyl phenylphosphorimidate, b. p. 44-45° ($1 \cdot 10^{-4}$ mm); n_D^{20} 1.5232; d_4^{20} 1.1713; found MR 56.10; calculated MR 56.82*.

Found %: C 50.58, 50.65; H 6.50, 6.73; P 14.03, 14.15.
$C_9H_{14}O_3NP$. Calculated %: C 50.23; H 6.51; P 14.43.

The product is a colorless liquid, soluble in ether and alcohol, insoluble in water and isooctane.

Triethyl phenylphosphorimidate. Experiment 1. The substance was prepared from 16.6 g (0.1 mole) of triethyl phosphite in 50 ml of ether and 11.9 g (0.1 mole) of phenyl azide in 20 ml of ether. Three successive fractionations yielded 16.3 g (63.0%) of triethyl phenylphosphorimidate, b. p. 135° (3.5 mm) and 118-119° (1.5 mm); n_D^{20} 1.5022; d_4^{20} 1.0743; found MR 70.66; calculated MR 70.67.

Found %: C 55.68, 55.66; H 7.85, 7.83; P 12.00, 12.15.
$C_{12}H_{20}O_3NP$. Calculated %: C 56.04; H 7.78; P 12.08.

The product is a brownish liquid, soluble in organic solvents, insoluble in water.

Experiment 2 (without isolation of phenyl azide). The substance was prepared from 41.5 g (0.25 mole) of triethyl phosphite in 50 ml of ether and 270 ml of an ether solution of phenyl azide which contained 35.7 g (0.3 mole) of phenyl azide. Three successive distillations yielded 55.2 g (86.2%) of triethyl phenylphosphorimidate, b. p. 100° (0.8 mm); n_D^{20} 1.5038; d_4^{20} 1.0752; found MR 70.79; calculated MR 70.67.

Tripropyl phenylphosphorimidate. This was prepared from 8.3 g (0.04 mole) of tripropyl phosphite in 25 ml of ether and 4.8 g (0.04 mole) of phenyl azide in 5 ml of ether. Two distillations gave 7.5 g (62.8%) of tripropyl phenylphosphorimidate, b. p. 122° (1 mm); n_D^{20} 1.4920; d_4^{20} 1.0297; found MR 84.30; calculated MR 84.52.

Found %: C 60.14, 60.41; H 8.81, 8.54; P 9.98, 10.23.
$C_{15}H_{26}O_3NP$. Calculated %: C 60.16; H 8.69; P 10.36.

Triisopropyl phenylphosphorimidate. Experiment 1. The substance was prepared from 6.3 g (0.03 mole) of triisopropyl phosphite in 25 ml of ether and 4.0 g (0.03 mole + 10% excess) of phenyl azide in 5 ml of ether. Two distillations in high vacuum yielded 5.6 g (64.3%) of triisopropyl phenylphosphorimidate, b. p. 49-50° ($2 \cdot 10^{-4}$ mm); n_D^{20} 1.4880; d_4^{20} 1.0116; found MR 85.21; calculated MR 84.52.

Found %: C 59.96, 59.82; H 8.52, 8.67; P 10.74, 10.53.
$C_{15}H_{26}O_3NP$. Calculated %: C 60.16; H 8.69; P 10.36.

The product is a yellowish liquid.

Experiment 2. Reaction was between 7.6 g (0.037 mole) of triisopropyl phosphite in 25 ml of ether and 5.3 g (0.045 mole) of phenyl azide in 5 ml of ether, and the first distillation gave a fraction (5.7 g) having b. p. 114-116° (1.5 mm) and n_D^{20} 1.4479; which we were unable to distill a second time (bath temperature up to 205°, p = 1.5 mm). When cool, the substance crystallized, and the crystals were pressed off on a porous plate (3.4 g of crystals, m. p. 117.5-118°). After crystallization from water containing a little alcohol, the crystals had m. p. 118.5-119°, undepressed by admixture of authentic diisopropyl phenylphosphoramidate.**

Tributyl phenylphosphorimidate. This was prepared from 7.5 g (0.03 mole) of tributyl phosphite in 25 ml of ether and 3.6 g (0.03 mole) of phenyl azide in 5 ml of ether. Two distillations gave 7.1 g (69.0%) of tributyl phenylphosphorimidate, b. p. 114-145° (1 mm); n_D^{20} 1.4885; d_4^{20} 1.0036; found MR 98.06; calculated MR 98.37.

* The atomic refraction of nitrogen was taken to be 5.78 (calculated from data obtained in the present and preceding [1] investigations).

** Diisopropyl phenylphosphoramidate was prepared by Atherton [8] from diisopropyl phosphite, bromotrichloromethane, and aniline; m. p. 119°. Other data in the literature for diisopropyl phenylphosphoramidate are: m. p. 120-121° [9]; 121-121.5° [10, 11].

Properties of Trialkyl Phenylphosphorimidates

Action of carbon disulfide on triethyl phenylphosphorimidate. When 6.8 g (0.09 mole) of carbon disulfide was added to 7.7 g (0.03 mole) of triethyl phenylphosphorimidate, no changes were observed. The solution was refluxed at 60-65° for six hours. Carbon disulfide was distilled off under reduced pressure, residual traces being removed by treatment for one hour at 50° and 15 mm pressure. The product, which had the odor of phenyl isothiocyanate, was treated with 2.8 g (0.03 mole) of aniline. The mixture, which crystallized out, was heated for 90 minutes at 65-70° in order to complete the reaction. The precipitate was separated and washed with ether (four 10-ml portions). The precipitate weighed 4.7 g (68.5%), m. p. 147.5°. After recrystallization from alcohol it melted at 151°. Melting point of a mixture with 1,3-diphenyl-2-thiourea was 151°. The ether extract was washed with two 10-ml portions of 10% sulfuric acid and then with water until the reaction was neutral. The ether solution was dried with calcined sodium sulfate, ether was distilled off under reduced pressure, and the residue was distilled. Two distillations yielded 4.2 g (47%) of O,O,O-triethyl phosphorothioate, b. p. 82° (7 mm); n_D^{20} 1.4550; d_4^{20} 1.0746; d_0^{20} 1.0733; found MR 49.99; calculated on $C_8H_{15}O_3PS$ MR 49.39. For O,O,O-triethyl phosphorothioate, the literature [12] gives b. p. 88.5° (8 mm); n_D^{20} 1.4480; d_0^{20} 1.0756.

A complex was prepared from 0.5 g (0.025 mole) of the triethyl phosphorothioate and 2.2 g (0.05 mole) of mercuric chloride by Pishchimuka's method [7]; it melted at 101-102° (from alcohol). A mixture with the complex prepared from authentic O,O,O-triethyl phosphorothioate melted at 100-101°. For a complex of composition $(C_2H_5O)_3P{=}S \cdot 2HgI_2$, the literature [7] gives m. p. 88°.

Hydrolysis of triethyl phenylphosphorimidate. When 10 ml of water was added to 2 g of triethyl phenylphosphorimidate, no reaction was observed. When the mixture had stood for 1.5 months, the oily layer crystallized. The crystals were separated and dried in a vacuum desiccator over phosphoric oxide. The product was 1.47 g (83%) of diethyl phenylphosphoramidate, m. p. 94-95°, unchanged by recrystallization from isooctane. A mixture with known diethyl phenylphosphoramidate melted at 94-95°. The literature gives melting points from 93° [13] to 96.5° [10].

Action of benzoic acid on triethyl phenylphosphorimidate. When 1.3 g (0.05 mole) of triethyl phenylphosphorimidate was added to a mixture of 0.6 g (0.05 mole) of benzoic acid and 5 ml of dry xylene, a homogeneous solution was formed and the odor of ethyl benzoate was noted. In order to complete reaction the mixture was heated at 90° for three hours. When solvent was removed under reduced pressure, the residue (a yellow liquid) crystallized. The crystals were washed with isooctane and dried in a vacuum desiccator. The yield of diethyl phenylphosphoramidate was 0.87 g (77%). It had m. p. 92.5-93°, raised to 94-95° by recrystallization from isooctane. A mixture with known diethyl phenylphosphoramidate melted at 94-95°.

Action of hydrogen chloride on triethyl phenylphosphorimidate. When dry hydrogen chloride is passed through a solution of 1.2 g triethyl phenylphosphorimidate in 5 ml isooctane (cooling with water) absorption of hydrogen chloride and formation of a white precipitate is observed. Passage of hydrogen chloride was continued for three minutes after absorption had ceased. After additional treatment with hydrogen chloride the solution was distilled in vacuum; the residue (crystals) was washed in isooctane and dried in a vacuum desiccator. Yield 0.975 g diethyl phenylphosphoramidate (96%); m. p. 93.5-94°. After recrystallization from isooctane it had m. p. 95°. A mixture with known diethyl phosphoramidate melted at 95°.

Action of hydrogen chloride on trimethyl phenylphosphorimidate. Dry hydrogen chloride was passed for ten minutes through 1 g of trimethyl phenylphosphorimidate under a layer of 5 ml of isooctane, the system being cooled with cold water. Hydrogen chloride and isooctane were distilled off under reduced pressure, and the residue (a very viscous mass) was pressed off on a porous plate (weight 0.75 g). After recrystallization from isooctane, 0.55 g (48%) of dimethyl phenylphosphoramidate was obtained; m. p. 88°. For dimethyl phenylphosphoramidate the literature [11] gives m. p. 88-88.5°.

Reaction of alkyl halides with triethyl phenylphosphorimidate. a) When 3.8 g (0.015 mole) of triethyl phenylphosphorimidate was mixed with 9.3 (0.06 mole) of ethyl iodide, no change was observed. After four days ethyl iodide was distilled off under reduced pressure and the residue was distilled. The product (3.5 g) was unchanged triethyl phenylphosphorimidate, b. p. 89° (0.5-0.6 mm), n_D^{20} 1.5025; d_4^{20} 1.0789.

b) A mixture of 5.1 g (0.02 mole) of triethyl phenylphosphorimidate and 11.3 g (0.08 mole) of methyl iodide was heated fro seven hours at 65-75° in a flask having a reflux condenser fitted with a calcium chloride tube. Methyl iodide was distilled off under reduced pressure, and distillation of the residue gave 4.4 g (90.5%) of diethyl methyl-

phenylphosphoramidate, b. p. 91-92° (1 mm); n_D^{20} 1.5030; d_4^{20} 1.1233; found MR 63.98.

Found %: C 54.14, 54.30; H 7.72, 7.61; P 12.59, 12.59.
$C_{11}H_{18}O_3NP$. Calculated %: C 54.32; H 7.41; P 12.76.

c) A mixture of 5.1 g (0.02 mole) of tritheyl phenylphosphorimidate and 11.3 g (0.08 mole) of methyl iodide was heated in a sealed tube for four hours at 100°. The yield of diethyl methylphenylphosphoramidate was 4.4 g (90.5%); b. p. 101° (1.5 mm); n_D^{20} 1.5030; d_4^{20} 1.1233.

d) A mixture of 3.8 g (0.015 mole) of triethyl phenylphosphorimidate and 9.3 g (0.06 mole) of ethyl iodide was refluxed at 65-70° for six hours. Ethyl iodide was distilled off under reduced pressure. Distillation of the residue gave 3.5 g (92%) of diethyl ethylphenylphosphoramidate, b. p. 91° (0.5 mm); n_D^{20} 1.4972; d_4^{20} 1.0917; found MR 68.94.

Found %: C 56.03, 56.23; H 7.90, 8.00; P 11.99, 12.07.
$C_{12}H_{20}O_3NP$. Calculated %: C 56.04; H 7.78; P 12.08.

Preparation of diethyl methylphenylphosphoramidate. N-Methylaniline (12.2 g, i. e., 0.14 mole) was added dropwise to 10.0 g (0.057 mole) of diethyl phosphorochloridate in 50 ml of ether contained in a three-necked flask fitted with stirrer, dropping funnel, and condenser. After a few minutes a crystalline precipitate began to form and gradually increased in quantity. After one day the precipitate was separated and washed with ether. The weight of methylaniline hydrochloride was 7.5 g (theory requires 8.2 g). Two successive distillations gave 5.5 g (40%) of dimethyl methylphenylphosphoramidate, b. p. 99° (1.5 mm), n_D^{20} 1.5030; d_4^{20} 1.1237.

Found %: C 54.03, 54.27; H 7.54, 7.67; P 12.59, 12.32.
$C_{11}H_{18}O_3NP$. Calculated %: C 54.32; H 7.41; P 12.76.

Action of acetyl chloride on triethyl phenylphosphorimidate. Acetyl chloride (3.1 g, i. e., 0.04 mole) was added dropwise to a solution of 10.3 g (0.04 mole) of triethyl phenylphosphorimidate in 2.5 ml of isooctane. When addition was complete, the solution was heated to 58°, when it became turbid. The mixture was heated under reflux for three hours at 70°. The lower, oily layer was separated and washed with 20 ml of isooctane. Traces of solvent were removed at 2 mm from a boiling water bath. The residue, a thick brown liquid, weighed 9.4 g. Distillation gave 7.4 g (68.2%) of diethyl acetylphenylphosphoramidate, b. p. 84-84.5° (0.01 mm); n_D^{20} 1.5038; d_4^{20} 1.1670; found MR 68.7.

Found %: P 11.41, 11.56.
$C_{12}H_{18}O_4NP$. Calculated %: P 11.44.

Hydrolysis of diethyl acetylphenylphosphoramidate. A mixture of 0.8 g of diethyl acetylphenylphosphoramidate and 8 ml of water was heated for three hours in a boiling water bath. Cooling resulted in the formation of 0.14 g of a crystalline precipitate, m. p. 113-114°, undepressed by admixture of acetanilide. The yield of acetanilide was 30%.

SUMMARY

1. Trialkyl phenylphosphorimidates $(RO)_3P{=}NC_6H_5$ were synthesized by reaction of trialkyl phosphites with phenyl azide.

2. Some properties of trialkyl phenylphosphorimidates were studied. It was shown that reaction of triethyl penylphosphorimidate with water, hydrogen chloride, or benzoic acid gave diethyl phenylphosphoramidate. Reaction of triethyl phenylphosphorimidate with alkyl halides gave diethyl alkylphenylphosphoramidates, and reaction with acetyl chloride gave diethyl acetylphenylphosphoramidate.

POLYORGANOSTANNO- AND POLYORGANOTITANOSILOXANES

K. A. Andrianov, T. N. Ganina, and E. N. Khrustaleva

In 1947 one of us showed that organosilicon compounds containining silico-attached hydroxyls react with metals and their hydroxides with formation of macromolecular compounds containing metallosiloxane groups [1]. We later synthesized nonaethylaluminoxytrisiloxane and established its structure [2]. Further investigations showed that polyorganometallosiloxanes were obtained also by an exchange reaction between the hydrolysis products of organosilicon monomers and salts of multivalent metals and by cohydrolysis of organosilicon monomers with salts of multivalent metals [3]. In the present paper we describe some new polymers: polyorganostanno- and polyorganotitanosiloxanes.

a) Polyorganostannosiloxanes. Glassy polyorganostannosiloxanes were prepared by the cohydrolysis of diethyltin dichloride with dichlorodiethylsilane and also with a mixture of dichlorodiethylsilane and trichlorophenylsilane with subsequent condensation of the cohydrolysis products. Investigation of the fractional composition of the polymer obtained from 0.6 mole of dichlorodiethylsilane, 0.3 mole of trichlorophenylsilane, and 0.1 mole of diethyltin dichloride showed that all fractions contained both silicon and tin, but the relative amounts varied: the alcohol-soluble fraction contained more tin than the acetone- and toluene-soluble fractions (Table 1).

TABLE 1

Substance	Amount (g)	Content (%)		Si : Sn ratio
		of silicon	of tin	
Polymer No. 4	8.6193	20.79	8.60	10.3 : 1
Alcohol fraction	0.6192	17.34	17.86	4.1 : 1
Acetone fraction	2.4127	21.18	9.69	9.3 : 1
Toluene fraction	4.5884	22.61	8.60	11.5 : 1
Losses	0.9890	–	–	–

The experimental results showed that the cohydrolysis of alkyl- or aryl-chlorosilanes with diethyltin dichloride resulted in the formation of glassy polyorganostannosiloxanes in accordance with the scheme:

$$R_2SiCl_2 + (C_2H_5)_2SnCl_2 \xrightarrow[NH_3]{H_2O} (-OR_2Si-)_m-O-\underset{\displaystyle C_2H_5}{\overset{\displaystyle C_2H_5}{\underset{|}{\overset{|}{Sn}}}}-O-,$$

in which m, as the experimental results show, varies from 4 to 11. The compositions of the polyorganostannosiloxanes vary according to the relative amounts of the monomers taken for reaction. Moreover, fractionation showed that a given polymer contains various fractions, in which the Si : Sn ratio varies from 4 to 11.

b) Polyorganotitanosiloxanes. By the cohydrolysis of alkyl- or aryl-chlorosilanes with tetrabutyl orthotitanate and by reaction of the hydrolysis products of alkyl- or aryl-chlorosilanes with tetrabutyl orthotitanate and subsequent condensation at 200°, glassy polymers are obtained which are soluble in organic solvents. For example, cohydrolysis of 0.66 mole of dichlorodimethylsilane, 0.33 mole of trichlorophenylsilane, and 0.1 mole of tetrabutyl orthotitanate gave an alcohol- and acetone-soluble polymer. Fractionation of this polymer showed that all

fractions contain both silicon and titanium (Table 2).

TABLE 2

Substance	Amount (g)	Content (%)		Si : Ti ratio
		of silicon	of titanium	
Polymer No. 5	6.3522	24.91	1.47	29.6 : 1
Alcohol fraction	1.8396	27.43	1.17	40.7 : 1
Acetone fraction	3.6028	26.46	1.84	24.8 : 1
Toluene fraction	0.4010	Not analyzed		
Losses	0.5088	–	–	–

Cohydrolysis of 0.66 mole of dichlorodiethylsilane, 0.33 mole of trichlorophenylsilane, and 0.1 mole of tetrabutyl orthosilicate gave an alcohol- and acetone-soluble polymer. Investigation of the fractional composition of this polymer showed that all fractions contain both silicon and titanium (Table 3).

TABLE 3

Substance	Amount (g)	Content (%)		Si : Ti ratio
		of silicon	of titanium	
Polymer No. 4	10.080	23.54	1.83	23.22 : 1
Alcohol fraction	0.797	23.22	1.62	24.51 : 1
Acetone fraction	8.930	23.99	2.25	18.23 : 1
Toluene fraction	0.205		Not analyzed	
Losses	0.148	–	–	–

The experimental results show that the organosilicon monomers react with tetrabutyl orthotitanate in accordance with the scheme:

$$R_2SiCl_2 + Ti(OC_4H_9)_4 \xrightarrow[NaOH]{H_2O} (-OR_2Si-)_m-O-\underset{\displaystyle OC_4H_9}{\overset{\displaystyle OC_4H_9}{\underset{|}{\overset{|}{Ti}}}}-O-$$

Table 4 gives the compositions of fractions of the polymer obtained by reaction of the cohydrolysis products from 0.66 mole of dichlorodimethylsilane and 0.33 mole of trichlorophenylsilane with 0.1 mole of tetrabutyl orthotitanate and subsequent condensation at 200°. All fractions contain both silicon and titanium, and the silicon-titanium ratio varies: acetone-soluble fractions contain considerably more titanium than alcohol-soluble fractions. Here, as in the case of polyorganostannosiloxanes, the relative amounts of silicon and metal in the polymers varies according to the monomer ratio in the mixture taken for reaction. Fractionation of polyorganotitanosiloxanes prepared by various methods showed that a polymer of given overall composition contains various fractions. For example, Polymer No. 8 (Table 4) contains an alcohol-soluble fraction having a Si : Ti ratio of 30 : 1 and an acetone-soluble fraction having a Si : Ti ratio of 5 : 1. The experimental results, therefore, show that m varies from 5 to 30.

EXPERIMENTAL

Substances used were: dichlorodimethylsilane of chlorine content 55.2% (calculated 54.98% Cl), dichlorodiethylsilane of chlorine content 44.5% (calculated 45.18% Cl), trichlorophenylsilane of chlorine content 50.1% (calculated 50.31% Cl). Diethyltin dichloride, m. p. 84°, was prepared by Kocheshkov's method [4]. Tetrabutyl orthotitanate, b. p. 200-202° (26 mm), was prepared by Nesmeyanov's method [5].

TABLE 4

Substance	Amount (g)	Content (%) of silicon	Content (%) of titanium	Si : Ti ratio
Polymer No. 8	6.1502	22.30	6.11	6.3 : 1
Alcohol fraction	1.0894	22.90	1.29	30.3 : 1

Toluene fraction	0.1464		Not analyzed	
Losses	0.5314	–	–	–

Synthesis of Polyorganostannosiloxanes by Cohydrolysis of Alkyl- and Aryl-chlorosilanes with Diethyltin Dichloride

The reaction was carried out in a three-necked flask fitted with mercury-sealed stirrer, thermometer, dropping funnel, and reflux condenser. The calculated amounts of 10% aqueous ammonia and toluene were introduced into the flask, heated to 50-55°, and stirred while a mixture of a toluene solution of diethyltin dichloride and the alkyl- or aryl-chlorosilane was added over a period of one hour. During the cohydrolysis, the mixture was kept alkaline (final pH 8.5). When reaction was complete, the toluene layer was separated and washed with water; toluene was distilled off under reduced pressure (20 mm; temperature 35°). Clear yellow liquid polymers were obtained; they were soluble in benzene, toluene, ether, acetone, and alcohol; when heated, they passed into a infusible, insoluble state. The yields of hydrolysis products and the analytical results are given in Table 5.

TABLE 5

Experiment No.	Amounts of reactants (moles): Dichlorodimethylsilane	Dichlorodiethylsilane	Trichlorophenylsilane	diethyltin dichloride	Yield of liquid polymer (g)	Content (%) of HO	Si	Sn	Si : Sn ratio
1	0.5	—	—	0.1	105,0	0.19	7.21	5.19	5.9 : 1
2	0.9	—	—	0.1	89,4	0.27	17.91	3.39	22.5 : 1
3	—	0.9	—	0.1	78,0	—	23.33	6.50	15.2 : 1
4	—	0.6	0.3	0.1	75,0	—	22.08	7.87	11.9 : 1

The liquid hydrolysis products were condensed to solid polymers at 105-150°. The analytical results on the condensation products so obtained are given in Table 6.

TABLE 6

Experiment No.	Amounts of reactants (moles): Dichlorodimethylsilane	Dichlorodiethylsilane	Trichlorophenylsilane	Diethyltin dichloride	Tin content of liquid polymer (%)	Content in polymer of: Silicon (%)	Tin (%)	Si : Sn ratio

4	—	0.6	0.3	0.1	7.87	20.79	8.60	10.3 : 1

Investigation of Polyorganostannosiloxanes

The polymer under investigation (0.2-0.3 g) and concentrated sulfuric acid (20 ml) were introduced into a glass beaker. When the polymer had dissolved, 2 g of potassium iodate was added, and the contents of the beaker were gradually heated until iodine vapor ceased to be evolved and the solution cleared. The excess of sulfuric acid was then evaporated off, and 50 ml of distilled water and 50 ml of dilute (3:2) hydrochloric acid were added. The resulting solution was diluted with distilled water to 400 ml. When the solution was boiled, a precipitate of silica was formed, which was filtered off through an ashless filter paper and washed with hot 5% hydrochloric acid and with water. The filter paper and precipitate were burnt and calcined, and the silicon was determined. The calculation was by the formula:

$$\text{silicon (\%)} = \frac{(\text{weight of ppt.}) \cdot 0.4672 \cdot 100}{(\text{weight of sample})}$$

To separate the tin the filtrate was evaporated down to 200 ml and neutralized with ammonia. Ammonium nitrate (25 g) was added, and the total volume was made up to 300 ml. The mixture was boiled, and the precipitate that formed was filtered off and washed with hot 2% ammonium nitrate solution. The filter paper and precipitate were burnt in an oxidizing flame. The tin content was calculated from the formula:

$$\text{tin (\%)} = \frac{(\text{weight of ppt.}) \cdot 0.7876 \cdot 100}{(\text{weight of sample})}$$

The results obtained are given in Tables 5 and 6.

Synthesis of Polyorganotitanosiloxanes

a) Cohydrolysis of alkyl- and aryl-chlorosilanes with tetrabutyl orthosilicate. A mixture of 10% caustic soda solution and toluene was prepared in a glass vessel fitted with stirrer, thermometer, and dropping funnel. The mixture was stirred, and a mixture of alkyl(aryl)chlorosilane and tetrabutyl orthotitanate was added from the dropping funnel over a period of 60-90 minutes at 20-22°. When hydrolysis was complete, the reaction mixture was a liquid containing a precipitate which was filtered off; the toluene layer of the filtrate was separated from water and washed, and toluene was distilled off under reduced pressure. Clear, light-yellow, liquid polymers were obtained. They were soluble in ether, benzene, toluene, alcohol, and acetone. When heated, they passed into a solid, infusible state. The yields of products and the results of their analysis are given in Table 7.

TABLE 7

Experiment No.	Amounts of reactants (moles)				Yield of liquid polymer (g)	Content (%) of		Si:Ti ratio

When the liquid polymers were heated to 200°, glassy products were obtained which were soluble in organic solvents. The results of the analysis of the condensation products are given in Table 8.

b) Reaction of hydrolysis products of alkyl- and aryl-chlorosilanes with tetrabutyl orthotitanate. The reaction was carried out in two stages: 1) hydrolysis of the alkyl(aryl)chlorosilanes, and 2) heating of the hydrolysis products with tetrabutyl orthotitanate. Water, the calculated amount of sodium carbonate, and toluene were introduced into the hydrolysis vessel. The contents of the vessel were stirred at 20-22° while the mixture of alkyl-(aryl)chlorosilanes was added from a dropping funnel over a period of one hour. The toluene layer was washed,

carefully separated from water, and transferred to a three-necked flask fitted with stirrer, thermometer, reflux condenser, and dropping funnel. The solution was stirred at 20°, and a 50% toluene solution of tetrabutyl orthotitanate was added from the dropping funnel over a period of one hour. The reaction mixture was then heated at 80-85° for 4-5 hours, after which toluene was distilled off under reduced pressure. Liquid polymers were obtained; they were soluble in ether, benzene, toluene, alcohol, and acetone. The yields of products and the results of their analysis are given in Table 9.

The liquid polymers were condensed by heating them at 200°. The products were glassy substances, soluble in organic solvents. Results of the analysis of the condensation products are given in Table 10.

Investigation of Polyorganotitanosiloxanes

The investigation of the polyorganotitanosiloxanes was carried out by the procedure described for polyorganostannosiloxanes. The filtrate after the precipitation of silica was rendered neutral with ammonia, and 2 g of ammonium chloride was added. The precipitate that formed was filtered off and washed with 2% ammonium chlo-

ride solution. The filter paper and precipitate were burnt and calcined; the ash was weighed. The calculation was carried out by the formula:

$$\text{titanium (\%)} = \frac{\text{(weight of ppt.)} \cdot 0.5994 \cdot 100}{\text{(weight of sample)}}$$

The results obtained are given in Tables 7, 8, 9, and 10.

SUMMARY

1. The syntheses were effected of new polymeric substances, i. e., polyorganostannosiloxanes and polyorganotitanosiloxanes, the chains of which contain not only siloxane links $-\overset{\diagdown\diagup}{\underset{\diagup\diagdown}{Si}}-O-\overset{\diagdown\diagup}{\underset{\diagup\diagdown}{Si}}-$, but also $-\overset{\diagdown}{\underset{\diagup}{Si}}-O-\overset{\diagdown}{\underset{\diagup}{Sn}}-$ and $-\overset{\diagdown}{\underset{\diagup}{Si}}-O-\overset{\diagdown}{\underset{\diagup}{Ti}}-$ links.

2. It was shown that $-\overset{\diagdown}{\underset{\diagup}{Si}}-O-\overset{\diagdown}{\underset{\diagup}{Sn}}-$ and $-\overset{\diagdown}{\underset{\diagup}{Si}}-O-\overset{\diagdown}{\underset{\diagup}{Ti}}-$ links in polyorganostanno- and polyorganotitanosiloxanes are broken down by strong sulfuric acid.

3. It was found that polyorganostanno- and polyorganotitanosiloxanes are soluble in organic solvents. The fractional compositions of these products were studied, and it was shown that they are cocondensation products.

REACTION OF TRIALKYLSILANES WITH IODINE AND HYDROGEN IODIDE

M. G. Voronkov and Yu. I. Khudobin

The simplest and most convenient methods for the synthesis of trialkyliodosilanes R_3SiI are reaction of hexaalkyldisiloxanes with aluminum iodide [1] or aluminum and iodine [2] and reaction of trialkylsilanes with elementary iodine [3-6]*. The literature [3-6] indicates that the latter reaction proceeds in accordance with the equation:

$$R_3SiH + I_2 \longrightarrow R_3SiI + HI,$$

i.e. with formation of hydrogen iodide. On the basis of kinetic data and on the assumption that reaction of trialkylsilanes with iodine does indeed proceed in accordance with the above equation, Deans and Eaborn [4, 5] concluded that the reaction is of the fourth (!) order.

As we doubted the correctness of these conclusions, we undertook an investigation of the reaction of trialkylsilanes with iodine. Our objects included also the preparation of some pure trialkyliodosilanes and the determination of their physical constants. We found that trialkylsilanes react readily and smoothly with iodine, both in a solvent medium (petroleum ether, carbon tetrachloride, etc.), and also in absence of solvent, with formation of the corresponding trialkyliodosilanes in 90-94% yield. The reaction was carried out by gradual addition of iodine to the trialkylsilane, as such or as a solution, at a molar ratio $I_2 : R_3SiH = 0.6$. Reaction was accompanied by the evolution of hydrogen (and not hydrogen iodide), and this was formed in almost theoretical amount.

This fact, and also the fact that only one-half of a molecular equivalent of iodine is necessary for the complete conversion of one molecular equivalent of trialkylsilane into trialkyiodosilane, indicates beyond doubt that reaction does not proceed in the way previously assumed, but in accordance with the overall equation:

$$2R_3SiH + I_2 \longrightarrow 2R_3SiI + H_2.$$

Evolution of hydrogen iodide (in addition to hydrogen) can be observed only when the order in which the reactants are added is reversed, i. e. when the trialkylsilane is added to excess of iodine, as was done by Eaborn in one of his investigations [3].

Our results show that, when trialkylsilanes are treated with iodine, two consecutive reactions occur:

$$R_3SiH + I_2 \longrightarrow R_3SiI + HI,$$

$$R_3SiH + HI \longrightarrow R_3SiI + H_2,$$

the hydrogen iodide liberated in the first reaction being capable of reacting almost completely with the trialkylsilane before leaving the sphere of reaction.

To obtain final confirmation of this scheme of reaction, we studied the reaction of trialkylsilanes with hydrogen iodide in absence of catalysts, and, as was expected, this led to the formation of the corresponding trialkyliodosilanes, the yields being 80-90%. In their investigations, Eaborn and Deans did not take account of the

* This reaction has been used also for the quantitative determination of trialkylsilanes [7].

Solvents: Petroleum ether, b. p. 60-80° was freed from unsaturated hydrocarbons by treatment with sulfuric acid and was then distilled over sodium. Carbon tetrachloride was distilled over phosphoric oxide.

Experimental Procedure

All experiments on the reaction of trialkylsilanes with iodine were carried out in a distilling flask fitted with a 20-cm Vigreux column and having a capacity of 100-150 ml. A solution of 0.1 mole of the trialkylsilane in 50 ml of petroleum ether or carbon tetrachloride was placed in the flask, and iodine powder (0.12-0.125 g-atom) was added in small portions from an ampoule. The distillation flask was connected to a Liebig condenser and receiver, which was further connected through a Tishchenko vessel containing concentrated sulfuric acid to a gas

possibility of reaction between trialkylsilanes and hydrogen iodide, although it had been shown as early as 1939 that iodine may replace hydrogen attached to silicon when SiH_4 reacts with HI in presence of AlI_3 [8, 9].

In view of the fact that replacement of silicon-attached hydrogen by halogen under the action of hydrogen halides is catalyzed by the corresponding aluminum halides [8-10], we studied the catalytic effect of aluminum iodide on the reactions of trialkylsilanes with iodine and hydrogen iodide. It was found that the reaction rate was considerably increased (by about 20-30%) in presence of small amounts of aluminum iodide, but the yields of trialkyliodosilanes were unchanged. It should be noted that, when the reaction of a trialkylsilane with iodine in presence of aluminum iodide is carried out in a carbon tetrachloride medium, a mixture of trialkyliodo- and trialkylchloro-silanes is formed owing to the occurrence of a catalytic exchange reaction with the solvent. It is therefore preferable to carry out syntheses of this sort in a petroleum ether medium.

The rate of reaction of a trialkylsilane with iodine or with hydrogen iodide diminishes as the length or ramification of the alkyl radical increases (iodination of tripropylsilane is five times as fast as that of triisopropylsilane [4, 5]). At the same time the polarization of the bond $\overset{\delta+}{Si}\text{—}\overset{\delta-}{H}$ must increase, i. e. the ease of its heterolytic fission, and therefore reactivity, must increase, so that the reaction of a trialkylsilane with iodine must be regarded as bimolecular nucleophilic replacement (S_N2 according to Ingold and Hughes), the mechanism of which can be represented as follows:

$$I^- + R_3SiH \rightarrow [I \ldots R_3Si \ldots H]^- \begin{cases} \xrightarrow{+I_2} R_3SiI + HI + I^- \\ \xrightarrow{+HI} R_3SiI + H_2 + I^- \end{cases}$$

This scheme indicates that reaction proceeds autocatalytically under the action of I^- ions.

Unlike this reaction, the reaction of trialkylsilanes with hydrogen bromide or chloride does not occur in absence of catalysts. We showed, for example, that in the reaction of triethylsilane with bromine no evolution of hydrogen could be detected, the process occurring strictly in accordance with the equation:

$$R_3SiH + Br_2 \rightarrow R_3SiBr + HBr,$$

The yield of bromotriethylsilane was 90%. This behavior can be explained by the fact that the affinities of bromine and chlorine for hydrogen are considerably greater than the affinity of iodine, so that the energy of the H—I bond (71.4 cal/mole) is less than that of the Si—H bond (75.0 cal/mole), whereas the energies of the H—Br and H—Cl bonds are greater (87.3 and 109.7 cal/mole, respectively) than that of the Si—H bond.

As there are no by-products, the reaction of trialkylsilanes with iodine makes it possible to prepare trialkyliodosilanes in a high degree of purity, which gives this method an advantage over other methods for their synthesis [11-13]. By treating trialkylsilanes with iodine we synthesized five pure trialkyliodosilanes, three of which were previously unknown. Their properties (refractometric constants for R_3SiI are given for the first time), analytical figures, and yields are given in Table 1.

EXPERIMENTAL

Reactants

The trialkylsilanes were prepared by reaction between trichlorosilane and the corresponding alkylmagnesium halides; they were purified by distillation through a column (under reduced pressure for the high-boiling compounds). Their yields, physical constants, and analytical figures are given in Table 2.

Hydrogen iodide was prepared by reaction of iodine and red phosphorus with dilute hydriodic acid. It was carefully freed from entrained iodine by passage through a tube containing red phosphorus moistened with hydriodic acid, and it was dried over phosphoric oxide. Iodine and aluminum powders were the commercial chemically pure products.

holder for the collection of hydrogen. Reaction was brought about by warming the mixture to 30-40°, and was complete when the evolution of hydrogen ceased. The course of the reaction could be readily followed from the volume of hydrogen evolved, the yield being usually theoretical. Solvent was driven off, and the residue of trialkyliodosilane was distilled. Reaction was sometimes carried out in absence of solvent, and the yields were almost the same. In absence of solvent, however, reaction was very vigorous and part of the iodine escaped in the form of hydrogen iodide.

The reactions of trialkylsilanes with hydrogen iodide were carried out in a 100-ml three-necked round-bottomed flask fitted with tube for the passage of gas, thermometer, and reflux condenser connected through a calcium chloride tube to a gas holder for the collection of hydrogen. The trialkylsilane (0.1 mole) was placed in the flask, and this was warmed while a stream of dry hydrogen iodide, free from iodine, was passed through. The course of the reaction was followed both by the volume of hydrogen evolved and by the temperature of the reaction mixture, which, in the case of triethylsilane, rose to a maximum when the theoretical amount of hydrogen had been evolved. The resulting trialkyliodosilane was isolated by distillation.

The trialkyliodosilanes obtained were immediately redistilled at ordinary or reduced pressure in diffuse light over copper powder in an atmosphere of pure dry nitrogen. They were quickly sealed in nitrogen-filled ampoules, which were then kept in the dark. The analyses and physical determinations on the trialkyliodosilanes were carried out as quickly as possible after their preparation, suitable precautions being taken against the introduction of traces of moisture.

The method of determining iodine in trialkyliodosilanes is described in our previous paper [2]. We shall now describe some typical experiments.

Reaction of Triethylsilane with Iodine. Iodine (15.9 g, i. e. 0.125 g-atom) was added in small portions to 11.6 g (0.1 mole) of triethylsilane dissolved in 50 ml of petroleum ether. The mixture was heated until the evolution of hydrogen ceased (two hours); 1.11 liters of hydrogen was formed. Solvent was distilled from the reaction mixture, and the residue was distilled over copper powder in a nitrogen atmosphere in diffuse light. The yield of triethyliodosilane, b. p. 186-189° (756 mm), was 22.0 g (91%). When the synthesis was carried out under quite analogous conditions, but in presence of 0.05 g of aluminum powder, evolution of hydrogen (1.14 liters) ceased after 90 minutes. The yield of triethyliodosilane, b. p. 185-188.5° (757 mm), was again 22.0 g.

Reaction of Tripropylsilane with Iodine in a Carbon Tetrachloride Medium in Presence of Aluminum. Aluminum powder (0.05 g) was added to a solution of 15.8 g (0.1 mole) of tripropylsilane in 50 ml of carbon tetrachloride, and then 15.3 g (0.125 g-atom) of iodine was added in small portions. The mixture was heated until hydrogen ceased to be evolved (two hours); the amount of hydrogen formed was 0.9 liter. Solvent was driven off, and fractional distillation of the residue gave 2.1 g of chlorotripropylsilane, b. p. 198-205° (770 mm) and 13.0 g of iodotripropylsilane, b. p. 229-240° (770 mm).

When this reaction was carried out in absence of aluminum, formation of chlorotripropylsilane was not observed and the yield of iodotripropylsilane, b. p. 230-233.5° (751 mm), was 24.7 g (87%). When carbon tetrachloride was replaced by petroleum ether, the yield of iodotripropylsilane, b. p. 229.5-234.5° (751 mm) was 91%.

Reaction of Tributylsilane with Iodine. Iodine (19.3 g, i. e. 0.125 g-atom) was added in small portions to a solution of 20.0 g (0.1 mole) of tributylsilane in 50 ml of petroleum ether. The mixture was heated until the evolution of hydrogen ceased (2.5 hours); the amount of hydrogen formed was 1.12 liters. Solvent was distilled from the mixture, and the residue was distilled. The yield of tributyliodosilane, b. p. 277.5-288.5° (748 mm) was 29.7 g (91%). In another experiment the reaction mixture was vacuum distilled; the yield of tributyliodosilane, b. p. 123-126° (4 mm) was then 84%.

Reaction of Trihexylsilane with Iodine in Absence of Solvent. Iodine (7.45 g, i. e. 0.06 g-atom) was added in small portions to 14.3 g (0.05 mole) of trihexylsilane. The mixture was heated until hydrogen ceased to be evolved (two hours); the amount of hydrogen formed was 0.52 liter. Vacuum distillation of the product over copper powder in a nitrogen atmosphere and in diffuse light gave 18.3 g (89%) of trihexyliodosilane, b. p. 190-192.5° (5 mm).

Reaction of Triethylsilane with Hydrogen Iodide. A stream of dry hydrogen iodide free from iodine was passed for four hours at the rate of 8-10 bubbles per minute through boiling triethylsilane (21.0 g, i. e. 0.18 mole). In the course of this time 3.9 liters of hydrogen came off and the boiling point of the reaction mixture rose from 108° to 188°. Distillation of the reaction product gave 34.0 g (78.2%) of triethyliodosilane, b. p. 188-193°. After

redistillation the triethyliodosilane had b. p. 191.8° (760 mm); d_4^{20} 1.3512; n_D^{20} 1.4948; $n_F^{20} - n_C^{20}$ 0.0127.

Found %: I 52.60, 52.31. $C_6H_{15}SiI$. Calculated %: I 52.39.

Reaction of Triisopentylsilane with Hydrogen Iodide. A stream of dry hydrogen iodide free from iodine was passed for 7.5 hours through 24.3 g (0.1 mole) of triisopentylsilane heated to 186°. The volume of hydrogen evolved was 2.2 liters. Vacuum distillation of the reaction mixture gave 33.5 g (91%) of iodotriisopentylsilane, b. p. 128-129° (1.5 mm). After redistillation the iodotriisopentylsilane had b. p. 126-126.5° (1 mm); d_4^{20} 1.1177; n_D^{20} 1.4842

Found %: I 34.63, 34.50. $C_{15}H_{33}SiI$. Calculated %: I 34.45.

Bromination of Triethylsilane. A solution of 16.0 g (0.1 mole) of bromine in 20 ml of carbon tetrachloride was added dropwise to a stirred, cooled (0°) solution of 11.6 g (0.1 mole) of triethylsilane in 50 ml of carbon tetrachloride. The added bromine was immediately decolorized until the theoretical amount had been added. There was vigorous evolution of hydrogen bromide, but no hydrogen was evolved.

After removal of solvent, distillation of the reaction mixture gave 17.5 g (90%) of bromotriethylsilane, b. p. 163-164° (736 mm). After redistillation through a column it had b. p. 166.3° (760 mm); d_4^{20} 1.1454; n_D^{20} 1.4573; $n_F^{20} - n_C^{20}$ 0.0088.

Found %: Br 41.11, 41.12. $C_6H_{15}SiBr$. Calculated %: Br 40.94.

SUMMARY

1. It was shown that reaction between trialkylsilanes and elementary iodine proceeds in accordance with the equation: $2R_3SiH + I_2 \rightarrow 2R_3SiI + H_2$.

2. Five trialkyliodosilanes, three of which were previously unknown, were synthesized in yields of 90-94%.

3. It was found that trialkyliodosilanes can be synthesized in high yield also by reaction between trialkylsilanes and hydrogen iodide, which occurs in absence of catalysts.

SYNTHESIS AND REACTIONS OF OXYGEN-CONTAINING ORGANOSILICON COMPOUNDS

COMMUNICATION 4. SYNTHESIS OF THE METHYL, ETHYL, PROPYL, AND ISOPROPYL DIMETHYLPHENYLSILYL ACETALS OF ACETALDEHYDE

M. F. Shostakovsky and Kh. I. Kondratyev

In previous papers Shostakovsky and coworkers [1-4] described the reaction between alkyl vinyl ethers and silanols, which results in the formation of mixed alkyl silyl acetals:

in which R is Alk or Ar.

In the preceding investigation [4] we studied this reaction for an aliphatic-aromatic silanol and the vinyl ethers of butyl alcohol and its isomers with the object of finding the relation between structure and reactivity for these compounds. The present investigation forms a continuation of this work.

We studied the reaction between dimethylphenylsilanol and alkyl vinyl ethers:

in which R = CH_3, C_2H_5, n-C_3H_7, i-C_3H_7.

These investigations showed that the reactivity of the alkyl vinyl ether increases with increase in the size of the radical, when this is of normal structure, for the yields of the corresponding acetals increase in the series:

in which R is $-Si(CH_3)_2C_6H_5$.

When the alkyl radical is branched, the yield of acetal falls with increasing ramification:

$$n\text{-}C_4H_9 > sec\text{-}C_4H_9 > t\text{-}C_4H_9;\quad n\text{-}C_3H_7 > i\text{-}C_3H_7.$$

The structure of the acetals was proved by hydrolysis:

We altered the hydrolysis conditions somewhat from those that we recommended previously [5].

Dimethylphenylsilanol was prepared [6, 7] by the following series of reactions:

We were the first to synthesize dimethylphenylsilanol in this way [4]. Its structure was confirmed both by the synthesis of the acetals enumerated above, and also by its conversion into symmetrical tetramethyldiphenyldisiloxane when distilled under normal pressure:

$$2C_6H_5(CH_3)_2SiOH \rightarrow C_6H_5(CH_3)_2SiOSi(CH_3)_2C_6H_5 + H_2O.$$

The symmetrical tetramethyldiphenyldisilazane that is formed in Stage (b) of the synthesis of the silanol was isolated in high yield and characterized for the first time. It was further confirmed that a mixture of chloro and bromo compounds is indeed formed in the reaction of C_6H_5MgBr with $(CH_3)_2SiCl_2$ [8], and a method for the quantitative determination of bromine in presence of chlorine in halosilanes was developed. The presence of bromo compound as impurity in the chloro compound does not deleteriously affect the course of the synthesis; nevertheless, we prepared some pure chlorodimethylphenylsilane by the method recommended by Dolgov and coworkers for the preparation of trialkylchlorosilanes [9]:

$$C_6H_5(CH_3)_2SiOSi(CH_3)_2C_6H_5 + AlCl_3 \rightarrow 2C_6H_5(CH_3)_2SiCl + AlOCl.$$

It follows that this method for the preparation of trialkylchlorosilanes from the corresponding hexaalkyldisiloxanes may be extended to the preparation of aliphatic-aromatic chlorosilanes.

EXPERIMENTAL

Preparation of Chlorodimethylphenylsilane and Bromodimethylphenylsilane

Dichlorodimethylsilane (258 g, i. e., 2 moles) was added over a period of one hour to a Grignard solution prepared from 52.8 g (2.1 moles) of magnesium, 680 ml of ether, and 314 g of bromobenzene. The liquid products were separated from the precipitate, ether was distilled off, and the residue was vacuum-fractionated. The chlorine and bromine contents of each fraction were determined by a method that is suitable when both halogens are present simultaneously: the overall content of chlorine and bromine was first determined by titration to phenolphthalein of a weighed portion (0.1-0.4 g) of the substance with 0.1 N NaOH (the sample was introduced into a flask containing 20 ml of water and 20 ml of ether); the aqueous layer was then separated, and its bromine

content was determined by the method described by Volyashko and others [10]. From the results of this analysis the contents of chlorodimethylphenylsilane and bromodimethylphenylsilane were calculated. The compositions of the fractions of the reaction product are given in Table 1.

TABLE 1

Fraction	B.p. in °C (p in mm)	Amount (g)	Content (%) of	
			$C_6H_5(CH_3)_2SiCl$	$C_6H_5(CH_3)_2SiBr$
I	71—74 (10)	27.1	81.2	Not determined
II	74—78 (10)	134.0	91.3	8.3
III	78—87 (10)	32.5	83.2	15.6
IV	87—98 (10)	25.6	63.2	33.0
V	98—132 (10)	9.0	15.3	51.7
VI	132—147 (10)	31.0	5.7	2.9

As will be seen from Table 1, Fractions II-IV consist almost entirely of a mixture of chloro- and bromodimethylphenylsilanes and can all equally well be used for the preparation of symmetrical tetramethyldiphenyldisilazane. Fraction II corresponds to chlorodimethylphenylsilane.

According to Lewis [8] chlorodimethylphenylsilane boils at 197° (766 mm) and the corresponding bromo compound at 215° (766 mm). Pure chlorodimethylphenylsilane, which we prepared by a method analogous to that of Dolgov and coworkers [9], had b. p. 195.5-197° (756.2 mm); d_4^{20} 1.0282; n_D^{20} 1.5002; found MR 48.90; calculated MR 49.58.

Found %: Cl 20.7
$C_8H_{11}ClSi$. Calculated %: Cl 20.8

Preparation of Symmetrical Tetramethyldiphenyldisilazane

Ether (260 ml) and Fraction II from the above-described experiment (75 g) were introduced into a three-necked flask fitted with mechanical stirrer, reflux condenser, thermometer, and tube for the passage of dry ammonia. The mixture was maintained at 0° and stirred while a stream of dry ammonia was passed. When reaction was complete, passage of ammonia was discontinued and the reaction mixture was set aside overnight. The liquid reaction products were filtered from the precipitate, ether and ammonia were distilled off, and the residue was vacuum distilled. A fraction amounting to 50 g was collected; it had b. p. 168-170° (9-10 mm) and 128-129° (2-3 mm); d_4^{20} 0.9850; n_D^{20} 1.5384; found MR 90.52; calculated MR 90.57; found M 283.8; calculated M 285.47.

Found %: C 67.92; 67.9; H 8.07; 7.94; N 4.94; 5.06; Si 19.54; 19.67.
$C_{16}H_{23}NSi_2$. Calculated %: C 67.31; H 8.12; N 4.92; Si 19.65.

On the basis of our results the substance isolated was symmetrical tetramethyldiphenyldisilazane (1,1,3,3-tetramethyl-1,3-diphenyldisilazane). It was obtained in 79.8% yield. It is hydrolyzed by water with formation of dimethylphenylsilanol or the condensation product of this compound, i. e., 1,1,3,3-tetramethyl-1,3-diphenyldisiloxane.

Preparation of Dimethylphenylsilanol

The reaction was carried out in a flask provided with mechanical stirrer, reflux condenser, thermometer, and dropping funnel. A mixture of 100 ml of water, a few drops of methyl orange indicator, 250 ml of ether, and 74 g of 1,1,3,3-tetramethyl-1,3-diphenyldisilazane was prepared in the flask and was stirred vigorously while 0.5 N HCl was added dropwise until there was a stable pink coloration, the addition being at such a rate that a yellow color was maintained in the flask for 2.5-3 hours. The ether layer was separated and dried with potassium carbonate. Ether was distilled off, and vacuum distillation of the residue gave 62.6 g of a substance

having b. p. 99-99.5° (10 mm): d_4^{20} 0.9968; n_D^{20} 1.5120; found MR 45.81; calculated MR 45.86; found M 163; calculated M 152.36.

Found %: C 63.08; 62.94; H 7.73; 7.77; Si 18.49; 18.87.
$C_9H_{12}OSi$. Calculated %: C 63.11; H 7.95; Si 18.43.

The results indicate that the product was dimethylphenylsilanol, the yield being 79.25%. Dimethylphenylsilanol is a clear mobile liquid having a pleasant odor reminiscent of turpentine. On standing, it changes slowly with formation of 1,1,3,3-tetramethyl-1,3-diphenyldisiloxane.

Preparation of Symmetrical Tetramethyldiphenyldisiloxane

Dimethylphenylsilanol (30.4 g) was heated at normal pressure in a Wurtz flask with a bunsen flame. A distillate (26.1 g) of b. p. 277-280° (760 mm) or 106-107° (3 mm) was obtained; it had d_4^{20} 0.9086; n_D^{20} 1.5176; found MR 88.40; calculated MR 88.26; found M 284.4; calculated M 286.46.

Found %: C 67.45; 67.30; H 7.66; 7.84; Si 19.50; 19.23.
$C_{16}H_{22}OSi_2$. Calculated %: C 67.08; H 7.74; Si 19.59.

The results correspond to symmetrical tetramethyldiphenyldisiloxane (1,1,3,3-tetramethyl-1,3-diphenyldisiloxane), the yield being 91.28%. The literature [8] gives b. p. 110-111° (1 mm); d_4^{20} 0.9763; n_D^{20} 1.5122.

Preparation of Alkyl Dimethylphenylsilyl Acetals

a) Acetaldehyde Dimethylphenylsilyl Methyl Acetal $CH_3-CH(OCH_3)OSi(CH_3)_2C_6H_5$. At −8° to −10° a mixture was prepared of 7.7 g of dimethylphenylsilanol, 46.1 g of freshly distilled methyl vinyl ether (b. p. 5.5°; n_D^{20} 1.3730; d_4^{20} 0.7725), and one drop of 30% hydrochloric acid in an ampoule cooled in an ice-salt mixture. The ampoule was sealed and kept in a metal sleeve filled with water, which was maintained at 20° for 20 minutes and then at 30° for six hours. The ampoule was cooled and opened. The reaction products were neutralized with potassium carbonate and vacuum distilled from a Favorsky flask. The product was 7 g of a substance having b. p. 66-66.5° (1 mm); d_4^{20} 0.9694; n_D^{20} 1.4802; found MR 61.5; calculated MR 61.74; found M 209.16; calculated M 210.31.

Found %: C 63.17; 63.09; H 8.28; 8.49; Si 14.14; 14.06.
$C_{11}H_{18}OSi$. Calculated %: C 62.82; H 8.63; Si 13.34.

The results indicate that the product was acetaldehyde dimethylphenylsilyl methyl acetal, the yield being 65.9%. The dimethylphenylsilyl methyl acetal is a clear mobile liquid having a feeble ethereal odor; it is readily soluble in organic solvents.

b) Acetaldehyde Dimethylphenylsilyl Ethyl Acetal $CH_3-CH(OC_2H_5)OSi(CH_3)_2C_6H_5$. A mixture of 12 g ethyl vinyl ether (b. p. 36°; n_D^{20} 1.3779; d_4^{20} 0.7525) and 19 g of dimethylphenylsilanol was prepared in a 100-ml flask fitted with thermometer and reflux condenser and cooled with ice water. The mixture was cooled to a temperature of from −5° to −6°, and one drop of 30% hydrochloric acid was added. The cooling bath was removed and, when the temperature reached 34°, heating was applied for two hours, so that the temperature gradually rose to 42°. The reaction products were neutralized with potassium carbonate and subjected to fractional distillation. The fraction collected, amounting to 21.4 g, had b. p. 76-77° (2.5-3 mm); d_4^{20} 0.9542; n_D^{20} 1.4742; found MR 65.90; calculated MR 66.37; found M 220.6; calculated M 224.37.

Found %: C 64.35; 64.15; H 8.89; 8.95; Si 12.35; 12.13.
$C_{12}H_{20}OSi$. Calculated %: C 64.24; H 8.89; Si 12.51.

The results indicated that the product was acetaldehyde dimethylphenylsilyl ethyl acetal, obtained in 76.5% yield. The dimethylphenylsilyl ethyl acetal is a colorless mobile almost odorless liquid; it is readily soluble in organic solvents.

In a similar way we prepared the following acetals:

c) Acetaldehyde Dimethylphenylsilyl Propyl Acetal $CH_3CH(OCH_2CH_2CH_3)OSi(CH_3)_2C_6H_5$. For this we obtained b. p. 78-79° (2 mm); d_4^{20} 0.9439; n_D^{20} 1.4742; found MR 70.93; calculated MR 71.00; found M 231.8; calculated M 238.37; yield 86.5%.

Found %: C 65.41; 65.22; H 9.31; 9.15; Si 12.24; 12.30.
$C_{13}H_{22}O_2Si$. Calculated %: C 65.50; H 9.30; Si 11.77.

d) Acetaldehyde Dimethylphenylsilyl Isopropyl Acetal $CH_3CH(O{-}CH(CH_3)_2)OSi(CH_3)_2C_6H_5$. For this we obtained b. p. 74-76° (2 mm); d_4^{20} 0.9410; n_D^{20} 1.4737; found MR 71.10; calculated MR 71.00; found M 230.6; calculated M 238.37; yield 82.6%.

Found %: C 65.84; 65.70; H 9.49; 9.52; Si 11.74; 11.72.
$C_{13}H_{22}O_2Si$. Calculated %: C 65.50; H 9.30; Si 11.77.

Hydrolysis of Acetals

In order to hydrolyze the acetals, mixtures of 25 ml of 0.1 N sodium bisulfite, 10 ml of 2% sulfuric acid, and 0.2-0.4 g of the acetal were shaken in 100-ml ampoules for 6-8 hours at 18-20°. The excess of bisulfite was titrated with 0.1 N iodine. The results of the hydrolysis are shown in Table 2. The acetals investigated differed in the readiness with which they were hydrolyzed, the extent of hydrolysis diminishing in the following order: $CH_3 > i\text{-}C_3H_7 > C_2H_5 > n\text{-}C_3H_7$.

TABLE 2

Formula of acetal	Duration of shaking (hours)	Extent of of hydrolysis of acetal (%)
$CH_3CH(OCH_3)OSi(CH_3)_2C_6H_5$	6	93.01
$CH_3CH(OC_2H_5)OSi(CH_3)_2C_6H_5$	6	90.44
	8	93.58
$CH_3CH(OCH_2CH_2CH_3)OSi(CH_3)_2C_6H_5$	6	69.39
	6	71.76
	8	74.76
	8	75.18
$CH_3CH(O{-}CH(CH_3)_2)OSi(CH_3)_2C_6H_5$	6	91.14
	8	94.92

SUMMARY

1. The investigation established the effect of the structure and composition of the alkyl radical of an alkyl vinyl ether on the reactivity of the ether in the reaction of silyl acetal formation.

2. The following compounds were synthesized and characterized for the first time: a) methyl, ethyl, propyl, and isopropyl dimethylphenylsilyl acetals of acetaldehyde; b) 1,1,3,3-tetramethyl-1,3-diphenyldisilazane.

3. Chlorodimethylphenylsilane was prepared by a new method.

4. A new method was proposed for the determination of halogens in mixtures of chloro- and bromo-silanes.

5. The method of hydrolyzing acetals was improved.

STEREOCHEMISTRY OF CYCLIC COMPOUNDS

COMMUNICATION 11. STEREOCHEMISTRY OF 1,2,3,5,6,7,8,8a-OCTAHYDRO-1,2-NAPHTHALENEDICARBOXYLIC ACIDS

I. N. Nazarov, V. F. Kucherov and V. M. Andreev

In the preceding communication [1] we showed that in the condensation of maleic anhydride with 1-vinyl-1-cyclohexene two isomeric cis anhydrides (I) and (X) are formed, the difference between them lying in the disposition of hydrogen at C-8a.

(I) (X)

In order to confirm their configurations, and also to investigate the stereochemistry of 1,2,3,5,6,7,8,8a-octahydro-1,2-naphthalenedicarboxylic acids, we studied the isomerization of cis-1,2,3,5,6,7,8,8a-octahydro-1,2-naphthalenedicarboxylic acids into the corresponding acids having a trans arrangement of the carboxyls. For this purpose it was most convenient to use the monoesters of these acids, which, when boiled with sodium methoxide in order to induce isomerization at the esterified carboxyl, should give the corresponding trans isomers having a definite spatial configuration of the carboxy groups. We prepared monoesters of the isomeric cis-1,2,3,5,6,7,8,8a-octahydro-1,2-naphthalenedicarboxylic acids by methods that we have developed [2]: reaction of anhydrides with methanol and partial hydrolysis of diesters [2]. It was found that for syn-cis- and anti-cis-1,2,3,5,6,7,8,8a-octahydro-1,2-naphthalenedicarboxylic acids these reactions are sterically specific, and owing to the steric nonequivalence of the carboxyls they enable the two isomeric monoesters to be prepared.

Thus, treatment of the syn-cis anhydride (I) with methanol gives a high yield of the syn-cis monoester (II), in which the carboxyl at C-2 is esterified; on the other hand, hydrolysis of the syn-cis diester (III) with one molecular equivalent of caustic potash gives mainly the isomeric syn-cis monoester (IV), in which the carboxyl at C-1 is esterified. The structures of these monoesters were proved by hydrogenation to the corresponding saturated cis-syn-cis monoesters (V) and (VI), which were converted by the Arndt-Eistert reaction into the isomeric carboxydecahydronaphthaleneacetic acids (VII) and (VIII), the dehydrogenation of which over palladized charcoal gave 1- and 2-methylnaphthalenes. As in the case of analogous compounds [1, 3], hydrogenation of the isomeric monoesters (II) and (IV) proceeds in a sterically selective fashion from the side opposite to the carboxyls with formation of the saturated monoesters (V) and (VI) of the cis-syn-cis series.

In this way, the monoester (II) was converted into cis-2-carboxydecahydro-1-naphthaleneacetic acid (VII), dehydrogenation of which gave 1-methylnaphthalene. Similarly, the isomeric monoester (IV) gave cis-1-carboxydecahydro-2-naphthaleneacetic acid (VIII), which gave 2-methylnaphthalene on dehydrogenation.

These results show, in complete agreement with molecular models, that in the acid (IX) the carboxyl at C-2 is the less effectively screened.

By the method described above we prepared also the isomeric monoesters of the anti-cis series. Treatment of the anti-cis anhydride (X) with methanol gave mainly the crystalline monoester (XI), which hydrogenated in a sterically selective fashion into the saturated trans-anti-cis monoester (XII), m. p. 86°. Selective hydrolysis of the anti-cis diester (XIII) with one molecular equivalent of caustic potash gave the liquid monoester (XIV), the hydrogenation of which gave the crystalline trans-anti-cis monoester (XV), m. p. 103°.

The isomeric monoesters (II), (IV), (XI), and (XIV) so obtained were subjected to trans isomerization with sodium methoxide at the boil, a process that is known to proceed only at esterified carboxyls and is a sterically specific method for the synthesis of trans-dicarboxylic acids. It was found that the monoesters (IV) and (XI) gave the same anti-trans acid (XVI), which formed the anhydride (XVIII) and the diester (XIX); on the other hand, the monoesters (II) and (XIV) gave the isomeric syn-trans acid (XVII), which formed the corresponding anhydride (XX) and diester (XXI).

It is not difficult to see that this can occur only when the corresponding monoesters (IV) and (XI), and also (II) and (XIV), are esterified on different carboxyls and are also epimeric with respect to hydrogen at C-8a. It follows that the original isomeric cis anhydrides (I) and (X) have the same respective configurations. The isomeric anti-trans- and syn-trans-1,2,3,5,6,7,8,8a-octahydro-1,2-naphthalenedicarboxylic acids (XVI) and (XVII), and also their anhydrides (XVIII) and (XX) were found to have low thermal stability, each being isomerized in high yield to the same anti-cis anhydride (X) when heated for one hour at 250°.

The anti-trans acid (XVI) and syn-trans acid (XVII) were prepared also by direct diene synthesis from 1-vinyl-1-cyclohexene and dimethyl fumarate. The liquid adduct, which was formed in 88% yield, was found to be a mixture of isomeric trans diesters (XIX) and (XXI), from which hydrolysis and fractional crystallization gave small amounts of the pure trans acids (XVI) and (XVII). These acids are very close in solubility, and their separation is extremely difficult. However, from melting-point determinations on various mixtures of the pure isomers it was shown that in this diene synthesis the two possible trans isomers (XIX) and (XXI) are formed in the proportions of approximately 1 : 1 [4].

An examination of molecular models enabled us to obtain a clear picture of the character of the changes occuring and the spatial configurations of the isomeric trans acids (XVI) and (XVII). The models show that the isomerization of the syn-cis monoester (IV) at the esterified carboxyl at C-1 and of the anti-cis monoester (XI) at the esterified carboxyl at C-2 should occur very readily owing to the conversion of a polar (p) carboxyl group into an equatorial (e), the same anti-trans acid (XVI)—having a diequatorial (trans) arrangement of carboxyls – being formed in each case.

In the case of the isomeric monoesters (II) and (XIV), reaction with sodium methoxide should occur at the equatorial carboxyls and result in a dipolar (trans) disposition of the carboxyls. Since the (p-p) arrangement of the ortho carboxyls is energetically unfavorable and trans-ortho-dicarboxylic acids exist only in the (e-e) form [7], in the course of the isomerization of the monoesters (II) and (XIV) bending of the cyclohexene ring must occur with formation in each case of the syn-trans acid (XVII) having an (e-e) arrangement of carboxyls, by virtue of which it can readily give the trans anhydride (XX).

Such spatial configurations for anti-trans- and syn-trans-1,2,3,5,6,7,8,8a-octahydro-1,2-naphthalenedicarboxylic acids (XVI) and (XVII) are in full accord with their formation in the diene condensation of 1-vinyl-1-cyclohexene with fumaric ester, since this condensation, which can proceed with equal probability in either of the possible directions a or b, can result only in the formation of the stereoisomers (XVI) and (XVII). This is in accord also with the thermal isomerization of the trans acids (XVI) and (XVII) into the anti-cis anhydride (X), which has the more energetically favorable (e-e) arrangement of ortho substituents and (e-p) arrangement of meta substituents.

Further study of some of the chemical reactions of all of the isomeric 1,2,3,5,6,7,8,8a-octahydro-1,2-naphthalenedicarboxylic acids gave us further confirmation of the proposed spatial configurations.

EXPERIMENTAL*

syn-cis Monoester (II)

The syn-cis anhydride (I) (12.0 g) was boiled for one hour with absolute methanol (60 ml). Methanol was distilled off under reduced pressure, and washing of the crystalline product on the filter with 60 ml of absolute ether gave 7.8 g of pure syn-cis monoester (II), m. p. 138-139°. Recrystallization from a large volume of ether did not affect the melting point. A further 0.7 g of the syn-cis monoester (II), m. p. 136-138°, could be isolated from the mother liquor by distilling off ether and recrystallizing the residue twice from ether.

Found %: C 65.78; 65.68; H 7.62; 7.52.
$C_{13}H_{18}O_4$. Calculated %: C 65.52; H 7.53.

cis-syn-cis Monoester (V)

The syn-cis monoester (II) (7.8 g) was dissolved in absolute methanol (80 ml) and hydrogenated over 0.1 g of platinum oxide. One molecular equivalent of hydrogen (740 ml) was absorbed. The catalyst was filtered off, methanol was distilled off, and the crystalline residue was washed on the filter with ether. The product was 7.2 g of the cis-syn-cis monoester (V), m. p. 140-142°. When crystallized from a 6 : 1 mixture of ether and acetone it separated in large well-formed crystals having a constant melting point of 143-144°. No other crystalline product could be isolated from the ethereal mother liquor.

Found %: C 65.12; 65.23; H 8.41; 8.49.
$C_{13}H_{20}O_4$. Calculated %: C 65.01; H 8.33.

cis-syn-cis-2-Carboxydecahydro-1-naphthaleneacetic Acid (VII)

Oxalyl chloride (2 ml) was added to a solution of 2.0 g of the cis-syn-cis monoester (V) in 20 ml of absolute benzene, and the mixture was allowed to stand at room temperature for three hours and then heated for 30 minutes at 50°. Benzene was distilled off under reduced pressure, the acid chloride that remained was dissolved in 10 ml of absolute ether, and with cooling and shaking a solution of 2.5 g of pure dry diazomethane in 150 ml of absolute ether was added dropwise. The solution was set aside at room temperature overnight, and ether was then distilled off under reduced pressure. The residue of liquid diazo ketone was dissolved with cooling in 40 ml of absolute methanol, 0.5 g of freshly prepared silver oxide was added, and the mixture was boiled for six hours. Silver oxide was filtered off, methanol was distilled off, and vacuum distillation of the residue gave 1.55 g of a diester (b. p. 141-143° (2 mm); n_D^{20} 1.4885), which was hydrolyzed by boiling it with 6.5 ml of 20% caustic potash solution for four hours. On acidification an oil separated which crystallized almost completely after a time. Crystallization from 50% aqueous acetone gave 0.5 g of pure cis-syn-2-carboxydecahydro-1-naphthaleneacetic acid (VII) melting constantly at 199-200°.

* All melting points are corrected.

Found %: C 64.96; 65.03; H 8.35; 8.41.
$C_{13}H_{20}O_4$. Calculated %: C 65.01; H 8.33.

Dehydrogenation of the Acid (VII)

A mixture of 0.8 g of cis-syn-cis-2-carboxydecahydro-1-naphthaleneacetic acid (VII), 40 ml of cryoscopic benzene, and 0.5 g of palladized charcoal (10% Pd) was heated in an autoclave in an atmosphere of nitrogen (20 atm) at 360-370° for 20 hours. The catalyst was filtered off, benzene was distilled off, and distillation of the residue at atmospheric pressure gave 0.26 g of the dehydrogenation product, b. p. 210-215° (n_D^{20} 1.5760); its picrate had m. p. 139-140°, undepressed by admixture of the picrate of 1-methylnaphthalene.

syn-cis Monoester (IV)

The syn-cis diester (III) (25.3 g) was added to a solution of 5.5 g of caustic potash in 260 ml of methanol and 90 ml of water, and the mixture was boiled for two hours. Methanol was distilled off under reduced pressure, and the aqueous solution was extracted with ether and acidified with hydrochloric acid. The resulting crystalline product was filtered off and washed with water. The yield of the syn-cis monoester (IV), m. p. 117-121°, was 20.1 g. After crystallization from ether or from a 1 : 1 mixture of diethyl ether and petroleum ether, the syn-cis monoester (IV) had a constant melting point of 125-126°.

Found %: C 65.50; 65.45; H 7.60; 7.50.
$C_{13}H_{20}O_4$. Calculated %: C 65.52; H 7.53.

When the neutral ether extract was distilled, 2.2 g of the original syn-cis diester (III) was obtained.

cis-syn-cis Monoester (VI)

The syn-cis monoester (IV) (6.7 g) was dissolved in absolute methanol (70 ml) and hydrogenated in presence of 0.1 g of platinum oxide. One molecular equivalent of hydrogen (635 ml) was absorbed. The catalyst was filtered off, methanol was distilled off under reduced pressure, and the crystalline residue was washed on the filter with a little ether. The yield of cis-syn-cis monoester (VI), m. p. 121-123°, was 6.4 g. After crystallization from ether it was obtained as large clear crystals melting constantly at 120-121°; a mixture with the original monoester (IV) had a greatly depressed melting point (90-105°).

Found %: C 65.06; 65.04; H 8.35; 8.47.
$C_{13}H_{20}O_4$. Calculated %: C 65.01; H 8.33.

cis-syn-cis-1-Carboxydecahydro-2-naphthaleneacetic Acid (VIII)

The cis-syn-cis monoester (VI) (2 g) was treated similarly to the isomeric monoester (V), and reaction with oxalyl chloride and treatment of the resulting acid chloride with excess of dry diazomethane in ether gave a diazo ketone, which was isomerized by boiling it in alcoholic solution with 1 g of silver oxide for eight hours. Distillation gave 1.36 g of the diester (b. p. 151-153° (at 4mm); n_D^{18} 1.4920), which was hydrolyzed by boiling it with 7 ml of 20% caustic potash solution for four hours. Acidification gave a viscous oil, which rapidly crystallized. Two crystallizations from 50% aqueous acetone gave 0.6 g of pure cis-syn-1-carboxydecahydro-2-naphthaleneacetic acid (VIII), melting constantly at 218-220°.

Found %: C 65.04; 65.03; H 8.28; 8.38.
$C_{13}H_{20}O_4$. Calculated %: C 65.01; H 8.33.

Dehydrogenation of the Acid (VIII)

A mixture of 1.15 g of cis-syn-cis-1-carboxydecahydro-2-naphthaleneacetic acid (VIII), 0.5 g of palladized charcoal (10% Pd), and 20 ml of benzene was heated in an atmosphere of nitrogen in an autoclave at 360-370° for 20 hours. Distillation at atmospheric pressure gave 0.45 g of the dehydrogenation product (b. p. 215-225°; n_D^{20} 1.5790); its picrate had m. p. 112-113°, undepressed by admixture of the picrate of 2-methylnaphthalene.

anti-cis Monoester (XI)

A solution of 6.3 g of the anti-cis anhydride (X) in 60 ml of absolute methanol was boiled for one hour. Methanol was distilled off under reduced pressure, and the liquid residue was dissolved in a little petroleum ether. After two days the solution gave 3.8 g of crystals, m. p. 130-134°. Crystallization from a mixture of acetone and petroleum ether gave 3.5 g of pure anti-cis monoester (XI), melting constantly at 136-137°.

Found %: C 65.53; 65.62; H 7.61; 7.84.
$C_{13}H_{20}O_4$. Calculated %: C 65.52; H 7.53.

trans-anti-cis Monoester (XII)

The anti-cis monoester (XI) (4 g) was dissolved in absolute methanol (40 ml) and hydrogenated in presence of a platinum catalyst. After one molecular equivalent of hydrogen (380 ml) had been absorbed, the methanol was distilled off under reduced pressure. The liquid residue crystallized when treated with petroleum ether. The product was 3.5 g of trans-anti-cis monoester, m. p. 82-83.5°, which, after being crystallized from a mixture of petroleum ether with a little diethyl ether, melted constantly at 84-85°. No other hydrogenation products could be isolated.

Found %: C 64.75; 64.78; H 8.48; 8.50.
$C_{13}H_{20}O_4$. Calculated %: C 65.01; H 8.33.

anti-cis Monoester (XIV)

The anti-cis diester (XIII) (4 g) was added to a solution of 0.8 g of caustic potash in 14 ml of water and 40 ml of methanol, and the mixture was boiled for two hours. Methanol was distilled off under reduced pressure, and the aqueous part was extracted with ether and acidified with hydrochloric acid. The liquid hydrolysis product, which did not crystallize on standing, was extracted with ether, and the extract was dried with sodium sulfate. Removal of ether by distillation gave 3 g of liquid anti-cis monoester (XIV), which we did not succeed in purifying, since it did not crystallize when cooled and treated with various solvents.

trans-anti-cis Monoester (XV)

The above-described liquid anti-cis monoester (XIV) (1.5 g) was dissolved in absolute methanol (20 ml) and hydrogenated over platinum oxide. One molecular equivalent of hydrogen (145 ml) was absorbed. The liquid hydrogenation product that remained after removal of methanol gradually crystallized when a mixture with petroleum ether was vacuum distilled. The crystalline product was filtered off and washed with petroleum ether. The yield of pure trans-anti-cis monoester (XV), m. p. 100-102°, was 0.95 g. After one crystallization from petroleum ether it melted constantly at 102-103°.

Found %: C 65.27; 65.20; H 8.55; 8.52.
$C_{13}H_{20}O_4$. Calculated %: C 65.01; H 8.33.

anti-trans Dicarboxylic Acid (XVI)

a) The syn-cis monoester (IV) (0.8 g) was added to a solution of 1.9 g of sodium in 50 ml of absolute methanol, and the mixture was boiled for 15 hours. Methanol was distilled off under reduced pressure, and the residue was dissolved in 35 ml of water. The solution was filtered and evaporated in a porcelain dish on a water bath to a thick slurry. The precipitate of salts was filtered off, washed with absolute methanol, and dissolved in 15 ml of water. The solution was acidified with hydrochloric acid, and the crystals that separated were filtered off. The product was 0.7 g of the anti-cis acid (XVI), m. p. 190-192°. After one crystallization from 25% aqueous acetone the acid melted constantly at 195-196°.

Found %: C 64.34; 64.25; H 7.14; 7.28.
$C_{12}H_{20}O_4$. Calculated %: C 64.27; H 7.19.

b) The anti-cis monoester (XI) (1 g) was added to a solution of 2.4 g of sodium in 8.5 ml of absolute methanol, and the mixture was boiled for 15 hours. Methanol was distilled off under reduced pressure, and the residue was dissolved in 30 ml of water. The solution was filtered and evaporated down in a dish on a water bath. Treatment as before gave 0.65 g of pure anti-trans acid (XVI), m. p. 194-195°, identical with the sample obtained in the previous experiment.

syn-trans Dicarboxylic Acid (XVII)

a) The syn-cis monoester (II) (5.6 g) was added to a solution of 11.5 g of sodium in 330 ml of absolute methanol, and the mixture was boiled for 16 hours. Methanol was distilled off under reduced pressure, and the residue was dissolved in 275 ml of water. The solution was filtered and evaporated in a porcelain dish on a water bath. The salts were filtered off, washed with absolute methanol, and dissolved in 100 ml of water. The solution was filtered and acidified. The oil that separated rapidly solidified. The product was 4.5 g of the syn-trans acid (XVII), m. p. 210-212°, which melted constantly at 215-216° after crystallization from a little acetone.

Found %: C 64.33; 64.26; H 7.13; 7.30.
$C_{12}H_{16}O_4$. Calculated %: C 64.27; H 7.19.

b) The liquid anti-cis monoester (XIV) (1.5 g) was added to a solution of 2.5 g of sodium in 90 ml of absolute methanol, and the solution was boiled for 15 hours. The crystalline product obtained by treatment as before was washed on the filter with 30% acetone and gave 0.75 g of the syn-trans acid (XVII), m. p. 210-212°, raised to 215-216° by crystallization from acetone; it was identical with the product of the previous experiment.

anti-trans Anhydride (XVIII)

A mixture of 0.9 g of the anti-trans acid (XVI) and 9 ml of acetyl chloride was boiled for 45 minutes. Acetyl chloride was distilled off, and the liquid residue was crystallized by repeatedly evaporating it down under reduced pressure with a mixture of benzene and petroleum ether. The crystals were washed on the filter with a 1 : 5 mixture of diethyl ether and petroleum ether. The product was 0.6 g of the anti-trans anhydride (XVIII), m. p. 80-82°, which melted constantly at 85-86° after crystallization from a 1 : 4 mixture of diethyl ether and petroleum ether.

Found %: C 69.88; 69.70; H 6.74; 6.96.
$C_{12}H_{14}O_3$. Calculated %: C 69.88; H 6.84.

Hydrolysis of the anti-trans anhydride (XVIII) with 5% caustic soda solution gave a quantitative yield of the original anti-trans acid (XVI), m. p. 195-196°.

anti-trans Diester (XIX)

An ethereal solution of 1.5 g of the anti-trans acid (XVI) was treated with excess of diazomethane, and distillation gave 1.4 g of the anti-trans diester (XIX), b. p. 131-132° (2 mm); n_D^{20} 1.4936; d_4^{20} 1.1162; Found MR 65.73; Calculated MR 65.29.

Found %: C 66.60; 66.50; H 7.95; 8.00.
$C_{14}H_{20}O_4$. Calculated %: C 66.65; H 7.99.

syn-trans Anhydride (XX)

A mixture of 1.1 g of the syn-trans acid (XVII) and 10 g of acetyl chloride was boiled for one hour. The oily substance remaining after removal of acetyl chloride by distillation crystallized when repeatedly evaporated down under reduced pressure in admixture with benzene and petroleum ether. The product was 0.75 g of the syn-trans anhydride (XX), m. p. 114-117°, which melted constantly at 116-117° after crystallization from absolute ether.

Found %: C 70.09; 70.18; H 6.98; 7.07.
$C_{12}H_{14}O_3$. Calculated %: C 69.88; H 6.84.

Hydrolysis of this anhydride with 5% caustic soda solution gave the original syn-trans acid (XVII), m. p. 215-216°.

syn-trans Diester (XXI)

A suspension of 0.5 g of the syn-trans acid (XVII) in ether was treated with excess of diazomethane, and removal of ether by distillation gave the crystalline syn-trans diester (XXI), m. p. 60-62°. After crystallization from a little petroleum ether, (XXI) melted constantly at 61-62°.

Found %: C 66.73; 66.76; H 7.96; 7.95.
$C_{14}H_{20}O_4$. Calculated %: C 66.65; H 7.99.

Condensation of 1-Vinyl-1-cyclohexene with Dimethyl Fumarate

A mixture of 10.4 g of dimethyl fumarate, 20 g of 1-vinyl-1-cyclohexene (2.5-fold excess), and 30 ml of benzene was heated in a sealed steel tube at 210-215° for 3.5 hours (in a nitrogen atmosphere and in presence of pyrogallol). Benzene was distilled off, and vacuum distillation of the residue gave 18 g of liquid adduct, b. p. 153-163° (6 mm). Redistillation with a column gave 16 g of a mixture of the trans diesters (XIX) and (XXI), b. p. 158-162° (7 mm) and n_D^{20} 1.4930. The yield was 88% on the amount of fumaric ester taken.

This mixture of trans diesters (10 g) was hydrolyzed for 8 hours at the boil with 30% caustic potash solution (50 ml). A small amount of undissolved material (dimer of vinylcyclohexene) was extracted with ether, and the aqueous solution was treated with charcoal and filtered. The solution was acidified, and an oil separated which gradually solidified; it was washed with water and vacuum dried. The product was 7.5 g of a mixture of the trans acids (XVI) and (XVII), m. p. 162-175°. This mixture was treated with 50 ml of ether, and the undissolved portion was filtered off (Fraction A, 2.8 g, m. p. 178-181°). The ethereal mother liquor was evaporated down to a volume of 15 ml and was then diluted with an equal amount of petroleum ether. Some crystals were precipitated (Fraction B, 2.7 g, m. p. 179-182°).

Fraction A was treated with 60 ml of boiling ether, and the undissolved part was filtered off; the product, amounting to 0.6 g, melted at 207-210°, and crystallization of this from acetone gave 0.4 g of pure syn-trans dicarboxylic acid (XVII), m. p. 214-215°, undepressed by admixture of the substance already obtained by the isomerization of the monoesters (II) and (XIV). Fraction B was recrystallized twice from a little of a 1 : 1 mixture of acetone and petroleum ether, and 0.5 g of crystals, m. p. 189-191°, was obtained. Recrystallization from a little acetone gave 0.4 g of pure anti-trans dicarboxylic acid (XVI), m. p. 193-194°, undepressed by admixture of the substance obtained by the isomerization of the monoesters (IV) and (XI).

Mixtures of the pure isomeric trans acids (XVI) and (XVII) in the proportions 1 : 1, 1 : 2, and 2 : 1 melted respectively at 163-173°, 177-180°, and 180-183°.

Thermal Isomerization of the trans Dicarboxylic Acids (XVI) and (XVII)

a) The anti-trans acid (XVI) (0.52 g) was heated in a current of nitrogen for one hour at 250° and then vacuum distilled. The product was 0.37 g of the anti-cis anhydride (X), b. p. 180-182° (9 mm) and n_D^{20} 1.5230. After hydrogenation over platinum, 0.25 g of the trans-anti-cis anhydride of m. p. 126-127° obtained previously [1] was obtained.

b) In a similar way, 0.44 g of the syn-trans acid (XVII) was heated for one hour at 250°, and distillation of the product gave 0.32 g of the liquid anti-cis anhydride (X), b. p. 189-191° (12 mm) and n_D^{20} 1.5235, the hydrogenation of which gave 0.2 g of the above-described trans-anti-cis anhydride, m. p. 127°.

SUMMARY

1. By the addition of methanol to the isomeric cis anhydrides (I) and (X) and by the partial hydrolysis of the cis diesters (III) and (XIII), all four of the isomeric monoesters (II), (IV), (XI), and (XIV) of syn-cis- and anti-cis-1,2,3,5,6,7,8,8a-octahydro-1,2-naphthalenedicarboxylic acids were prepared.

2. It was shown that the isomerization of the monoesters (IV) and (XI) by means of sodium methoxide gives the anti-trans acid (XVI), whereas similar treatment of the monoesters (II) and (XIV) gives the isomeric syn-trans

acid (XVII). This proves the configurations of the isomeric cis anhydrides (I) and (X) as epimers with respect to the hydrogen at C-8a.

3. 1-Vinyl-1-cyclohexene was condensed with fumaric ester, and an 88% yield of a mixture of equal amounts of the anti-trans and syn-trans diesters (XIX) and (XXI) was obtained.

4. An examination of molecular models has enabled us to explain the spatial configurations of all four isomeric 1,2,3,5,6,7,8,8a-octahydro-1,2-naphthalenedicarboxylic acids and some of their reactions.

ACETYLENE DERIVATIVES

COMMUNICATION 175. ALCOHOLYSIS OF 2-CYANOETHYL ETHERS OF ACETYLENIC ALCOHOLS

I. N. Nazarov and G. A. Shvekhgeimer

There are no references in the literature to the alcoholysis of 2-cyanoethyl ethers of acetylenic alcohols. The method that we have developed for the alcoholysis of bis-2-cyanoethyl ethers of glycols [1] was found to be inapplicable for this case: concentrated sulfuric acid completely resinifies 2-cyanoethyl ethers of acetylenic alcohols. The alcoholysis of these ethers was successfully accomplished by boiling them with methanol saturated with dry hydrogen chloride. Their alcoholysis can be effected smoothly also by the action of a saturated solution of hydrogen chloride in methanol at room temperature.

When 2-cyanoethyl ethers of secondary acetylenic alcohols (I) are boiled with methanol saturated with hydrogen chloride, the methyl esters (II) are obtained in 75-92% yield:

(I) (II)

R = CH_3, C_2H_5, n-C_3H_7, i-C_3H_7.

When 2-cyanoethyl ethers of tertiary acetylenic alcohols (III) are alcoholyzed under the same conditions, the yields of methyl esters (IV) fall progressively from 97% to 55% as the size of the radical in the alcohol increases. However, if this reaction is carried out under milder conditions – at room temperature for 24-60 hours – methyl esters (IV) carrying large radicals (R = n-C_6H_{13}, n-C_8H_{17}) may also be prepared in yields of more than 90%.

(III) (IV)

R = CH_3, C_2H_5, n-C_3H_7, n-C_6H_{13}, n-C_8H_{17}.

Increase in the size of both radicals in 2-cyanoethyl ethers of tertiary acetylenic alcohols (V) has a still greater deleterious effect on the alcoholysis, the yields of the methyl esters (VI) being only 45-32% when the reaction is carried out with heating and 75-65% when the reaction is carried out at room temperature.

(V) (VI)

R = C_2H_5, n-C_3H_7.

The alcoholysis of the 2-cyanoethyl ethers of 1-ethynylcyclopentanol (VII) (proceeds at room temperature), 1-ethynylcyclohexanol (IX; R = H), and 2-ethynyldecahydro-2-naphthol (XI) proceeds smoothly with formation of the methyl ethers (VIII), (X; R = H), and (XII) in yields of more than 90%. Alcoholysis under the same conditions (with heating) of the 2-cyanoethyl ether of 1-ethynyl-2-methylcyclohexanol (IX; R = CH_3) gives the methyl ester (X; R = CH_3) in a yield of only about 60%.

(VII) (VIII)

(IX) (X)

R = H, CH_3.

(XI) (XII)

The 2-cyanoethyl ethers (XIII) and (XV) of heterocyclic acetylenic alcohols are readily converted by treatment with boiling methanolic hydrogen chloride into the methyl esters (XIV) and (XVI) in yields of 70-80%.

(XIII) (XIV)

(XV) (XVI)

The alcoholysis of the 2-cyanoethyl ethers (XVII) and (XIX) also proceeds smoothly: the corresponding methyl esters (XVIII) and (XX) are formed in yields of more than 80-90%.

(XVII) (XVIII)

R = CH_3, C_2H_5.

(XIX) (XX)

Instead of the diethylamine residue, the piperidine residue may be introduced:

(XXI) (XXII)

Alcoholysis of the 2-cyanoethyl ether of 3-isopropyl-4-methyl-1-pentyn-3-ol (XXIII) under mild conditions (without application of heat) results in the formation of the methyl ester (XXIV) in 58% yield:

(XXIII) (XXIV)

EXPERIMENTAL

Alcoholysis of 2-Cyanoethyl Ethers of Acetylenic Alcohols at the Boil

1) A mixture of 6 g of the 2-cyanoethyl ether of 3-butyn-2-ol (I; R = CH_3), b. p. 83-84° (12 mm), and 90 ml of methanol containing 20 g of dry hydrogen chloride was boiled under reflux in a round-bottomed flask for two hours in a water bath. The reflux condenser was replaced by a Wurtz still head, and methanol was removed at 50-60° under the vacuum of the water pump. Water (150 ml) was stirred with the residue, which was then saturated with potassium carbonate and extracted with ether. The ether extract was dried with magnesium sulfate and vacuum-fractionated. The product was 5.7 g of the methyl ester (II; R = CH_3), b. p. 85-86° (15 mm); n_D^{20} 1.4326; d_4^{20} 1.0005; found MR 40.19; calculated MR 40.38.

Found %: C 61.00; 61.04; H 7.69; 7.82.
$C_8H_{12}O_3$. Calculated %: C 61.54; H 7.69.

The alcoholysis of the 2-cyanoethyl ethers of the other acetylenic alcohols was carried out under similar conditions.

2) Reaction was between 10 g of the 2-cyanoethyl ether of 1-pentyn-3-ol (I; R = C_2H_5), b. p. 104-105° (15 mm), and 100 ml of methanol containing 18.5 g of dry hydrogen chloride. The product was 11 g of the methyl ester (II; R = C_2H_5), b. p. 95-96° (14 mm); n_D^{20} 1.4347; d_4^{20} 0.9822; found MR 45.14; calculated MR 44.99.

Found %: C 63.86; 64.08; H 8.22; 8.25.
$C_9H_{14}O_2$ Calculated %: C 63.53; H 8.23.

3) Reaction was between 11.5 g of the 2-cyanoethyl ether of 1-hexyn-3-ol (I; R = n-C_3H_7), b. p. 90-91° (6 mm), and 120 ml of methanol containing 18.5 g of dry hydrogen chloride. The product was 12.9 g of the methyl ester (II; R = n-C_3H_7), b. p. 104-105° (12 mm); n_D^{20} 1.4362; d_4^{20} 0.9678; found MR 49.72; calculated MR 49.61.

Found %: C 65.51; 65.58; H 8.67; 8.83.
$C_{10}H_{16}O_2$ Calculated %: C 65.22; H 8.69.

4) Reaction was between 8 g of the 2-cyanoethyl ether of 4-methyl-1-pentyn-3-ol (I; R = i-C_3H_7), b. p. 83-85° (5.5 mm), and 150 ml of methanol containing 18 g of dry hydrogen chloride. The product was 6.3 g of the methyl ester (II; R = i-C_3H_7), b. p. 95-96° (10 mm); n_D^{20} 1.4345; d_4^{20} 0.9646; found MR 49.70; calculated MR 49.61.

Found %: C 64.72; 64.86; H 8.68; 8.64.
$C_{10}H_{16}O_2$ Calculated %: C 65.22; H 8.69.

5) Reaction was between 13.7 g of the 2-cyanoethyl ether of 2-methyl-3-butyn-2-ol (III; R = CH_3), b. p. 100° (22 mm), and 130 ml of methanol containing 18 g of dry hydrogen chloride. The product was 16.6 g of the methyl ester (IV; R = CH_3), b. p. 83-84° (12 mm); n_D^{20} 1.4290; d_4^{20} 0.9698; found MR 45.19; calculated MR 44.99.

Found %: C 63.57; 63.69; H 8.36; 8.35.
$C_9H_{14}O_2$ Calculated %: C 63.53; H 8.23.

6) Reaction was between 15.1 g of the 2-cyanoethyl ether of 3-methyl-1-pentyn-3-ol (III; R = C_2H_5), b. p. 64° (2.5 mm), and 165 ml of methanol containing 25 g of dry hydrogen chloride. The product was 12.6 g of the methyl ester (IV; R = C_2H_5), b. p. 91-92° (11 mm); n_D^{20} 1.4338; d_4^{20} 0.9712; found MR 49.32; calculated MR 49.61.

Found %: C 65.62; 65.66; H 8.68; 8.79.
$C_{10}H_{16}O_2$ Calculated %: C 65.22; H 8.69.

7) Reaction was between 10 g of the 2-cyanoethyl ether of 3-methyl-1-hexyn-3-ol (III; R = n-C_3H_7), b. p. 112-114° (15 mm), and 120 ml of methanol containing 18.5 g of dry hydrogen chloride. The product was 6.9 g of the methyl ester (IV; R = n-C_3H_7), b. p. 104-105° (12 mm); n_D^{20} 1.4374; d_4^{20} 0.9594; found MR 54.11; calculated MR 54.23.

Found %: C 66.23; 66.71; H 9.41; 9.36.
$C_{11}H_{18}O_2$ Calculated %: C 66.66; H 9.09.

8) Reaction was between 10.5 g of the 2-cyanoethyl ether of 3-methyl-1-nonyn-3-ol (III; R = n-C_6H_{13}), b. p. 115-116° (2.5 mm), and 100 ml of methanol containing 18.5 g of dry hydrogen chloride. The product was 6.9 g of the methyl ester (IV; R = n-C_6H_{13}), b. p. 115-116° (3 mm); n_D^{20} 1.4423; d_4^{20} 0.9405; found MR 67.56; calculated MR 68.08.

Alcoholysis of 2-Cyanoethyl Ethers of Acetylenic Alcohols at Room Temperature

1) A mixture of 8 g of the 2-cyanoethyl ether of 3-methyl-1-hexyn-3-ol (III; R = n-C_3H_7) and 100 ml of methanol containing 19 g of dry hydrogen chloride was left in a round-bottomed flask for 60 hours at room temperature. The flask was fitted with a Wurtz still head, and methanol was removed under the vacuum of the water pump at 25-30°. Water (150 ml) was added to the residue, and the mixture was stirred and saturated with potassium carbonate. The product was extracted with ether and dried with magnesium sulfate. Vacuum fractionation gave 8.2 g of the methyl ester (IV; R = n-C_3H_7), b. p. 80-82° (2.5 mm).

Alcoholysis at room temperature was carried out on 2-cyanoethyl ethers of the other acetylenic alcohols under similar conditions.

2) Reaction was between 8 g of the 2-cyanoethyl ether of 3-methyl-1-nonyn-3-ol (III; R = n-C_6H_{13}) and 100 ml of methanol containing 18 g of dry hydrogen chloride. The product was 8.4 g of the methyl ester (IV; R = n-C_6H_{13}), b. p. 118-120° (3.5 mm).

3) Reaction was between 8 g of the 2-cyanoethyl ether of 3-methyl-1-undecyn-3-ol (III; R = n-C_8H_{17}) and 100 ml of methanol containing 18 g of dry hydrogen chloride. The product was 8.5 g of the methyl ester (IV; R = n-C_8H_{17}), b. p. 145-147° (3.5 mm).

4) Reaction was between 8.5 g of the 2-cyanoethyl ether of 2-ethyl-1-pentyn-3-ol (V; R = C_2H_5) and 100 ml of methanol containing 19 g of dry hydrogen chloride. The product was 9 g of the methyl ester (VI; R = C_2H_5), b. p. 103-104° (10 mm).

5) Reaction was between 8 g of the 2-cyanoethyl ether of 3-propyl-1-hexyn-3-ol (V; R = n-C_3H_7) and 100 ml of methanol containing 19 g of dry hydrogen chloride. The product was 7.6 g of the methyl ester (VI; R = n-C_3H_7), b. p. 123-125° (11 mm).

6) Reaction was between 10 g of the 2-cyanoethyl ether of 1-ethynylcyclopentanol (VII), b. p. 125-127° (14 mm), and 100 ml of methanol containing 18 g of dry hydrogen chloride; duration of reaction 25 hours. The product was 10.8 g of the methyl ester (VIII), b. p. 98-100° (4 mm); n_D^{20} 1.4625; d_4^{20} 1.0302; found MR 52.35; calculated MR 52.03.

Found %: C 67.21; 67.39; H 8.11; 8.06.
$C_{11}H_{16}O_3$. Calculated %: C 67.35; H 8.16.

7) Reaction was between 8 g of the 2-cyanoethyl ether of 4-ethynyltetrahydro-2,2-dimethylpyran-4-ol (XIII) and 100 ml of methanol containing 18 g of dry hydrogen chloride; duration of reaction 24 hours. The product was 7.5 g of the methyl ester (XIV), b. p. 126-128° (3.5 mm).

8) Reaction was between 10 g of the 2-cyanoethyl ether of 2-methyl-5-piperidino-3-pentyn-2-ol (XXI), b. p. 146-147° (3 mm), and 110 ml of methanol containing 21 g of dry hydrogen chloride. The product was 10.6 g of the methyl ester (XXII), b. p. 145-146° (3 mm); n_D^{20} 1.4739; d_4^{20} 1.0056; found MR 74.60; calculated MR 74.44.

Found %: N 5.36; 5.47.
$C_{15}H_{25}NO_3$ Calculated %: N 5.24.

9) Reaction was between 20 g of the 2-cyanoethyl ether of 6-diethylamino-3-methyl-4-hexyn-3-ol (XVII; R = C_2H_5), b. p. 134-135° (3.5 mm), and 120 ml of methanol containing 25 g of dry hydrogen chloride. The product was 21.7 g of the methyl ester (XVIII; R = C_2H_5), b. p. 135-136° (4 mm); n_D^{20} 1.4520; d_4^{20} 0.9542; found MR 76.16; calculated MR 76.64.

Found %: N 5.14; 5.08.
$C_{15}H_{27}NO_3$ Calculated %: N 5.20.

10) Reaction was between 8 g of the 2-cyanoethyl ether of 3-isopropyl-4-methyl-1-pentyn-3-ol (XXIII), b. p. 126-128° (13 mm), and 100 ml of methanol containing 19 g of dry hydrogen chloride. The product was 6.8 g of the methyl ester (XXIV), b. p. 122-124° (14 mm); n_D^{20} 1.4446; d_4^{20} 0.9676.

Found %: C 68.78; 68.64; H 9.61; 9.64.
$C_{13}H_{22}O_3$ Calculated %: C 69.02; H 9.73;

SUMMARY

1. When treated with methanol and hydrogen chloride, 2-cyanoethyl ethers of secondary and tertiary acetylenic alcohols are readily converted into the corresponding methyl esters in high yield.

2. The yields of methyl esters are often increased considerably by carrying out the alcoholysis at room temperature.

REACTIONS OF MERCAPTO AMINO ACIDS

COMMUNICATION 11. α,β-DISUBSTITUTED α-ACYLAMINO CARBOXYLIC ACIDS

O. V. Kildisheva, M. G. Linkova, Z. V. Benevolenskaya, and I. L. Knunyants

The investigation of α-acylamino carboxylic acids having a group such as amino, hydroxy, or mercapto in the α-position, i. e.,

in which X = NH_2, NHCOR, NHR, OH, OR, SH, SR, presents considerable interest, for it is not improbable that such compounds enter into the composition of certain proteins, a view that receives indirect support from the fact that α-keto acids can be isolated from the hydrolyzates of some proteins.

It was shown fairly recently that 2-hydroxyalanine and 2-hydroxyvaline enter into the composition of the molecules of almost all ergot alkaloids [1, 2]; it is considered also [3] that a 2-hydroxyalanine residue is present in the molecule of the antibiotic lycomarasmine (I):

(I)

α,α-Bisacylamino carboxylic acids (II) have been known for a long time and are readily prepared by the condensation of keto acids with acid amides [4, 5] or nitriles [6]:

(II)

These acids are stable compounds; in aqueous solution they remain unchanged for several weeks, and they can be crystallized from alcohol without decomposition. By dehydration in presence of acetic anhydride they are readily converted into saturated oxazolinones (III) [6f, 7]:

(III)

When these products are decomposed with alcohol in presence of moisture, α-acylamino α-amino carboxylic acids (IV) are formed [4, 6e]:

(IV)

Unlike 2,2-bisacylaminopropionic acids, α-acylamino α-amino carboxylic acids are unstable: they readily decompose in aqueous solution with formation of equivalent amounts of pyruvic acid and ammonia. However, 2-acetamido-2-aminopropionic acid reacts with ketene in aqueous N NaOH with formation 2,2-diacetamidopropionic acid, and it reacts with benzoyl chloride in sodium bicarbonate solution with formation of 2-acetamido-2-benzamidopropionic acid (V) [4]:

(V)

α-Acylamino α-hydroxy carboxylic acids (VI) are also known [8-13]:

(VI)

Like α,α-bisacylamino carboxylic acids, they are generally prepared by the condensation of keto acids and amides, though under milder conditions:

Equimolecular amounts of pyruvic acid and formamide will react at room temperature with formation of N-formyl-2-hydroxyalanine (VII) in quantitative yield [8]:

(VII)

Herbst [9] condensed pyruvic acid with acetamide and obtained N-acetyl-2-hydroxyalanine $CH_3C(OH)(COOH)NHCOCH_3$ (VIII) in the form of a molecular compound with two molecules of acetamide.

Condensation of 2-oxoglutaric acid with acetamide under mild conditions (not above 70°) gives the lactone of 2-acetamido-2-hydroxyglutaric acid (IX) [10]:

In this case the intermediate α-acylamino α-hydroxy acid is stabilized by lactone formation. α-Acylamino α-hydroxy carboxylic acids are unstable compounds; they are readily decomposed by water with formation of a keto acid and ammonia, and the hydroxy group is extremely reactive. Thus, for N-formyl-2-hydroxyalanine, it is only necessary to keep it over calcium chloride in a vacuum desiccator in order to remove the hydroxy group in the form of water and obtain 2-formamidoacrylic acid $CH_2=C(COOH)NHCHO$ [8]. In presence of excess of amide the hydroxy group is readily replaced by an amide residue with formation of α,α-bisacylamino carboxylic acids [10]:

When derivatives of α,α-bisacylamino carboxylic acids are treated with solutions of mineral acids, the acylamino groups are readily lost with formation of derivatives of keto acids [7]. Under milder hydrolysis conditions, only one amide residue may be removed; for example, hydrolysis of N^2-[N-(2,2-diacetamidopropionyl) glycyl]asparagine with 0.2 N HCl gave N-[N-(N-acetyl-2-hydroxyalanyl)glycyl]aspartic acid (X) [11]:

The ethyl ester of α-hydroxyphenaceturic acid (XI) was prepared by Sus [12] by oxidizing the monoethyl ester of (2-phenylacetamido)malonic acid with lead tetraacetate and decarboxylating the product, and Sus showed that the intermediate compound "A" can be prepared, in quantitative yield, also by hydrolysis of the monoethyl ester of bromo(2-phenylacetamido)malonic acid:

(XI)

By the hydrolysis of 4-bromo-2-phenyl-2-oxazolin-5-ones, Chaman and Shelyakin [13] prepared N-benzoyl-2-hydroxyglycine, N-benzoyl-2-hydroxyalanine, and 2-benzamido-2-hydroxybutyric acid:

R = H, CH_3, C_2H_5.

The replacement of bromine by a hydroxy group and the opening of the oxazolinone ring proceed simultaneously when the dichloroethane solution of the bromooxazolinone is treated with water; the bromooxazolinone is not isolated in the pure state.

The possibilities for the synthesis of multifunctional α-acylamino carboxylic acids are greatly extended now that the N-acyl-2,3-dihaloalanines (XII) recently synthesized by us [14] are available:

(XII)

As we have already shown, halogen in the 2-position in N-acyl-2,3-dihaloalanines is considerably more reactive than halogen in the 3-position, being readily removed by treatment with water or alcohols with formation of 2-hydroxy- or 2-alkoxy-N-acyl-3-haloalanines (XIII) [15]:

(XIII)

in which Hal = Cl, Br, R' = H, Alk; R = C_6H_5, $CH_2C_6H_5$.

In the present investigation we continued our study of N-acyl-2,3-dihaloalanines and 4-acetoxy-4-(halomethyl)-2-phenyl-2-oxazolin-5-ones.

Reaction of 2,3-dibromo-N-(phenylacetyl)alanine with methanol readily gave 3-bromo-2-methoxy-N-(phenylacetyl)alanine (XIV), m. p. 125-126°.

(XIV)

Treatment of the acid (XIV) with ethereal diazomethane gave the methyl ester of 3-bromo-2-methoxy-N-(phenylacetyl)alanine (XV), m. p. 104-106°. When 2,3-dibromo-N-(phenylacetyl)alanine was treated with excess of ethanethiol, both halogen atoms were replaced by ethylthio with formation of S-ethyl-2-(ethylthio)-N-(phenylacetyl)cysteine (XVI), m. p. 128-130°:

(XVI)

Treatment of N-benzoyl-2,3-dichloroalanine with aniline in ethereal solution readily gave the stable aniline salt of 2-anilino-N-benzoyl-3-chloroalanine (2-anilino-2-benzamido-3-chloropropionic acid) (XVII):

(XVII)

By treatment with ethereal diazomethane, this aniline salt or the free acid was converted into the methyl ester of 2-anilino-N-benzoyl-3-chloroalanine (XVIII), m. p. 126-128°:

(XVIII)

Various derivatives of the same type of acid were readily prepared from 3-acetoxy-4-(chloromethyl)-2-phenyl-2-oxazolin-5-one, which we had synthesized previously [14]:

Investigation of the reactions of this oxazolinone with aniline showed that scission of the oxazolinone ring is accompanied by replacement of the acetoxy group. Thus, treatment of the oxazolinone with aniline in alcohol gave an 87% yield of the anilide of 2-anilino-N-benzoyl-3-chloroalanine (XIX), m. p. 139-140°:

(XIX)

Reaction in presence of catalytic amounts of potassium carbonate gave the methyl ester of 2-anilino-N-benzoyl-3-chloroalanine, identical with the product (XVIII) already obtained.

Reaction of 3-acetoxy-4-(chloromethyl)-2-phenyl-2-oxazolin-5-one with piperidine in alcohol gave the methyl ester of N-benzoyl-3-chloro-2-piperidinoalanine (XX), m. p. 103-104°:

(XX)

The structure of (XX) was confirmed by its hydrolysis with alcoholic caustic soda to (benzoyloxy)pyruvic acid, which was isolated in the form of its 2,4-dinitrophenylhydrazone, m. p. 167°, identical with the 2,4-dinitrophenylhydrazone prepared from known (benzoyloxy)pyruvic acid.

Reaction between equimolecular amounts of the methyl ester of 3,3-dimethylcysteine and 4-acetoxy-4-(chloromethyl)-2-phenyl-2-oxazolin-5-one in chloroform solution gave a cyclic peptide, the methyl ester of 6-benzamido-6-(chloromethyl)-2,2-dimethyl-5-oxo-3-thiamorpholinecarboxylic acid (XXI), m. p. 152-153°:

(XXI)

EXPERIMENTAL

3-Bromo-2-methoxy-N-(phenylacetyl)alanine (XIV)

Absolute methanol (2 ml) was mixed with 0.365 g (0.001 mole) of 2,3-dibromo-N-(phenylacetyl)alanine. The precipitate of the acid (XIV) was filtered off and washed with alcohol. After being precipitated from alcohol with water it melted with decomposition at 125-126°.

Found %: C 45.16; H 4.51; Br 25.82; N 4.10.
$C_{12}H_{14}O_4NBr$. Calculated %: C 45.60; H 4.42; Br 25.40; N 4.42.

Treatment of the acid (XIV) with ethereal diazomethane gave the methyl ester of 3-bromo-2-methoxy-N-(phenylacetyl)alanine (XV), m. p. 104-106°.

Found %: N 4.13.
$C_{13}H_{16}O_4NBr$. Calculated %: N 4.24.

S-Ethyl-2-(ethylthio)-N-(phenylacetyl)cysteine (XVI)

A mixture of 0.365 g (0.001 mole) of 2,3-dibromo-N-(phenylacetyl)alanine with excess of ethanethiol was left at room temperature until complete dissolution occurred (3-4 hours). Excess of ethanethiol was then removed in a vacuum. The residue crystallized when rubbed out with water. The product was 0.2 g of (XVI), m. p. 128-130° (from alcohol).

Found %: C 55.09; H 6.63; N 4.38.
$C_{15}H_{21}O_3NS_2$. Calculated %: C 55.04; H 6.42; N 4.28.

2-Anilino-N benzoyl 3-chloroalanine (XVII)

A solution of 1.68 ml (0.02 mole) of aniline in 5 ml of absolute ether was added gradually to a stirred solution of 2.62 g (0.01 mole) of N-benzoyl-2,3-dichloroalanine in 30 ml of absolute ether. The precipitate formed was filtered off and washed with water. The product was 2.1 g of the aniline salt of 2-anilino-N-benzoyl-3-chloroalanine (XVII), m. p. 120-121° (from methanol and ethyl acetate).

Found %: N 10.2.
$C_{22}H_{22}O_3N_3Cl$. Calculated %: N 10.2.

The aniline salt of (XVII) (0.2 g) was dissolved in saturated aqueous sodium bicarbonate. Aniline was removed by extraction with ether. The residue was acidified carefully in the cold with 2N HCl. The free acid (XVII), m. p. 90° (from ether), was obtained. It rapidly decomposed with keeping.

Found %: N 9.15.
$C_{16}H_{15}O_3N_2Cl$. Calculated %: N 8.79.

Methyl Ester of 2-Anilino-N-benzoyl-3-chloroalanine (XVIII)

a) The aniline salt (XVII) (0.41 g, i. e., 0.001 mole) was mixed with 5 ml of absolute ether and treated with excess of an ethereal solution of diazomethane. The product was the ester (XVIII), m. p. 125-126°.

Found %: N 8.46.
$C_{17}H_{17}O_3N_2Cl$. Calculated %: N 8.45.

b) 4-Acetoxy-4-(chloromethyl)-2-phenyl-2-oxazolin-5-one (0.26 g, i. e., 0.001 mole) was mixed with 2.5 ml of absolute methanol containing a catalytic amount of potassium carbonate, and 0.1 ml of aniline was added. The product was 0.15 g of the methyl ester of 2-anilino-N-benzoyl-3-chloroalanine, m. p. 126-128° (from ether). In admixture with the product of method (a) there was no depression of melting point.

Anilide of 2-Anilino-N-benzoyl-3-chloroalanine (XIX)

Aniline (2 ml) was added to a stirred mixture of 2.67 g (0.01 mole) of 4-acetoxy-4-(chloromethyl)-2-phenyl 2-oxazolin-5-one in 25 ml of absolute methanol. After some time complete dissolution occurred. A crystalline precipitate of (XIX) formed and was filtered off. An 87% yield of the acid (XIX), m. p. 139-140° (from alcohol), was obtained.

Found %: C 67.01; H 5.35; Cl 9.15; N 10.42.
$C_{22}H_{20}O_3N_3Cl$. Calculated %: C 67.09; H 5.08; Cl 9.02; N 10.67.

The mother liquor gave 0.3 g of (XVIII), m. p. 125-126°, undepressed by admixture of the substance obtained by method (a) (above).

Methyl Ester of N-Benzoyl-3-chloro-2-piperidinoalanine (XX)

A mixture of 0.53 g (0.002 mole) of 4-acetoxy-4-(chloromethyl)-2-phenyl-2-oxazolin-5-one and 2 ml of absolute methanol was treated with a solution of 0.004 mole of piperidine in 2 ml of methanol. Heat was evolved, and complete dissolution occurred. Alcohol was removed under reduced pressure, and (XX) was extracted with 25% sulfuric acid. The acid solution was neutralized with solid sodium bicarbonate, and the ester (XX), m. p. 103-104° (from ether), was obtained.

Found %: C 59.22; H 6.7; Cl 10.72; N 8.37.
$C_{16}H_{21}O_3N_2Cl$. Calculated %: C 59.10; H 6.47; Cl 10.94; N 8.62.

Methanolic caustic soda (1 ml of 2 N) was added to a mixture of 0.052 g of (XX) and 1 ml of absolute methanol. The mixture was left at room temperature until the next day, and alcohol was then removed under reduced pressure. The residue was dissolved in 2 ml of water and acidified with 2 N HCl. 2,4-Dinitrophenylhydrazine was added, and 0.06 g of the hydrazone of (benzoyloxy)pyruvic acid, m. p. 167°, was obtained. A mixture with an authentic sample showed no depression of melting point.

Methyl Ester of 6-Benzamido-6-(chloromethyl)-2,2-dimethyl-5-oxo-3-thiamorpholinecarboxylic Acid (XXI)

The methyl ester of 3,3-dimethylcysteine (7.2 g, i. e., 0.04 mole) was added to a solution of 11.8 g (0.04 mole) of 4-acetoxy-4-(chloromethyl)-2-phenyl-2-oxazolin-5-one in 60 ml of dry chloroform, and the mixture was heated at 40-45° for three hours. The solution was cooled, washed with N HCl and with water to remove unchanged dimethylcysteine ester, and dried over magnesium sulfate. Chloroform was removed under reduced pressure, and the residue was diluted with absolute ether. The crystalline precipitate then formed was filtered off and washed with ether. The product was 7.1 g of the peptide (XXI), m. p. 149°. A further 0.8 g of (XXI) was isolated from the mother liquor, the total yield being 48%. After being recrystallized from benzene the product melted with decomposition at 152-153°. The substance is readily soluble in alcohol, less readily soluble in benzene, and insoluble in ether and in water.

Found %: C 52.08; H 5.16; N 7.55.
$C_{15}H_{19}O_4N_2SCl$. Calculated %: C 51.82; H 5.12; N 7.56.

SUMMARY

1. It was shown that α-halo in α,β-dihalo α-acylamino carboxylic acids is replaced in reactions with amines and thiols with formation of α-acylamino carboxylic acids having a new substituent in the α-position.

2. It was shown that N-acyl-2,3-dihaloalanines can be converted into derivatives of 2-alkoxy- and 2-(alkylthio)-cysteine.

3. Various derivatives of the same acids were prepared by the action of amines and alcohols on 4-acetoxy-4-(chloromethyl)-2-phenyl-2-oxazolin-5-one.

4. By the acylation of the methyl ester of 3,3-dimethylcysteine with 4-acetoxy-4-(chloromethyl)-2-phenyl-2-oxazolin-5-one a peptide was obtained which was shown to be a derivative of α-substituted α-acylamino carboxylic acids.

ADDITION REACTIONS OF PERFLUOROOLEFINS

COMMUNICATION 5. CONJUGATED ADDITION OF HALOGENS

I. L. Knunyants, E. Ya. Pervova, and V. V. Tyuleneva

Addition of halogens to perfluoroolefins generally proceeds under the conditions of free-radical reactions. It is probably for this reason that conjugated-addition reactions between these substances, which would undoubtedly be ionic reactions, have not yet been brought about. However, it appears likely that reactions of this sort could occur under conditions such that the halogen molecule is strongly ionized, with increase in the nucleophilic character of the halogen anion. It was in fact found that many polyfluoroolefins readily combine with bromine in glacial acetic acid solution. When polyfluoroolefins were passed into a solution of bromine and mercuric acetate or sulfate in glacial acetic acid, acetoxybromopolyfluoroparaffins were formed. In particular, trifluoroethylene, 1,1-difluoroethylene, and others form esters of α,α-difluoro alcohols of formula $RCOCF_2R'$. Only one representative of this type of compounds has been described in the literature, namely, perfluorobutyrolactone $\begin{matrix}CF_2\text{—}CF_2\text{—}CF_2\\ O\text{———}CO\end{matrix}$ [1], which is an extremely reactive compound, reacting with water, ammonia, ethanol, and ethanethiol at about 0° with formation of compounds of the type

$$X\text{—}\overset{\overset{O}{\|}}{C}\text{—}CF_2\text{—}CF_2\text{—}\overset{\overset{O}{\|}}{C}\text{—}X \quad (X = OH,\ OC_2H_5,\ NH_2,\ SC_2H_5).$$

Our preliminary investigations showed that 3,3,3-trifluoropropene, trifluoroethylene, and 1,1-difluoroethylene readily combine with bromine in glacial acetic acid solution with formation of the corresponding dibromides; in the case of 1,1-difluoro- and trifluoro-ethylenes, some acetoxy-bromo addition products are also formed. The readiness with which addition of bromine to fluoroolefins occurs in glacial acetic acid may be explained by increased polarization of the bromine molecule in the polar solvent with formation of Br_3^- and $Br_2CH_3COO^-$ complexes, which carry out an anionoid attack on the enfeebled π-bonds of the fluoroolefins.

When fluoroolefins were treated in glacial acetic acid solution with bromine in presence of mercuric acetate or sulfate, the reaction gave only acetoxy-bromo addition products, evidently owing to the preferential formation of the complex $Br_2CH_3COO^-$:

$$Br_2CH_3COO^- \ldots > \underset{CFH}{\overset{CF_2}{\|}} \longrightarrow \overset{\ominus}{\underset{CFH}{|}}\overset{CF_2OCOCH_3}{|}$$

$$\overset{\ominus}{\underset{CFH}{|}}\overset{CF_2OCOCH_3}{|} + Br^+ \ldots Br^- \rightarrow \underset{CFHBr}{|}\overset{CF_2OCOCH_3}{|} + Br^-$$

$$Hg^{++} + 2Br^- \rightarrow HgBr_2.$$

The formation of only acetoxy compounds under these conditions to the complete exclusion of dibromides caused us to doubt the correctness of the above mechanism. It naturally occurred to us that the first stage of the reaction might be the formation of an organomercury derivative of the fluoroolefin, which would be subsequently decomposed by bromine with formation of the acetoxy bromo compound. For verification purposes we investigated the behavior of the same olefins toward solutions of mercuric acetate in acetic acid, alcohol, and water.

Under these conditions we were unable to effect the addition of mercuric acetate to 3,3,3-trifluoropropene and to trifluoroethylene. Positive results were obtained only in the reaction of mercuric acetate with 1,1-difluoroethylene. The addition products then obtained were found to be extremely unstable compounds, readily converted into derivatives of (acetoxymercuri)acetic acid.

When 1,1-difluoroethylene was passed into a solution of mercuric acetate in glacial acetic acid, the gas was absorbed very rapidly and hydrogen fluoride soon began to be evolved; the other reaction product was (acetoxymercuri)acetic acid, the formation of which indicates the extreme readiness with which fluorine atoms in the β-position with respect to mercury are hydrolyzed.

When 1,1-difluoroethylene was passed into a solution of mercuric acetate in absolute ethanol, ethyl (acetoxymercuri)acetate was obtained. This was formed by the hydrolysis of 2-ethoxy-2,2-difluoroethylmercury acetate, the product of the conjugated addition of an ethoxyl and a mercuric acetate residue to 1,1-difluoroethylene:

The negative results obtained for the addition of mercuric acetate to 3,3,3-trifluoropropene and trifluoroethylene refute the suggestion that mercury derivatives are formed as intermediaries and support the above-described mechanism of conjugated addition of bromine to fluoroolefins.

All of the acetoxy-bromo compounds obtained are readily soluble in organic solvents and are insoluble in water. Physical and analytical data for these compounds are given in the table. 2-Bromo-3,3,3-trifluoropropyl acetate is a stable colorless liquid having a pleasant ester odor. 2-Bromo-1,1-difluoroethyl acetate and 2-bromo-1,1,2-trifluoroethyl acetate are unstable colorless liquids having a sharp odor characteristic of anhydrides and producing irritation of the mucous membrane. When kept in a glass vessel they slowly decompose, but they can be kept for several months in a paraffined vessel without change.

Although there could be no doubt about the structures of the acetoxy-bromo compounds obtained, since they were determined by the well defined polarities of the reactants, it was nevertheless necessary to confirm these structures by experiment.

The structures of 2-bromo-1,1-difluoroethyl acetate and 2-bromo-1,1,2-trifluoroethyl acetate were proved by hydrolysis, the respective hydrolysis products being bromoacetic and bromofluoroacetic acids:

The formation of four molecular equivalents of acid in both cases was confirmed by titration with alkali (3.9 equivalents of caustic potash was required).

When 2-bromo-1,1,2-trifluoroethyl acetate was boiled with aqueous alkali, glyoxylic acid, isolated as the 2,4-dinitrophenylhydrazone, was obtained in 80% yield. This acid is formed as a result of the further hydrolysis

TABLE

No.	Fluoroolefin	Acetoxy-bromo addition product of fluoroolefin	Yield (%)	B.p. in °C (p in mm)	n_D^{20}	d_4^{20}	Analysis									
							Found					Calculated				
							MR	C (%)	H (%)	Br (%)	F (%)	*MR*	C (%)	H (%)	Br (%)	F (%)
1	$CF_2CH=CH_2$	$CF_2\underset{\displaystyle Br}{\underset{\vert}{C}}HCH_2OCOCH_3$	78	149	1.3980	1.6352	34.70	25.05	2.57	34.50	23.4	34.68	25.53	2.55	34.04	24.25
2	$CF_2=CFH$	$CF_2\underset{\displaystyle OCOCH_3}{\underset{\vert}{C}}FHBr$	56	46 (30)	1.3820	1.70	30.25	21.98	1.82	36.05	25.11	30.21	21.72	1.81	36.20	25.79
3	$CF_2=CH_2$	$CF_2\underset{\displaystyle OCOCH_3}{\underset{\vert}{C}}H_2Br$	50	41 (20)	1.4030	1.6752	30.13	23.93	2.68	38.96	—	30.09	23.64	2.46	39.40	18.71

of bromofluoroacetic acid:

$$CFBrH{-}CF_2{-}OCOCH_3 \xrightarrow{H_2O} [CHFBrCOOH] \xrightarrow{H_2O} [HOCHFCOOH] \xrightarrow{-HF} HOC{\cdot}COOH$$

Analogous reactions of bromofluoroacetates are known [2].

In the cold, 2-bromo-1,1-difluoroethyl acetate does not react with absolute ethanol, but heating of the reaction mixture results in alcoholysis with formation of ethyl acetate, ethyl bromoacetate, and hydrogen fluoride:

$$CH_2Br-CF_2-OCOCH_3 \xrightarrow{C_2H_5OH} [CH_2Br-CF_2OH] + CH_3COOC_2H_5$$
$$[CH_2Br-CF_2OH] \xrightarrow{-HF} [CH_2Br-COF]$$
$$[CH_2Br-COF] \xrightarrow{C_2H_5OH} CH_2BrCOOC_2H_5$$

Hence, the acetoxy-bromo compounds that we obtained have the character of mixed anhydrides.

Apart from conjugated addition of bromine in acetic acid, we effected also the addition of bromine to 3,3,3-trifluoropropene and to trifluoroethylene in a medium of water. In presence of mercuric acetate, trifluoroethylene gave bromofluoroacetic acid:

$$CF_2=CHF + Br_2 + H_2O \xrightarrow{Hg(OAc)_2} [CFBrH-CF_2OH] \xrightarrow{-HF} [CFBrHCOF] \rightarrow$$
$$\rightarrow CFBrHCOOH$$

This is simpler as a method of preparation than that given in the literature [2] and may be a general method for the preparation of α-fluoro α-halo carboxylic acids. Under these conditions 3,3,3-trifluoropropene gave the bromohydrin, 2-bromo-3,3,3-trifluoro-1-propanol, b. p. 127°*:

$$CF_3CH=CH_2 + Br_2 + H_2O \xrightarrow{Hg(OAc)_2} CF_3CHBrCH_2OH.$$

The 1-naphthylurethan of this bromohydrin melted at 88°.

The development of convenient methods for the synthesis of 2-bromo-3,3,3-trifluoro-1-propanol and 2-bromo-3,3,3-trifluoropropyl acetate provided us with a simple synthesis for 2,3-epoxy-1,1,1-trifluoropropane, which has been previously obtained from trifluoroacetone [4]:

$$CF_3CHBrCH_2OCOCH_3 \xrightarrow{NaOH} CF_3-CH-CH_2$$
$$CF_3CHBrCH_2OH \xrightarrow{NaOH} \quad\quad O$$

EXPERIMENTAL

Addition of Bromine to 3,3,3-Trifluoropropene in Acetic Acid

A solution of 8 g of bromine in 25 ml of glacial acetic acid was stirred vigorously at room temperature, and 3,3,3-trifluoropropene was passed in until the solution was decolorized (1.25 liters). Reaction proceeded with evolution of heat. The reaction solution was diluted with an equal amount of water. The organic layer was separated and washed with water, with sodium carbonate solution, and again with water. The product was dried with calcium chloride. The yield of crude 2,3-dibromo-1,1,1-trifluoropropane was 10.3 g (82%). It had b. p.

* A patent published in 1955 described the formation of 2-bromo-3,3,3-trifluoro-1-propanol by the addition of hypobromous acid to 3,3,3-trifluoropropene [3].

114° and n_D^{25} 1.4300; the literature gives b. p. 115° and n_D^{25} 1.4286.

Addition of Bromine to 1,1-Difluoroethylene in Acetic Acid

Reaction of 0.75 liter of 1,1-difluoroethylene with bromine in accordance with the above procedure gave 3 g (43%) of 1,2-dibromo-1,1-difluoroethane, b. p. 94° and n_D^{25} 1.4430 (the literature gives b. p. 93° and n_D^{25} 1.4456), and a very small amount of 2-bromo-1,1-difluoroethyl acetate, b. p. 60° (60 mm), n_D^{25} 1.4080.

Addition of Bromine to Trifluoroethylene in Acetic Acid

In a similar way, 1.5 liters of trifluoroethylene gave 5 g (50%) of 1,2-dibromo-1,1,2-trifluoroethane, b. p. 72-73° and n_D^{25} 1.410 (the literature gives b. p. 76° and n_D^{25} 1.4191), and a very small amount of 2-bromo-1,1,2-trifluoroethyl acetate, b. p. 46° (35 mm) and n_D^{25} 1.3880.

General Method for the Preparation of Bromo-Acetoxy Addition Compounds of Fluoroolefins

A mixture of 50 ml of glacial acetic acid and 20 g of mercuric acetate or sulfate was prepared in a three-necked flask. The mixture was cooled with ice water and stirred vigorously. Bromine (16 g) was added dropwise, and simultaneously the fluoroolefin was passed so as to decolorize the solution. The precipitate of mercuric bromide was filtered off and washed with water and ether. The filtrate was diluted with 100 ml of ice water, and the organic layer was separated. The acidic aqueous mother liquor was partially neutralized with strong caustic soda solution and extracted with ether. The ether extract was combined with the organic layer, washed with water, with sodium carbonate solution, and again with water, and dried with magnesium sulfate. Ether was removed, and the residue was vacuum distilled. It was found that all operations with di- and tri-fluoroethylenes must be carried out within one day, as otherwise the yields were greatly reduced. Physical and analytical data for the bromoacetoxy compounds that we prepared are given in the table.

Reaction of 1,1-Difluoroethylene with Mercuric Acetate in Glacial Acetic Acid

At room temperature, 2.5 liters of 1,1-difluoroethylene was passed through a vigorously stirred mixture of 25 ml of glacial acetic acid and 10 g of mercuric acetate contained in a three-necked flask. The whole of the mercuric acetate dissolved. The reaction with alkali for mercuric ion was negative. When the solution was cooled a new precipitate formed. It was filtered off, and the filtrate was evaporated to dryness. The yield of (acetoxymercuri)acetic acid was quantitative. The (acetoxymercuri)acetic acid was converted in the usual way into (bromomercuri)acetic acid, m. p. 197° (the literature gives 198°).

Found %: C 6.43; H 0.86.
$C_2H_3O_2HgBr$. Calculated %: C 7.07; H 0.88.

Reaction of 1,1-Difluoroethylene with Mercuric Acetate in Absolute Methanol

Analogous treatment of mercuric acetate with 1,1-difluoroethylene in absolute methanol gave a quantitative yield of methyl (acetoxymercuri)acetate, m. p. 134° (from aqueous alcohol). The melting point of methyl (chloromercuri)acetate was 88° (from aqueous alcohol).

Found %: C 11.68; H 1.69; Cl 12.33.
$C_3H_5O_2HgCl$. Calculated %: C 11.67; H 1.62; Cl 11.82.

Hydrolysis of 2-Bromo-1,1-difluoroethyl Acetate

2-Bromo-1,1-difluoroethyl acetate (4 g) was shaken mechanically with aqueous caustic soda for three hours. The alkaline solution was extracted with ether, acidified with 2 N H_2SO_4, saturated with common salt, and again extracted with ether. The ether extract was dried, and the ether was distilled off. Vacuum distillation of the residue gave acetic acid and bromoacetic acid, b. p. 117° (15 mm) and m. p. 49°.

Neutralization equivalent calculated for $C_2H_3BrO_2$ 139
Value found 140.3.

Hydrolysis of 2-Bromo-1,1,2-trifluoroethyl Acetate

2-Bromo-1,1,2-trifluoroethyl acetate (3 g) was boiled with aqueous caustic soda for 30 minutes. The precipitate formed was filtered off, and to the filtrate, after acidification, a 2% solution of 2,4-dinitrophenylhydrazine in hydrochloric acid was added. The yield of hydrazone was 2 g (80%). After being recrystallized from water, the 2,4-dinitrophenylhydrazone of glyoxylic acid melted with decomposition at 190°.

Found %: C 38.42; H 2.33; N 22.55.
$C_9H_6O_8N_4$. Calculated %: C 37.80; H 2.36; N 22.09.

Reaction of 2-Bromo-1,1-difluoroethyl Acetate with Ethanol

A solution of 10 g of 2-bromo-1,1-difluoroethyl acetate in 7 ml of absolute ethanol was refluxed for 30 minutes. The precipitate was filtered off. A solution of the filtrate in ether was washed with water, with bicarbonate solution, and again with water. The solution was dried, and ether was driven off. Distillation of the residue through a column gave 1.8 g of ethyl acetate and 5.2 g of ethyl bromoacetate, b. p. 155° and n_D^{18} 1.4520 (the literature gives b. p. 159° and n_D^{18} 1.4542).

Synthesis of Bromofluoroacetic Acid

A mixture of 50 ml of water and 20 g of mercuric acetate was stirred at room temperature in a three-necked flask. Bromine (16 g) was added dropwise, and trifluoroethylene (2.5 liters) was passed in simultaneously. The precipitate of mercuric bromide was filtered off. The solution was salted out with common salt and extracted with ether. The ether extract was dried with magnesium sulfate, and the ether was distilled off. Vacuum distillation of the residue gave 4.6 g (30%) of bromofluoroacetic acid, b. p. 103° (20 mm).

Neutralization equivalent calculated for $C_2H_2O_2FBr$ 157
Value found 154

Preparation of 2-Bromo-3,3,3-trifluoro-1-propanol

In a similar way, 30 ml of water, 8 g of bromine, 10 g of mercuric acetate, and 1 liter of 3,3,3-trifluoropropene gave 4.5 g (62%) of 2-bromo-3,3,3-trifluoro-1-propanol, b. p. 34° (12 mm) and 126-127° (760 mm); n_D^{20} 1.4029.

Found %: C 18.66; H 2.43; Br 41.27.
$C_3H_4OF_3Br$. Calculated %: C 18.67; H 2.09; Br 41.41.

The 1-naphthylurethan was prepared with aid of pyridine as catalyst; it melted at 87-88° (the melting point of the 1-naphthylurethan of 3-bromo-1,1,1-trifluoro-2-propanol is 134° [4]).

Found %: C 46.87; H 3.12; N 3.88.
$C_{14}H_{11}F_3Br_3NO_2$. Calculated %: C 46.43; H 3.06; N 3.87.

Preparation of 2,3-Epoxy-1,1,1-trifluoropropane

a) From 2-bromo-3,3,3-trifluoropropyl acetate. 2-Bromo-3,3,3-trifluoropropyl acetate (10 g) was added to a stirred 57% aqueous solution of caustic soda (25 ml) at 100° contained in a three-necked flask. The epoxide was collected in a receiver cooled with a freezing mixture. The yield of aqueous epoxide was 3 g (50%). Water was removed by freezing-out. Fractionation through a column gave a colorless liquid having a very pleasant aromatic odor; b. p. 37-40°; n_D^{20} 1.3050; d_4^{20} 1.382; found MR 15.41; calculated MR 15.97. The literature [4] gives b. p. 39° (748 mm), n_D^{18} 1.2997.

b) From 2-bromo-3,3,3-trifluoro-1-propanol. In a similar way, 6.7 g of 2-bromo-3,3,3-trifluoro-1-propanol gave 0.9 g (26%) of 2,3-epoxy-1,1,1-trifluoropropane.

SUMMARY

1. It was shown that 3,3,3-trifluoropropene, trifluoroethylene, and 1,1-difluoroethylene readily undergo

addition of bromine in glacial acetic acid.

2. For the first time, fluoroolefins were caused to undergo conjugated addition. By the action of bromine on some fluoroolefins in glacial acetic acid, some acetic esters of β-bromo α,α-difluoro alcohols were prepared.

3. It was shown that compounds of this new type have the character of mixed acid anhydrides.

4. By conjugated addition of bromine in water, the bromohydrin of 3,3,3-trifluoropropene was obtained, and this was converted into 2,3-epoxy-1,1,1-trifluoropropane.

5. By conjugated addition of bromine to trifluoroethylene in water, bromofluoroacetic acid was obtained.

6. The addition of mercuric acetate to 1,1-difluoroethylene was effected in acetic acid and in alcohol, the products being the unstable 2-acetoxy-2,2-difluoroethylmercury and 2-ethoxy-2,2-difluoroethylmercury acetates, which are readily transformed into a (halomercuri)acetic acid and its esters.

DECARBOXYLATION OF α-ACYLAMINO β-HALO CARBOXYLIC ACIDS

O. V. Kildisheva, N. P. Gambaryan, M. M. Polonskaya,

and I. L. Knunyants

It is well known that β-halo acids are readily converted into β-lactones. Thus, at 40-45° sodium 3-bromobutyrate gives the β-lactone in 60-70% yield together with a very small amount of propene [1]. Already at room temperature, salts of 3-bromo-2-methyl- and 3-bromo-2-ethyl-butyric acids form the corresponding lactones, together with olefins and carbon dioxide [2]. There are two different views on the mechanism of the formation of olefins in these and analogous reactions. Erlenmeyer [3] considered that the olefin is formed by decomposition of the intermediately formed β-lactone. It is true that the decomposition of β-lactones into olefins and carbon dioxide is characteristic of these compounds [4], but the conditions necessary are usually more severe than those required for olefin formation from β-bromo acids: under the conditions of the latter reaction, β-lactones usually only undergo hydrolysis with formation of β-hydroxy acids. For this reason, in 1953 Cristol and Norris [5] and, independently, Gravenstein and Lee [6] proposed another mechanism for the formation of olefins from β-halo acids. In a study of the mechanism of the decomposition of salts of α,β-dibromohydrocinnamic acids in aqueous and alcoholic solutions, they concluded that the decarboxylation of α,β-dibromohydrocinnamic acids is accompanied by simultaneous elimination of bromine in the form of an anion.

There are no data in the literature on the decarboxylation of N-acyl-2,3-dihaloalanines. Investigation showed that, when treated with water at room temperature, N-benzoyl-2,3-dichlorovaline (I) behaves like N-acyl-2,3-dihaloalanines [7] and is readily converted into N-benzoyl-3-chloro-2-hydroxyvaline (II). Further transformations of this acid under the action of aqueous sodium bicarbonate solution might proceed in two competing directions: with formation of a five-membered oxazoline system (III), and with formation of a four-membered β-lactone system (IV):

N-Acyl-3-halo-2-hydroxyalanines react with aqueous sodium bicarbonate in accordance with the first scheme, the oxazolines formed being hydrolyzed to acyloxypyruvic acids under the conditions of the experiment [7]. N-Benzoyl-3-chloro-2-hydroxyvaline behaves quite differently, and even at room temperature it is very readily decarboxylated with formation of N-isobutyrylbenzamide (V) in 80% yield. It would appear that, in this case, as a result of the presence of two methyl groups on the β-carbon atom, dehydrohalogenation occurs in accordance with the second scheme, the β-lactone (IV) formed being further decomposed into N-isobutyrylbenzamide. The ready decomposition of lactones of this type is confirmed by the recent work of Gresham and coworkers [8].

who showed that isovalerolactone is very unstable, even at room temperature, being decomposed in aqueous solution into isobutene and carbon dioxide. When treated with acetic anhydride or ketene, N-benzoyl-2,3-dichlorovaline and N-benzoyl-3-chloro-2-hydroxyvaline react like their dedimethyl analogs [9] with formation of 4-acetoxy-4-(1-chloro-1-methylethyl)-2-phenyl-2-oxazolin-5-one (VI):

The view that replacement of chloro by acetoxy precedes ring closure is confirmed by the fact that no such replacement occurs when 4-chloro-4-(1-chloro-1-methylethyl)-2-phenyl-2-oxazolin-5-one (VII) is heated with an equimolecular amount of acetic acid in presence of acetic anhydride.

EXPERIMENTAL

N-Benzoyl-2,3-dichlorovaline (I)

2-Benzamido-3-methylcrotonic acid (11 g, i. e., 0.05 mole) was treated with excess of chlorine dissolved in carbon tetrachloride (7.1 g of chlorine in 71 ml of carbon tetrachloride). Reaction proceeded with evolution of heat. After one day the precipitate was filtered off, washed with carbon tetrachloride, and dried. The product, amounting to 13.4 g (93%), was N-benzoyl-2,3-dichlorovaline, obtained in the form of colorless crystals, m. p. 104° (with decomposition). When allowed to stand in the air it decomposed into benzamide, hydrogen chloride, isobutyric acid, and a carbonyl compound, the composition of which was not determined.

Found %: Cl 23.3.
$C_{12}H_{13}NO_3Cl_2$. Calculated %: Cl 24.5.

N-Benzoyl-3-chloro-2-hydroxyvaline (II)

N-Benzoyl-2,3-dichlorovaline (7.5 g, i. e., 0.026 mole) was treated with 30 ml of water. After some time the dichloro acid was converted into a viscous mass, which crystallized when rubbed out. After two hours the precipitate was filtered off, washed with water, and dried. The product, amounting to 5.1 g (73%), was N-benzoyl-3-chloro-2-hydroxyvaline, m. p. 70-75° (with decomposition). The acid (II) is very readily soluble in alcohols, acetone, ethyl acetate, chloroform, and ether; it is insoluble in petroleum ether. N-Benzoyl-3-chloro-2-hydroxyvaline is more stable than N-benzoyl-2,3-dichlorovaline, but it decomposes into the same products when allowed to stand in the air.

Found %: Cl 13.0.
$C_{12}H_{14}NO_4Cl$. Calculated %: Cl 13.1.

4-Acetoxy-4-(1-chloro-1-methylethyl)-2-phenyl-2-oxazolin-5-one (VI)

a) A mixture of 5.8 g (0.02 mole) of (I), 50 ml of acetic anhydride, and 25 ml of carbon tetrachloride was heated under reduced pressure at 70-80°. The crystalline precipitate was filtered off and washed with a little absolute alcohol. The yield of (VI), m. p. 95° (from absolute alcohol), was 3.8 g (65%). This substance is very readily soluble in ether, chloroform, acetone, and dioxane; it can be crystallized from ethanol and acetic anhydride.

Found %: C 57.12; H 5.00; N 4.77; Cl 11.85.
$C_{14}H_{14}NO_4Cl$. Calculated %: C 57.0; H 4.75; N 4.75; Cl 12.00.

4-Acetoxy-4-(1-chloro-1-methylethyl)-2-phenyl-2-oxazolin-5-one remains practically unchanged when heated for a long time with acetic anhydride and acetic acid or with methanol containing a catalytic amount of potassium carbonate. In presence of an equimolecular amount of potassium carbonate, however, (VI) is immediately decomposed; even at room temperature, with formation of acetic acid, benzamide, and a carbonyl compound of undetermined composition. The substance (VI) may be preserved in the open for several months, but it decomposes in a sealed tube.

b) Ketene was passed into a suspension of 1.45 g (0.005 mole) of (I) in 20 ml of absolute benzene until solution was complete. The solution was evaporated at room temperature under reduced pressure, and the crystals precipitated were filtered off. The yield of white crystals of (VI), m. p. 94-95°, was 0.4 g (29%). The filtrate was treated with sodium bicarbonate, and crystals of m. p. 155°, identified as N-isobutyrylbenzamide (see below), were isolated.

c) A mixture of 2.4 g (0.0088 mole) of (II), 25 ml of acetic anhydride, and 20 ml of carbon tetrachloride was heated under reduced pressure at 70-80°. The crystalline precipitate was filtered off and washed with a little absolute alcohol. The yield of white crystals of (VI), m. p. 95°, was 0.95 g (40%).

4-Chloro-4-(1-chloro-1-methylethyl)-2-phenyl-2-oxazolin-5-one (VII)

A mixture of 2.9 g (0.01 mole) of N-benzoyl-2,3-dichlorovaline, 2.1 g (0.01 mole) of phosphorus pentachloride, and 20 ml of absolute benzene was heated for two hours. It was then evaporated to dryness under reduced pressure, and the residue was crystallized from petroleum ether. The product, amounting to 2 g (72%), was (VII), obtained in the form of colorless crystals, m. p. 60-64° (with decomposition). This substance is very soluble in the usual organic solvents. It is decomposed when allowed to stand in the air for a few hours.

Found %: Cl 25.25.
$C_{13}H_{11}NO_4Cl_2$. Calculated %: Cl 26.10.

A mixture of 0.55 g (0.002 mole) of 4-chloro-4-(1-chloro-1-methylethyl)-2-phenyl-2-oxazolin-5-one, 0.12 g (0.002 mole) of glacial acetic acid, and 5 ml of acetic anhydride in 5 ml of carbon tetrachloride was heated at 70-80° under reduced pressure, the solvent being distilled off. The product (0.5 g) consisted of crystals of m. p. 60-64°. A mixture test with (VII) showed no depression of melting point.

N-Isobutyrylbenzamide (V)

a) The substance (I) (2.9 g, i. e., 0.01 mole) was treated at room temperature with a solution of 0.85 g (0.01 mole) of sodium bicarbonate in 10 ml of water*. Almost the whole of (I) went into solution, but crystals then began to be precipitated. Evolution of carbon dioxide continued until the next day. After two days the precipitate was filtered off. The product, amounting to 0.46 g (77%), consisted of snow-white crystals, m. p. 155° (from absolute alcohol). N-Isobutyrylbenzamide readily dissolves in alkalis and is reprecipitated unchanged when the solution is carefully acidified.

Found %: C 68.95; H 6.98; N 7.57.
$C_{11}H_{13}NO_2$. Calculated %: C 69.20; H 6.80; N 7.35.

N-Isobutyrylbenzamide (0.95 g, i. e. 0.005 mole) was boiled for 30 minutes with a solution of 1 g of potas-

* The reaction is more rapid in presence of a large amount of bicarbonate, but the yield of N-isobutyrylbenzamide is not increased.

sium hydroxide in 10 ml of water. The solution was neutralized with sulfuric acid, and the precipitate formed was filtered off. The product, amounting to 0.19 g (80%), consisted of crystals which melted at 121° after recrystallization from water. A mixture with known benzoic acid showed no depression of melting point. A volatile acid was steam-distilled from the filtrate, 0.0047 mole (93%) being obtained. The solution of the acid was neutralized with caustic soda and evaporated, and the salt that remained was treated with thionyl chloride and aniline. Clear crystals of m. p. 104° (from aqueous alcohol) were obtained. A mixture with isobutyranilide melted at the same temperature.

b) The substance (II) (1.37 g, i. e., 0.005 mole) was treated with a solution of 0.42 g (0.005 mole) of sodium bicarbonate in 5 ml of water. After two days 0.75 g (81%) of N-isobutyrylbenzamide, m. p. 155°, was filtered off.

c) The substance (II) (1.37 g, i. e., 0.005 mole) was treated with 10 ml of water. After ten days 0.82 g (86%) of N-isobutyrylbenzamide, m. p. 155°, was filtered off. A mixture with a sample from experiment (a) melted at the same temperature.

d) The substance (VII) (1.37 g, i. e., 0.005 mole) was left in the air for one day. The resulting oil was treated with sodium bicarbonate solution. After two days 0.67 g (70%) of N-isobutyrylbenzamide crystals, m. p. 155°, were filtered off.

SUMMARY

1. It was shown that N-benzoyl-3-chloro-2-hydroxyvaline is readily decarboxylated with formation of N-isobutyrylbenzamide.

2. 4-Chloro-4-(1-chloro-1-methylethyl)-2-phenyl-2-oxazolin-5-one and 4-acetoxy-4-(1-chloro-1-methylethyl)-2-phenyl-2-oxazolin-5-one were prepared for the first time.

SOME CONDENSATIONS OF ALIPHATIC NITRO CARBOXYLIC ESTERS*

V. M. Belikov

In a previous communication [1] we showed that, under certain conditions, nitroacetic ester condenses with aliphatic aldehydes with formation of β-hydroxy α-nitro carboxylic esters. Also, nitroacetic ester was cyanoethylated, and the mono- and bis-2-cyanoethyl derivatives were isolated. The biscyanoethyl derivative was converted into the corresponding tricarboxylic ester. In the present investigation we made a more detailed study of the transformations which can be undergone by condensation products of nitroacetic ester, and we also extended these condensation reactions to 3-nitropropionic and 4-nitrobutyric esters.

We found previously that 3-hydroxy-2-nitrobutyric ester, obtained by the condensation of nitroacetic ester with acetaldehyde, boils over a fairly wide range. We suggested that in this reaction two diastereoisomeric forms were obtained. In the hope of separating the isomers, we have vacuum distilled the product through a column having a filling of annealed nichrome spirals. Two fractions were obtained: the first was the dehydration product of the hydroxy nitro ester, i. e., 2-nitrocrotonic ester, and the second was hydroxynitrobutyric ester:

$$CH_3CHCHCOOC_2H_5 \rightarrow CH_3CH=CCOOC_2H_5.$$
$$\quad\;\; |\quad\;\; | \qquad\qquad\qquad\quad\;\; |$$
$$\quad HO\;\; NO_2 \qquad\qquad\qquad\quad NO_2$$

However, the occurrence of this partial dehydration of the hydroxy nitro ester leaves the question of the presence of two diastereoisomeric forms in the product open. The view that two such forms are present is supported by the fact that the products obtained by distillation in the ordinary way have varying refractive indices and densities, but constant molecular weight and composition. Partial dehydration during distillation can be explained by a greater tendency in one of the diastereoisomeric forms to undergo dehydration.

As attempts to obtain a crystalline derivative of 3-hydroxy-2-nitrobutyric ester were not successful, we had recourse to its reactions. Egorov [2] reduced the product of the addition of oxides of nitrogen to crotonic ester with tin and hydrochloric acid and obtained threonine. We attempted to hydrogenate 3-hydroxy-2-nitrobutyric ester catalytically. Hydrogenation without addition of acid gave an amine of composition $C_8H_{15}O_2N$, which we did not investigate further. When oxalic acid was added to the reaction mixture, two crystalline products were isolated. One of these corresponded in analysis to the monohydrate of ammonium hydrogen oxalate, and the other to the oxalate of the ethyl ester of threonine:

$$CH_3CH-CHCOOC_2H_5 \rightarrow CH_3CH-CHCOOC_2H_5 + C_2O_4H_4\cdot NH_3\cdot H_2O.$$
$$\quad\;\; |\quad\;\; | \qquad\qquad\quad\;\; |\quad\;\; |$$
$$\quad HO\quad NO_2 \qquad\qquad\quad HO\quad NH_2C_2O_4H_2$$

For neither product did the yield exceed 30%.

We then hydrogenated the monocyanoethyl derivative of nitroacetic ester in the hope of obtaining arginine, but under our conditions of reaction (pyridine was used as solvent) the nitro group was only partially reduced (to the nitroso stage). The product – the oxime of 4-cyano-2-oxobutyric ester – was isolated as the O-benzoyl derivative. This substance did not dissolve in alkalis in the cold, but it dissolved at a higher temperature with

* This paper forms part of a thesis for a candidates's diploma and describes work carried out under the supervision of Academician V. M. Rodionov.

evolution of ammonia; when the solution was acidified, benzoic acid was liberated.

$$NCCH_2CH_2CHCOOC_2H_5 \xrightarrow[Pd]{H_2} NCCH_2CH_2CCOOC_2H_5.$$
$$\quad NO_2 \qquad\qquad\qquad\quad NOCOC_6H_5$$

When biscyanoethylated nitroacetic ester was hydrolyzed with aqueous-alcoholic caustic soda, simultaneous decarboxylation occurred with formation of 4-nitropimelonitrile in 78% yield. This substance was obtained by Buckley [3] in very poor yield by the cyanoethylation of nitromethane, taken in large excess.

It was of interest to investigate the effect of increasing the distance between the nitro group and the ester grouping on the ease of reaction and the nature of the products. With this object we synthesized the methyl esters of 3-nitropropionic and 4-nitrobutyric acids. The first of these, like 3-nitropropionic esters in general, has not been described before. There are instructions for the preparation of the ethyl ester in a paper by Lewkowitsch [4], who distilled the products of reaction between 3-iodopropionic ester and silver nitrite and obtained two fractions: one boiling at 161-165° and one boiling over the range 200-230°. He took the first fraction to be the required 3-nitropropionic acid, and the second he did not investigate further.

Our attempts to reproduce Lewkowitsch's results were unsuccessful. The first fraction was obtained in very small amount, and its boiling point was 15° higher than that given by Lewkowitsch; it readily decomposed with evolution of oxides of nitrogen. When we vacuum distilled the reaction product, we obtained two fractions. The first fraction, b. p. 26-27° (2 mm) had a strong odor of oxides of nitrogen; the second boiled at 73-74° (2 mm). At atmospheric pressure the second fraction boiled with decomposition at above 220°.

Boiling point tables [5] indicate that the first fraction, which corresponds to the substance that Lewkowitsch regarded as nitropropionic ester, is nitrous ester. The second, high-boiling fraction, which corresponds to the substance that he did not investigate, was in fact the desired product. We found that the same results were obtained when the iodo derivative was replaced by the more readily available bromo derivative:

$$BrCH_2CH_2COOCH_3 \xrightarrow{AgNO_2} O_2NCH_2CH_2COOCH_3$$

The performance of the Meyer reaction was greatly simplified by dilution of the reaction mixture with benzene or acetonitrile. In this way we prepared methyl 3-nitropropionate in 70% yield.

The recent paper by Treibs and Reinheckel [6] contains some very doubtful data on the preparation of 3-nitropropionic ester: they obtained a product of doubtful purity – no constants are given – by treating the monoethyl ester of bromosuccinic acid with sodium nitrite, and they took it to be 3-nitropropionic ester because they obtained a very small yield of β-alanine hydrochloride when they reduced it. We tried to prepare 3-nitropropionic acid by the hydrolysis and decarboxylation of the 1-nitro-1,1,2-ethanetricarboxylic ester that we had prepared previously, but treatment with concentrated hydrochloric acid at 100° did not affect it, and treatment with this acid at the boil decomposed it completely. β-Nitro carboxylic acids are extremely stable to the action of alkalis.

The condensation of methyl 3-nitropropionate with acetaldehyde was carried out by warming the reactants in presence of potassium carbonate. The product was methyl 4-hydroxy-3-nitrovalerate. No product of higher boiling point – a dihydroxy or dinitro compound – was formed in appreciable amount. The high boiling point of this compound – 133° (2 mm) – is noteworthy: the isomeric ethyl 3-hydroxy-2-nitrobutyrate boils at about 90° at the same pressure.

$$O_2NCH_2CH_2COOCH_3 \xrightarrow{CH_3CHO} CH_3CHCHCH_2COOCH_3$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\quad HO \quad NO_2$$
$$O_2NCH_2CH_2COOCH_3 \xrightarrow{CH_2=CHCN} NCCH_2CH_2CHCH_2COOCH_3$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad NO_2$$

The condensation of 3-nitropropionic ester with acrylonitrile proceeded considerably more readily than

that of nitroacetic ester. In presence of Rodionov's catalyst, an exothermic reaction occurred already at room temperature, and we obtained methyl 5-cyano-3-nitrovalerate together with some unchanged nitropropionic ester. Some noncrystallizing viscous oil remained as a residue from the distillation.

The acetaldehyde and acrylonitrile condensation reactions were extended also to 4-nitrobutyric ester. This has been prepared previously by Leonard and Beck [7] by the condensation of an excess of nitromethane with methyl acrylate in presence of a solution of Triton B in tert-butyl alcohol. As Triton B was not available, we used a solution of trimethylphenylammonium ethoxide in ethanol and obtained the desired substance in 20-22% yield. Appreciable amounts of dimethyl 4-nitropimelate were obtained at the same time.

Reaction of 4-nitrobutyric ester with acetaldehyde proceeded readily at room temperature in presence of an anion-exchange resin (Anionite). The condensation did not proceed so readily in presence of potassium carbonate. In both cases the product was methyl 5-hydroxy-4-nitrohexanoate:

The cyanoethylation of 4-nitrobutyric ester proceeded very readily in the cold, even in the presence of sodium methoxide, and the product was methyl 6-cyano-4-nitrohexanoate. The cyanoethylation of nitroacetic ester does not go in presence of sodium methoxide, even when heat is applied.

EXPERIMENTAL

2-Nitrocrontic Ester

The product obtained by the condensation of nitroacetic ester with acetaldehyde [1], which boiled over a range of 20°, was fractionated through a 30-cm column filled with nichrome spirals. At 5 mm two fractions were obtained, and after redistillation from an ordinary Claisen flask these gave the following results:

Fraction I, b. p. 81.5-82° (4 mm); n_D^{20} 1.4498; d_4^{20} 1.1469; weight 10 g; 2-nitrocrotonic ester.

Found %: C 44.99; 45.22; H 5.48; 5.34; N 8.37; 8.57.
$C_4H_5O_4N$. Calculated %: C 45.28; H 5.66; N 8.81.

Found M: 159.5; 157.1 (cryoscopically in benzene).
Calculated M: 159.

Fraction II, b. p. 89-91° (4 mm); n_D^{20} 1.4392; weight 8 g; 3-hydroxy-2-nitrobutyric ester.

Found M: 175.1; 175.9 (cryoscopically in benzene).
$C_4H_{11}O_5N$. Calculated M: 177.16.

Residue in flask and entrapment, 5.7 g; b. p. 91.5-92.5° (4 mm); n_D^{20} 1.4350; d_4^{20} 1.1262.

Hydrogenation of 3-Hydroxy-2-nitrobutyric Ester

1. A mixture of 3.5 g of the nitro compound, 2.5 g of crystalline oxalic acid, 3.5 g of palladium catalyst (5% Pd on $BaSO_4$), and 10 ml of dioxane was prepared in a 50-ml shaking autoclave. In two hours at room temperature the hydrogen pressure fell from 127 to 70 atm, and after 20 hours the pressure was 67 atm. The catalyst was filtered off and washed with dioxane. The filtrate was evaporated down as far as possible on a water bath. The thick yellow oily residue was dissolved in 10 ml of 2-butanone, and the solution was cooled in an ice bath. Rubbing with a glass rod caused a precipitate to form. It was filtered off and washed with ether; it then weighed 3 g. The product was found to be a mixture of approximately equal amounts of two substances. One substance was soluble in hot 2-butanone, and the other was insoluble. After three recrystallizations from 2-butanone the

soluble part was obtained in the form of a white powder. This sintered at 82°, became clear at 106-107°, and formed a sharp meniscus at 111-112°. It was found to be the oxalate of the ethyl ester of threonine.

Found %: C 40.83; 40.90; H 6.40; 6.37; N 6.02; 5.93.
$C_6H_{13}O_5N$. Calculated %: C 40.52; H 6.33; N 5.91.

The part that was insoluble in 2-butanone was recrystallized from a 1:1 mixture of water and 2-butanone. It sintered at 201° and melted at 205-206° (with decomposition). It was found to be the monohydrate of ammonium hydrogen oxalate.

Found %: C 19.01; 19.17; H 6.60; 5.54; N 10.87; 10.67
$C_2H_7O_5N$. Calculated %: C 19.2; H 5.6; N 11.2.

2. A mixture of 8 g of hydroxynitrobutyric ester, 6 ml of alcohol, and some Raney nickel was prepared in a 50-ml shaking autoclave. In five hours the pressure fell from 140 to 89 atm. The catalyst was filtered off, alcohol was distilled off under reduced pressure, and the residue was distilled at 14 mm. The product (2 g) boiled over the range 75-95°, and considerable decomposition occurred toward the end of the distillation. Redistillation gave 0.76 g of a colorless mobile liquid having an amine odor: b. p. 88-89° (5 mm); n_D^{20} 1.4337; d_4^{20} 0.9955.

Found %: C 54.10; 53.84; H 9.22; 9.23; N 7.80; 7.66.

The analytical data correspond to $C_8H_{15}O_3N$. The compound was not investigated further.

Hydrogenation of (2-Cyanoethyl)nitroacetic [4-Cyano-2-nitrobutyric] Ester

A mixture of 5 g (0.027 mole) of the nitro compound, 10 ml of dry pyridine, and 1 g of Pd-$BaSO_4$ (5%) was prepared in a 50-ml shaking autoclave. The autoclave was shaken at room temperature for seven hours and then heated by passage of steam through the sleeve until the pressure ceased to fall (one hour). The catalyst was filtered off and washed with pyridine. The pyridine solution was cooled in an ice-salt mixture, and 7.5 g (0.054 mole) of benzoyl chloride was added a little at a time. The mixture was warmed to room temperature, 40 ml of water and 20 ml of alcohol were added, and the mixture was heated to 60°. After being cooled to 0° and rubbed with a glass rod, the precipitated oil solidified and formed brown flocs. It was filtered off and washed twice with cooled dilute alcohol. The product was 4.1 g of colorless crystals, and 3.2 g (0.026 mole) of benzoic acid was isolated from the filtrate. The product was recrystallized twice from 60% alcohol, and it then melted at 95.5-96.5°. It was found to be the O-benzoyl derivative of the oxime of ethyl 4-cyano-2-oxobutyrate.

Found %: C 61.40; 61.34; H 5.22; 5.07; N 10.35; 10.43.
$C_{14}H_{14}N_2O_4$. Calculated %: C 61.4; H 5.13; N 10.22.

4-Nitropimelonitrile

(Bis-2-cyanoethyl)nitroacetic ester [4-cyano-2-(2-cyanoethyl)-2-nitrobutyric ester] (12 g, i. e., 0.05 mole) was warmed with 40 ml of alcohol until dissolved. An oil separated when the solution was cooled, and a solution of 2.2 g (0.055 mole) of caustic soda in aqueous alcohol was added to this mixture. The temperature rose a little, and a precipitate then formed. The mixture was heated for a few minutes in a water bath. When the amount of precipitate ceased to increase, it was filtered off. The solution was set aside at room temperature for two days. The small amount of precipitate that formed during this time was separated, and the solution was acidified to litmus with dilute hydrochloric acid, cooling being applied. Rubbing with a rod caused a precipitate to appear, and this was filtered off and washed with cold methanol; weight 4.8 g. By successive evaporations, a further 1.7 g of pure product and 0.5 g of impure product was obtained from the mother liquor. The total yield of pure product was 6.5 g, i. e., 0.039 mole (78%). It formed long colorless needles, m. p. 64.6-64.9° (from alcohol in presence of activated charcoal). The literature [3] gives m. p. 63°.

Found %: C 50.27; 50.39; H 5.65; 5.61; N 25.29; 25.59.
$C_7H_9N_3O_2$. Calculated %: C 50.2; H 5.39; N 25.2.

Methyl 3-Nitropropionate

1. Methyl 3-bromopropionate (10 g, i. e., 0.06 mole) was mixed with a few grams of sand in a 50-ml flask fitted with a stirrer having a rubber seal. An addition was made of 10 g (0.065 mole) of dry silver nitrite that had been recrystallized from water. Under stirring and periodic shaking, the almost dry mixture was heated at 60-65° in a water bath. After 90 minutes all the nitrite had settled on the bottom and formed a thick slurry, which could still be stirred, however. After two hours the mixture had thickened to such an extent that it could no longer be stirred. It was heated for a further 30 minutes and then cooled. It was mixed with ether, and the precipitate was filtered off and washed twice with ether. The ether solution was dried with calcium chloride. Ether was distilled off, and the residue was distilled at a residual pressure of 2 mm. Two fractions were obtained:

Fraction I, b. p. 26-27°; 1.9 g
Fraction II, b. p. 73-74°; 4.0 g.

After redistillation of Fraction II a 50% yield was obtained of a substance having b. p. 68° (1 mm); n_D^{20} 1.4350; d_4^{20} 1.2486; found MR 27.86; calculated MR 27.95.

Found %: C 36.33; 36.04; H 5.54; 5.43; N 10.45; 10.61.
$C_4H_7O_4N$. Calculated %: C 36.11; H 5.21; N 10.52.

2. A mixture of 30 g (0.18 mole) of methyl 3-bromopropionate, 30 g (0.195 mole) of silver nitrite, and 30 ml of dry benzene was heated, as above, with exclusion of air for 15 hours at 58°. The precipitate was filtered off, and the filtrate was heated with 9.5 g of fresh silver nitrite for ten hours. The mixture was filtered, benzene was distilled off at the pump, and the product was again filtered and was vacuum distilled. The yield of methyl 3-nitropropionate was 16.7 g (70%).

Methyl 4-Hydroxy-3-nitrovalerate

3-Nitropropionic ester (4 g, i. e., 0.03 mole) was dissolved in 5 ml of ethanol. Acetaldehyde (4 ml) and an aqueous solution of 0.1 g of potassium carbonate were added at 10°. The mixture was diluted with water until a homogeneous solution was obtained. A further 3.5 ml of acetaldehyde was added at room temperature, and the mixture was heated for ten minutes in a water bath at 50°. The mixture was cooled, and an equal volume of ethylene dichloride was added. The aqueous layer was separated, and the organic layer was washed again with water. Solvent was distilled off, and distillation of the residue at 2 mm gave 3.0 g (57%) of product, b. p. 122-135° (only a few drops distilled above this range). A second distillation gave a colorless oil, b. p. 133° (2 mm); n_D^{20} 1.4608; d_4^{20} 1.2579.

Found %: C 40.96; 41.03; H 6.20; 6.36; N 7.96; 8.07.
$C_6H_{11}O_5N$. Calculated %: C 40.67; H 6.26; N 7.90.

Methyl 5-Cyano-3-nitrovalerate

A mixture of 4 g (0.03 mole) of 3-nitropropionic ester and 1.7 g (0.032 mole) of acrylonitrile was prepared, and a catalyst prepared by the decomposition of 0.5 g of trimethylphenylammonium benzenesulfonate with the theoretical amount of sodium ethoxide [1] was added. Heat was evolved. The mixture was cooled and acidified with concentrated hydrochloric acid. An equal volume of ethylene dichloride was added. The organic layer was washed with water, solvent was distilled off, and the residue was distilled at 1 mm. Unchanged reactants were distilled off below 100° (2.7 g). The cyanoethyl derivative (0.5 g) came over at 162-170° (1 mm); n_D^{23} 1.4638.

Found %: N 15.32; 15.30.
$C_7H_{10}O_4N_2$. Calculated %: N 15.05.

Methyl 5-Hydroxy-4-nitrohexanoate

1. A mixture of 1.5 g of 4-nitrobutyric ester, 6 g of 40% alcoholic acetaldehyde, and a solution of 0.1 g of potassium carbonate in 5 ml of water and 2 ml of alcohol was set aside overnight. The mixture was then heated for one hour at 50°. It was cooled, acidified with dilute (1:1) sulfuric acid, and extracted with ether. The ether

layer was washed with water, dried with anhydrous sodium sulfate, and distilled, the residue after removal of ether being distilled at 3 mm. The product, amounting to 0.62 g, had b. p. 135-137° and n_D^{20} 1.4777.

2. A mixture of 2 g of 4-nitrobutyric ester, 10 g of 40% methanolic acetaldehyde, and 0.5 g of Anionite was shaken for six hours. The mixture was set aside overnight. The catalyst was filtered off and washed with ether, the washings being added to the reaction mixture. The lower-boiling fractions were distilled off, and the residue was distilled at 2 mm. The product (1.2 g) had b. p. 133-135° and n_D^{20} 1.4778.

The products of the two experiments were combined and found to have a density of d_4^{20} 1.0811.

Found %: N 7.95; 7.38.
$C_7H_{13}O_5N$. Calculated %: N 7.35.

Methyl 6-Cyano-4-nitrohexanoate

A mixture of 5 g (0.034 mole) of 4-nitrobutyric ester and 2 g (0.06 mole) of acrylonitrile was cooled to 0°, and a solution of sodium (a piece about as big as a lentil) in 3 ml of methanol was added. It was necessary to cool periodically with ice water in order to maintain the temperature of the mixture below 25°. The mixture was set aside at room temperature for several hours and then acidified with concentrated hydrochloric acid. An equal amount of ethylene dichloride was added, the organic layer was washed with water, and the solvent was distilled off. Vacuum distillation of the residue gave 2.1 g of product boiling at 166-174° (2 mm). For the purpose of analysis the substance was redistilled, and a sample of b. p. 161-163° (1 mm) had the following constants: n_D^{20} 1.4588 and d_4^{20} 1.1901. This sample gave a qualitative reaction for a secondary nitro compound.

Found %: N 13.82; 13.74.
$C_8H_{12}O_4N$. Calculated %: N 14.00.

1-Nitro-1,1,2-ethanetricarboxylic Ester

A mixture of 50 g of fuming nitric acid and 40 g of acetic anhydride was heated to 50°, and 36 g of triethyl 1,1,2-ethanetricarboyxlate was added dropwise. The temperature of the reaction mixture was maintained in the range 45-50° by external cooling. After the whole of the ester had been added, the mixture was set aside until heat ceased to be evolved and was then poured into 1 liter of cold water. After 90 minutes the oil that had separated was extracted with ether. The ether solution was washed with sodium carbonate solution and then with sodium chloride solution; it was dried with sodium sulfate. The volatile components were evaporated off at the pump. The residue was 39 g of a colorless oil, which could not be distilled without decomposition.

This product (30 g) was heated with 100 ml of concentrated hydrochloric acid in a water bath until gas ceased to be evolved (1 hour). The oil remaining at the bottom was extracted with ether, the ether solution was dried with calcium chloride, and ether was distilled off. Vacuum distillation of the residue gave 9 g of a product boiling over the range 149-152° (1.5 mm). A fraction taken in the range 150-151° (1.5 mm) had d_4^{20} 1.2068 and n_D^{20} 1.4450; a thick colorless odorless oil.

Found %: C 44.91; 45.06; H 5.85; 5.93; N 5.00; 5.14.
$C_{11}H_{17}O_8N$. Calculated %: C 45.36; H 5.84; N 4.81.

SUMMARY

1. It was found that partial dehydration occurred when ethyl 3-hydroxy-2-nitrobutyrate was distilled.

2. The hydrogenation of 3-hydroxy-2-nitrobutyric ester and of monocyanoethylated nitroacetic ester was studied. Biscyanoethylated nitroacetic ester, subjected to hydrolysis and then decarboxylation, gave 4-nitropimelonitrile in 78% yield.

3. Methyl 3-nitropropionate was prepared in 50-70% yield from 3-bromopropionic ester by Meyer's reaction.

4. The condensation products formed by acetaldehyde and by acrylonitrile with methyl 3-nitropropionate and with methyl 4-nitrobutyrate were prepared.

5. Triethyl 1-nitro-1,1,2-ethanetricarboxylate was prepared by the nitration of triethyl 1,1,2-ethanetricarboxylate.

PRIMARY RADICAL FORMATION IN THE VAPOR-PHASE NITRATION OF ALKANES WITH NITROGEN DIOXIDE

A. V. Topchiev and N. N. Kaptsov

In order to explain the vapor-phase nitration of alkanes by nitric acid, the following radical mechanism has been assumed in the literature [1-3]:

$$HONO_2 \rightarrow OH + NO_2. \quad (1)$$
$$RH + OH \rightarrow R + H_2O. \quad (2)$$
$$R + HONO_2 \rightarrow RNO_2 + OH. \quad (3)$$
$$OH + RH \rightarrow R + H_2O \text{ etc.} \quad (4)$$
$$R + NO_2 \rightarrow RNO_2. \quad (5)$$

This mechanism comprises Reactions (1), (2), (3), and (4), in which free alkyl and hydroxyl radicals are formed, and Reaction (5), in which alkyl radical combines with the monomeric form of nitrogen dioxide. This last reaction is the fundamental elementary act in the formation of nitroalkanes.

It is considered [4-6] that, when nitrogen dioxide is used as nitrating agent, free-radical formation occurs by reaction between radical-like [6, 7] nitrogen dioxide and the alkane in accordance with the equation:

$$RH + NO_2 \rightarrow R + HNO_2. \quad (6)$$

According to Titov [4, 8], Reaction (6) is the main source of alkyl radicals, even in the vapor-phase nitration of alkanes with nitric acid, the latter compound then serving only as a source of nitrogen dioxide and as a means of regenerating it from lower nitrogen oxides. In the gas phase the probability of the occurrence of the elementary act is identical for all molecules [9], and all NO_2 molecules have radical properties in equal measure; it may therefore be assumed that the elementary process (6) takes place on the scale of a macro system consisting of nitrogen dioxide and hydrocarbon molecules.

It would appear possible, therefore, to estimate the probability of the formation of alkyl radicals in the reaction of nitrogen dioxide with alkanes from the change in free energy. The temperature dependence of free energy for the vapor-phase nitration of methane and ethane with nitric acid is given in the literature [10]:

$$CH_4(g) + HNO_3(g) = CH_3NO_2(g) + H_2O(g). \quad (7)$$
$$\Delta Z^\circ_T = -25975 - 5.76\,T. \quad (8)$$
$$C_2H_6(g) + HNO_3(g) = C_2H_5NO_2(g) + H_2O(g). \quad (9)$$
$$\Delta Z^\circ_T = -28050 - 3.15\,T. \quad (10)$$

For the vapor-phase nitration of cyclohexane with nitrogen dioxide in accordance with the equation:

$$C_6H_{12} + 1.5\ NO_2 = C_6H_{11}NO_2 + 0.5\ NO + 0.5\ H_2O \quad (11)$$

the temperature-dependence of ΔZ°_T is obtained [11], by the substitution of known values of ΔZ°_T in suitable thermodynamic expressions, in the form of the equation:

$$\Delta Z^\circ_T = -22055 - 3.65\,T \ln T + 5.03 \cdot 10^{-3} T^2 - 0.65 \cdot 10^{-6} T^3 + 0.34\,T, \quad (12)$$

which may be reduced to the linear form:

$$\Delta Z^{\circ}_{T} = -21560 - 18.35\,T. \qquad (13)$$

The above-cited relationships between ΔZ°_{T} and temperature show that at all temperatures the nitration reactions of hydrocarbons in the vapor phase are spontaneous processes, i.e., proceed with reduction in free energy, when nitric acid or oxides of nitrogen are used as nitrating agent. Hence, the intermediate stages of the reaction (regarded from the macroscopic point of view) must also be thermodynamically possible.

Heat Contents and Free Energies of Formation of Some Aliphatic Radicals [14]

Radical	$\Delta H^{\circ}_{298.2}$ (cal/mole)	$\Delta Z^{\circ}_{298.16}$ (cal/mole)
CH_3	32022	32600
C_2H_5	25175	31600
C_3H_7	18091	32100
CH_3 / $CH-$ / CH_3	12100	26200
C_4H_9	12099	32700
C_5H_{11}	6411	34000
C_6H_{13}	1151	35700
C_7H_{15}	−3775	37000
C_8H_{17}	−8701	39800

For the reaction

$$CH_4(g) + NO_2(g) \longrightarrow CH_3(g) + HNO_2(g) \qquad (14)$$

we have [12]:

$\Delta Z^{\circ}_{298}CH_4 = -12.14$ kcal/mole.
$\Delta Z^{\circ}_{298}NO_2 = 12.26$ kcal/mole.
$\Delta Z^{\circ}_{298}CH_3 = 31.5$ kcal/mole.
$\Delta Z^{\circ}_{298}HNO_2 = -4.8$ kcal/mole.

The free energy of formation of gaseous nitrous acid is found from the standard entropy, as given by spectroscopic data [13]:

$S^{\circ}_{298}HNO_2(g) = 56$ entropy units

and from its heat of formation, which is easily found to be 14.2 kcal from the following thermodynamic equations:

$$H_2 + \tfrac{1}{2}O_2 = H_2O(g) + 57.8 \text{ kcal.} \qquad (15)$$

$$\tfrac{1}{2}N_2 + \tfrac{1}{2}O_2 = NO(g) - 21.5 \text{ kcal.} \qquad (16)$$

$$\tfrac{1}{2}N_2 + O_2 = NO_2(g) - 7.96 \text{ kcal.} \qquad (17)$$

Hence, for reaction of methane with nitrogen dioxide (Equation 14) we have:

$$\Delta Z^{\circ}_{298} = 31.5 - 4.8 + 12.14 - 12.26 = 26.6 \text{ kcal.}$$

The value of ΔZ° obtained indicates a very low probability for the formation of methyl radicals in reaction between NO_2 and CH_4 in accordance with Equation 14. Similar conclusions follow also for reactions of nitrogen dioxide with other alkanes. The values of ΔZ°_{298} for various radicals are given in the table.

As the reactions of alkanes with nitrogen dioxide in accordance with Equation 6 are all of one type, then according to Kireev [15, 16] the following relationship holds:

$$\Delta H^{\circ}_1 - \Delta H^{\circ}_2 = \Delta Z^{\circ}_1 - \Delta Z^{\circ}_2, \qquad (18)$$

in which ΔH°_1, ΔZ°_1, ΔH°_2, and ΔZ°_2 are the heat-content and free-energy changes for two of these reactions.

On the basis of this relationship, for the reaction between ethane and nitrogen dioxide in accordance with the equation:

$$C_2H_6 + NO_2 \rightarrow C_2H_5 + HNO_2$$

the change of free energy is

$$\Delta Z_2^\circ = \Delta Z_1^\circ + (\Delta H^\circ_{C_2H_5} - \Delta H^\circ_{CH_3}) + (\Delta H^\circ_{CH_4} - \Delta H^\circ_{C_2H_6}), \quad (19)$$

in which ΔZ_1° = 26.6 kcal, the standard free-energy change for the reaction of methane with nitrogen dioxide in accordance with Equation 14.

Substituting the appropriate values of ΔH°_{298}, we obtain:

$$\Delta Z_{298}^\circ = 22.7 \text{ kcal.}$$

An analogous calculation for the reaction of propane with nitrogen dioxide gives the value ΔZ°_{298} = 20.1 kcal.

The temperature-dependence of the change of free energy in the reaction of methane with nitrogen dioxide in accordance with Equation 14 can be expressed, to a first approximation, by the formula:

$$\Delta Z_T = \Delta H^\circ_{298} - T\Delta S^\circ_{298}.$$

Substituting the values

$$\Delta H^\circ_{298} = \Delta H^\circ_{298}CH_3 + \Delta H^\circ_{298}HNO_2 - \Delta H^\circ_{298}CH_4 - \Delta H^\circ_{298}NO_2$$

and

$$\Delta S^\circ_{298} = S^\circ_{298}CH_3 + S^\circ_{298}HNO_2 - S^\circ_{298}CH_4 - S^\circ_{298}NO_2$$

we arrive at the equation:

$$\Delta Z^\circ = 27 - 0.0012\ T. \quad (20)$$

From this equation it may be inferred that it is impossible to obtain methyl radicals by Reaction (14) at any temperature that could be used in practice in the vapor-phase nitration of alkanes.

Kireev [16] has shown that for reactions of the same type the difference between values of ΔH° (Equations 18 and 19) is independent of temperature, so that, on the basis of Equations 20 and 19 it may be inferred that the formation of free radicals by the general equation $RH(g) + NO_2(g) \rightarrow R(g) + HNO_2(g)$ (regarded from the macroscopic point of view) is very unlikely also for temperatures other than 25°.

The low potency of the monomeric form of nitrogen dioxide in the generation of radicals follows also from a comparison of values of ΔZ°_{298} for the typical reaction:

$$X + H_2 \rightarrow HX + H; \quad (21)$$

$$Cl + H_2 \rightleftarrows HCl + H; \quad Br + H_2 \rightleftarrows HBr + H; \quad I + H_2 \rightarrow HI + H;$$

$$\Delta Z^\circ_{298} = 0{,}6 \text{ kcal}; \quad \Delta Z^\circ_{298} = 16{,}5 \text{ kcal}; \quad \Delta Z^\circ_{298} = 34{,}3 \text{ kcal};$$

$$NO_2 + H_2 \rightarrow HNO_2 + H; \quad \Delta Z^\circ_{298} = 31{,}2 \text{ kcal}$$

These data show that the ability of NO_2 to break the H—H bond is approximately the same as that of atomic iodine. Actually, whereas a chain mechanism with participation of the above reactions has been established experimentally for chlorine and bromine, the reaction of iodine with hydrogen is not a chain reaction, but proceeds according to the equation:

$$H_2 + I_2 \rightleftarrows 2HI.$$

On the basis of thermochemical data Semenov [17] showed that NO_2 is again a radical of low activity in reactions of the type

$$R + R'X \rightarrow RX + R',$$

in which

$$R = NO_2,\ R' = CH_3,\ X = CH_3,\ NH_2.$$

As vapor-phase nitration, particularly with oxides of nitrogen, is carried out at temperatures below those required for the cracking of hydrocarbons, then, in view of the high energy required for the rupture of C—H bond (80-90 kcal/mole), it is very unlikely that free radicals will be generated thermally by the reaction:

$$RH \rightarrow R + H.$$

The thermodynamic calculations given above do not indicate the impossibility of the formation of radicals in the system RH (g) + NO_2 (g) in other ways.

The vapor-phase nitration of alkanes with nitrogen dioxide is usually carried out at 250-350° for a long (of the order of several minutes) period of contact. In view of the partial dissociation of nitrogen dioxide which undoubtedly occurs under these conditions, it may be possible to explain the primary radical formation on the basis of reaction of oxygen formed by dissociation of nitrogen dioxide with the alkane by the chain mechanism [18]:

$$RH + O_2 \rightarrow RO_2H.$$
$$RO_2H \rightarrow RO + OH.$$
$$OH + RH \rightarrow R + H_2O.$$
$$RO + RH \rightarrow ROH + R.$$
$$R + O_2 \rightarrow RO_2.$$
$$RO_2 + RH \rightarrow RO_2H + R \text{ etc.}$$

We must point out that, in some papers on the oxidation of hydrocarbons in presence of nitrogen dioxide [19, 20] and on the oxidation of hydrocarbons by pure nitrous oxide [21], it is assumed that reaction is initiated by oxygen atoms formed by the thermal dissociation of a nitrogen oxide. It is emphasized in the literature [5] that only the formation of alkyl radicals is a chain reaction, the combination of R and NO_2 being a free-radical reaction. As a result of the entry of the oxygen into reaction with the alkane, the dissociation equilibrium of NO_2 will be displaced with increase in the oxygen concentration, thus creating the conditions necessary for the formation of alkyl radicals. Alkyl radicals, by reacting with undecomposed NO_2 molecules, give nitroalkanes.

Data on the nitration of propane with nitrogen dioxide in the vapor phase at not above 300° in presence of oxygen show [5] that rise in oxygen concentration in the reaction zone, by increasing the opportunities for radical formation, raises the yield of nitroalkanes to an appreciable extent. When the same process is carried out at a higher temperature (350°), there is a sharp fall in the yield and extent of conversion and there is an appreciable increase in the CO content of the exit gases. It would appear that, in the high-temperature nitration of alkanes with nitrogen dioxide in presence of oxygen, conditions are created under which the rate of the reaction

$$R + NO_2 \rightarrow RNO_2$$

is evidently less than that of the reaction

$$R + O_2 \rightarrow \text{oxidation products.}$$

One of the possible causes of the development of an oxidative course in the nitration reaction lies in the thermal decomposition of nitrous esters, which, as Titov [7] showed, are formed as by-products in the nitration of alkanes with oxides of nitrogen. The study of the oxidation reactions of hydrocarbons shows that the addition of alkyl nitrites provides a means of introducing active initiating centers [22], which shorten the induction period and bring about a great increase in reaction rate [23].

According to Joffe [6], a mixture of pentane and nitrogen dioxide of composition $C_5H_{12} + 4NO_2$ reacts explosively at 432° under a pressure of 14.2 mm. The period of induction then observed (2.5 seconds) is reduced to zero when a trace of ethyl nitrite is added. In this paper [6] it is suggested that a critical concentration of nitrous esters may be formed during the induction period.

The initiation of radical formation in the vapor-phase nitration of alkanes with nitrogen oxides and nitric acid is closely related to other phenomena observed by various authors, namely, the catalysis of the reaction by chlorine [24, 25], bromine [26], iodine [26], and mixtures of these halogens with oxygen. According to a patent [27], when oxygen and halogens are used simultaneously, the degree of conversion of nitric acid is 50% greater than in the usual procedure, in which oxygen and halogens are not used.

The results of Maizus and Emanuel [28] on the catalytic effects of chlorine, bromine, and hydrogen halides (HCl and HBr) on the oxidation of hydrocarbons can be applied also to the nitration reaction, and they enable us to associate the observed accelerating effects of small additions of halogens with their initiation of radical formation, for example in accordance with the scheme [25]:

$$X_2 \rightleftharpoons 2X.$$
$$RH + X \rightarrow R + HX.$$
$$R + NO_2 \rightarrow RNO_2.$$
$$R + X_2 \rightarrow RX + X.$$
$$HX \xrightarrow{O_2,NO_2} H_2O + X_2.$$

In explanation of the primary generation of active halogen atoms, in particular chlorine atoms, Titov [7] proposed the following equations:

$$Cl_2 + NO \rightarrow NOCl + Cl.$$
$$Cl_2 + NO_2 \rightarrow NO_2Cl + Cl.$$

In vapor-phase nitration of alkanes with nitrogen dioxide, increase in the yield of nitroalkane can be attained both by increase in the rate of radical formation and by retardation of oxidative reactions in which the free radicals take part. It is probable that the catalytic effect of molecular iodine on the nitration of propane with nitrogen dioxide observed by Bachman and others [26] is to be associated largely with the tendency of rather inactive iodine atoms to retard the oxidation of hydrocarbons in particular cases. Actually, it is found that in presence of 0.15% I_2 [26] the CO content of the reaction products is reduced from 22.1% to 5.2% [26]. Simultaneously, the yield of nitro compounds is increased by 10%.

The presence of free nitric oxide in the sphere of reaction has an unfavorable effect on the nitration reaction. Nitric oxide may be formed both by the dissociation of nitrogen dioxide and also by the reaction:

$$2RH + 3NO_2 \rightarrow 2RNO_2 + NO + H_2O.$$

The effect of nitric oxide is particularly notable in the nitration of propane with nitric acid at 420° [25]. At a molar ratio of $NO/HNO_3 = 0.009$, in spite of the presence of oxygen ($O_2/HNO_3 = 1.05$), the degree of conversion of HNO_3 was reduced from 38.9% (NO absent) to 34.5% (NO present). At the same time the CO content of the exit gases rose from 6.2% to 11.9%, and the ethylene content rose from 2.3% to 5.7%.

Being a powerful inhibitor of chain reactions [29], nitric oxide reduces the rate of radical formation and the rate of combination of radicals with nitrogen dioxide. On the other hand, the increases observed in the CO and C_2H_4 contents of the exit gases indicates the development of processes of hydrocarbon cracking and of far-reaching oxidation of hydrocarbons.

In the papers of Shtern and coworkers [30, 31] on the oxidation of propane by oxygen in presence of nitrogen dioxide, the shortening of the induction period is considered to be due to the effect of nitric oxide formed by dissociation. However, the addition of nitric oxide inhibits the oxidation of propane by nitrous oxide in the temperature range 505-605° [32]. Above 655° the inhibiting effect of nitric oxide disappears. As Semenov has pointed out [17], nitric oxide can simultaneously show both accelerating and retarding effects on chain reactions; the overall effect may be positive or negative.

SUMMARY

It is shown with the aid of thermodynamic calculations that it is very unlikely that free radicals will be formed by reaction of nitrogen dioxide with alkanes in accordance with the equation $RH + NO_2 \rightarrow R + HNO_2$.

CATALYTIC HYDROCONDENSATION OF CARBON MONOXIDE WITH OLEFINS

COMMUNICATION 17. PARTICIPATION OF 2-BUTENE IN THE HYDROCONDENSATION REACTION WITH CARBON MONOXIDE

Ya. T. Eidus and R. I. Izmailov

We have previously reported results on the hydrocondensation of carbon monoxide with 1-butene [1] and 2-butene [2] under identical conditions: temperature 190°, pressure atmospheric, carbon monoxide concentration 4-6% on the original gas mixture of 70-75% butene and 20-25% hydrogen, space velocity about 100 hour^{-1}. Comparison of the hydrocondensation products of 1-butene and 2-butene*, of the physical constants of fractions having an identical boiling range, and of the Raman spectra of these fractions shows that these products do not differ qualitatively and consist essentially of hydrocarbons of normal structure: there is an admixture of only a very small amount of branched hydrocarbons having one methyl side group. This result was very unexpected for reaction with 2-butene, since normal hydrocarbons can be formed by hydrocondensation only from 1-butene: as in this process the reaction center in the olefin molecule is the double bond, 2-butene should give only branched hydrocarbons. The mild conditions of the reaction practically exclude the possibility of skeletal isomerization. Hence, if unchanged 2-butene were to undergo the hydrocondensation reaction at any appreciable rate, it would be expected that appreciable amounts of branched hydrocarbons would be found among the reaction products, which is not observed experimentally. The same could be said of the products of the hydrocondensation of 1-butene, for it has been shown previously [3] that 1-butene is readily isomerized to 2-butene under the conditions of the reaction.

Our results give reason to suppose that, in the hydrocondensation of 1- or 2-butene, the products are always formed from 1-butene, into which 2-butene must first be isomerized. On this basis we should expect that no difference would be observed between 1- and 2-butenes in the hydrocondensation reaction. However, when the results on the hydrocondensation of carbon monoxide with 1-butene [1] and with 2-butene [2] are compared, not only resemblances, but also substantial differences can be observed.

The identical extents to which hydrogen participates in the overall process should be noted: in both cases it reacts to the extent of 54-55%, calculated on the original amount of hydrogen. There is little difference also in the extents to which carbon monoxide takes part: 52.2% in the case of 1-butene and 45.6% in the case of 2-butene. The same may be said of the hydrocracking products, which amount to not more than 3-4% of the 1- or 2-butene that undergoes reaction. Among the differences that should be noted we must first of all refer to the considerable difference in the value of the total yield of liquid hydrocarbons: 730-975 ml/cu.m, or 70-100 ml/liter·hour, for the reaction of 1-butene and 350-540 ml/cu.m, or 35-55 ml/liter·hour, for the reaction of 2-butene (ratio about 2). Correspondingly, the degree of conversion of 1-butene is 74%, and that of 2-butene is 47%. There is a difference also in the content of unsaturated hydrocarbons in the hydrocondensate (52% and 37%); moreover, the average molecular weight of these is greater in the case of 2-butene, as can be seen from the relative amounts of heavy and light oils and the sizes of the individual fractions. In the hydrogenated hydrocondensate the C_8 fractions amount to 8% and 0.8% respectively, the C_8 fractions to 8.6% and 6.1%, and the C_7 fractions to 9.7% and 8.4%. The yield of butane, which characterizes the hydrogenation of the butenes, is 9.4% for 1-butene and 5.0% for 2-butene (on the amount of original olefin that reacted). This increased yield of butane and greater total yield of hydrocarbons in the reaction with 1-butene must explain the equal extent to which hydrogen takes part in the two cases.

At first glance it may appear that all those features of the 2-butene reaction which we have described as

* See Table 3 and Fig. 2 in our Communications 15 [1] and 16 [2].

substantially different from those of the 1-butene reaction must contradict the view that the hydrocondensation products from 2-butene are formed essentially from 1-butene, into which 2-butene is first isomerized. However, on a closer examination it is found that these differences not only do not contradict this view, but, on the contrary, find their explanation in this general scheme of reaction and confirm the hypothesis that the rate of the reaction of 1-butene in hydrocondensation with carbon monoxide is very much greater than the rate for 2-butene, the direct reaction of which is extremely slow:

$$^{v}C_4H_8\text{-}1 \gg {}^{v}C_4H_8\text{-}2; \quad {}^{v}C_4H_8\text{-}2 \to 0, \tag{1}$$

and that the hydrocondensation reaction of 2-butene proceeds essentially via the intermediate formation of 1-butene.

Let us examine the relative amounts of the reactants on the catalyst surface in the two cases. In the reaction with 1-butene, the catalyst contains adsorbed hydrogen, carbon monoxide, 1-butene, and a fairly large amount of 2-butene, which is formed from 1-butene and will not exceed the latter in amount. We have shown previously [3] that, under the same reaction conditions but in absence of carbon monoxide, the relative amounts of 1- and 2-butenes in the gas phase of the reaction product is 1 : 1.1 when the original hydrocarbon is 1-butene (in presence of hydrogen). It was found also [1] that, when carbon monoxide is added, the amount of 1-butene that isomerizes to 2-butene is 16% on the amount of olefin that reacts. Hence, for the butene concentrations at the catalyst surface in experiments on the hydrocondensation of carbon monoxide with 1-butene we may write:

$$[C_4H_8 - 1]' \geq [C_4H_8 - 2]'. \tag{2}$$

When the original hydrocarbon is 2-butene, hydrogen and carbon monoxide are adsorbed on the catalyst surface in about the same amounts as in the experiments with 1-butene; 2-butene and small amounts of 1-butene formed from 2-butene are also adsorbed. The fact that the 1-butene concentration is indeed low in this case is clear from the results of our previous investigations [1, 3], in which no 1-butene could be detected in the gas phase after experiments with mixtures of 2-butene, hydrogen, and carbon monoxide or of 2-butene and hydrogen. The explanation is that, when the volume of the original 2-butene is comparatively small, the 1-butene formed from it in small amount remains adsorbed on the catalyst surface; in presence of carbon monoxide it enters the hydrocondensation reaction, being continually regenerated by isomerization from 2-butene.

Hence, for the butene concentrations at the catalyst surface in experiments on the hydrocondensation of carbon monoxide with 2-butene we may write:

$$[C_4H_8 - 2]' \gg [C_4H_8 - 1]'. \tag{3}$$

However, it is clear from experiments on the isomerization of 1- and 2-butenes [3] that

$$[C_4H_8 - 2]' \geq [C_4H_8 - 2] \tag{4}$$

and from (3) and (4) it follows that

$$[C_4H_8 - 2]' \gg [C_4H_8 - 1]', \tag{5}$$

and from (2) and (5) we have

$$[C_4H_8 - 1]' \gg [C_4H_8 - 1]'. \tag{6}$$

On the basis of the above considerations it follows that

$$\frac{[H]'}{[C_4H_8 - 1]'} \gg \frac{[H]}{[C_4H_8 - 1]} \tag{7}$$

and

$$\frac{[CO]'}{[C_4H_8 - 1]'} \gg \frac{[CO]}{[C_4H_8 - 1]}, \tag{8}$$

in which [H]' and [CO]' are the hydrogen and carbon monoxide concentrations (expressed in any form) at the catalyst surface in experiments with 1-butene and [H]" and [CO]" are the corresponding concentrations for experiments with 2-butene.

The relationship (7) shows that, in the hydrocondensation of carbon monoxide with 2-butene, the ratio of the hydrogen concentration to the concentration of 1-butene reacting is greater than the same ratio for reaction with 1-butene. As shown previously [1], a relative increase in the hydrogen concentration results mainly in a fall in the total yield of liquid hydrocarbons, an increase in their saturation, and, finally, a lowering of their average molecular weight. In the hydrocondensation of carbon monoxide with 2-butene the total yield of hydrocarbons is indeed lower and the reaction product is more saturated than in the 1-butene reaction. The average molecular weight, however, is not lower, but higher. This unexpected contradiction is completely resolved by an examination of the relationship (8), from which it can be seen that in the hydrocondensation of carbon monoxide with 2-butene the ratio of the concentrations of carbon monoxide and 2-butene at the catalyst is very much greater than for the same reaction with 1-butene. As we have already found [4], a relative increase in the carbon monoxide concentration results in an increased yield of the heavier hydrocarbons; moreover, increase in the carbon monoxide concentration beyond a definite limit results in retardation of the reaction and fall in overall yield. Hence, increases in the concentrations of hydrogen and of carbon monoxide have antagonistic effects on the average molecular weight of the reaction products. It would appear that in this case the effect of carbon monoxide is predominant, so that in experiments with 2-butene the product is heavier than in the 1-butene reaction.

We must consider yet another peculiarity observed in the hydrocondensation of carbon monoxide with 1-butene: the presence of isopentene in the hydrocondensate, which was not found in the 2-butene reaction. In the latter reaction the total yield of the C_5 fraction was only 0.8% of the liquid hydrocondensate [2], which is probably to be explained by the effect of the enhanced carbon monoxide concentration at the catalyst surface and the more rapid further hydrocondensation of the pentenes formed.

It is very probable that the branched pentene isomers are formed mainly not from 2-butene, but from 1-butene by the mechanism indicated previously [2]. In fact, if they arise from 2-butene, then the inequalities (4) and (6) indicate that we must expect the greater amounts of branched C_5 hydrocarbons not in the 1-butene experiments, but in hydrocondensation of carbon monoxide with 2-butene, which is not observed experimentally.

SUMMARY

1. The products of the hydrocondensation of carbon monoxide with 1-butene and with 2-butene are in both cases mainly normal aliphatic hydrocarbons admixed with a very small amount of slightly branched hydrocarbons.

2. In the hydrocondensation of carbon monoxide with 1-butene, a more unsaturated, lighter product is obtained than in the same reaction with 2-butene.

3. A comparison of our results on the two reactions enables us to infer that the mechanism is the same in both cases, but in the 2-butene reaction the 2-butene is largely isomerized into 1-butene, which then undergoes hydrocondensation with carbon monoxide.

MECHANISM OF THE THERMAL DECOMPOSITION AND CHLORINOLYSIS OF HEXACHLOROPROPENE AND OCTACHLORO-1,3-PENTADIENE

M. G. Gonikberg

This paper gives an analysis of available data on the pyrolysis of hexachloropropene and octachloro-1,3-pentadiene at 450-500° in a flow system at atmospheric pressure, and also on the chlorinolysis of these compounds [1], our object being the elucidation of various aspects of the mechanism of these reactions.

Among compounds formed in the thermal decomposition of hexachloropropene are carbon tetrachloride, tetrachloroethylene, hexachloroethane, the compound C_6Cl_8 (see below), and hexachlorobenzene. The first stage of the process may consist either in the elimination of a chlorine atom (Reaction Ia, Ib, and Ic), in the breaking of a C—C bond (Reaction Id), or in disproportionation of chlorine (Reaction IIa):

$$CCl_2=CCl-CCl_3 \rightarrow CCl_2=\dot{C}Cl-\dot{C}Cl_2 + \dot{C}l. \quad (Ia)$$

$$CCl_2=CCl-CCl_3 \rightarrow CCl_2=\dot{C}(CCl_3) + \dot{C}l. \quad (Ib)$$

$$CCl_2=CCl-CCl_3 \rightarrow \dot{C}Cl=CCl-CCl_3 + \dot{C}l. \quad (Ic)$$

$$CCl_2=CCl-CCl_3 \rightarrow CCl_2=\dot{C}Cl + \dot{C}Cl_3. \quad (Id)$$

$$2C_5Cl_6 \rightarrow C_5Cl_5 + C_5Cl_7. \quad (IIa)$$

The rates of reactions of Types I and II are determined by the equations [2]:

$$\omega_I \approx 10^{13} e^{-E_I/RT} c \quad (1)$$

and

$$\omega_{II} \approx 10^{-10} e^{-E_{II}/RT} c^2, \quad (2)$$

in which c is the number of molecules per cc; at 500° and 1 atm, $c \approx 10^{19}$.

$$\frac{\omega_I}{\omega_{II}} \approx 10^{4} e^{-(E_I - E_{II})/RT}. \quad (3)$$

We shall now examine some data on the C—Cl and C—H bond energies in aliphatic compounds (Table 1).

For the compounds given in Table 1:

$$Q_{C-Cl} \approx Q_{C-H} - 19(\pm 1.5) \text{ kcal/mole}.$$

From Table 1 we conclude $E_{(Ia)} \approx 40$-50 kcal/mole and $E_{(Ic)} \approx 60$-80 kcal/mole. In order to evaluate $E_{(Ib)}$ we may use the data for Q_{C-H} in $(CH_3)_3CH$—H (89 kcal/mole). When we take into account the replacement of an ordinary bond by a double one and hydrogen atoms by chlorine, we find that $E_{(Ib)}$ must also be more than 60 kcal/mole. The same may be inferred for $E_{(Id)}$ on the basis of data for Q_{C-C} in CH_2=CH—CH_3 (90 kcal/mole?) and in CH_3CH_2—CH_3 (82 kcal/mole). Hence, on the basis of these very approximate estimates we may state, with a high measure of confidence, that, of the possible reactions of unimolecular decomposition of hexachloropropene, Reaction (Ia) has the lowest activation energy.

TABLE 1

Some C—Cl and C—H Bond Energies [2]

Compound	Q_{C-Cl} (kcal/mole)	Compound	Q_{C-H} (kcal/mole)	$Q_{C-H}-Q_{C-Cl}$
CCl_3-Cl	68.4	CCl_3-H	89	20.6
$CHCl_2-Cl$	73.5	$CHCl_2-H$	93.2	19.7
CH_2Cl-Cl	78.5	CH_2Cl-H	97.4	18.9
CH_3-Cl	83.5	CH_3-H	101	17.5
CH_3CH_2-Cl	80	CH_3CH_2-H	98	18
$CH_2=CH-Cl$	86?	$CH_2=CH-H$	104?	18?
$CH_3CH_2CH_2-Cl$	77	$CH_3CH_2CH_2-H$	95	18
$CH_2=CHCH_2-Cl$	58	$CH_2=CHCH_2-H$	77	19

There is very little information in the literature on the activation energies of reactions of Type II. The following values of E are known for reactions in which two radicals are formed by reaction between two molecules (with participation of olefins [2]): $C_2H_4 + C_2H_6 \rightarrow 2\dot{C}_2H_5$ ($E \approx 60$ kcal/mole); $Cl_2 + C_2H_4 \rightarrow \dot{C}_2H_4Cl + \dot{C}l$ ($E \approx 41$ kcal/mole); in the polymerization of olefins E = 35-38 kcal/mole. Let us assume a minimal activation energy (35-40 kcal/mole) for Reaction (IIa). Then it follows from Equation 3 ($E_{(Ia)} = 50$ kcal/mole and $E_{(IIa)} = 35$ kcal/mole) that

$$\omega_{(Ia)} \gg \omega_{(IIa)}.$$

If however we take account of the fact that there are undoubtedly steric difficulties in Reaction (IIa) (steric factor $f < 1$), we obtain

$$\omega_{(Ia)} > \omega_{(IIa)}. \qquad (4)$$

In our opinion, therefore, the most probable first stage in the thermal decomposition of hexachloropropene is Reaction (Ia), which proceeds with formation of the radical $\dot{C}_3Cl_5$. The compound C_6H_{10} is not found among the reaction products, but the presence of C_6Cl_8 (see below) has been established. This suggests that in the course of reaction either a diradical $\dot{C}_3Cl_4\dot{C}$ is formed, or a molecule of the same composition (tetrachloroallene or chloro(trichloromethyl)acetylene).

Let us now examine the reaction between the atomic chlorine formed by Reaction (Ia) with the original hexachloropropene. We consider that this reaction is a process of destructive chlorination, which, unlike the usual chlorinolysis, proceeds in absence of excess of chlorine. In our opinion, the mechanism of destructive chlorination is to some extent analogous to that of the homogeneous destructive hydrogenation of aromatic compounds [3, 4]: it is a peculiar radical reaction of substitution distinguished by the fact that the interaction of the atom (radical) with the molecule results in the removal from the molecule not of an atom, but of a more or less complex radical. In the case of a molecule containing a double bond, this interaction appears to occur in two stages: addition of the attacking atom (radical) at the double bond, and breakdown of the resulting radical at the C—C bond [5].

Thus, the following scheme is possible for hexachloropropene:

$$\dot{C}_3Cl_4 + \dot{C}l \rightarrow \dot{C}_3Cl_5;$$
$$\dot{C}_3Cl_5 \rightarrow C_2Cl_4 + \dot{C}Cl_3.$$

It will be shown below that the hypothesis that we have advanced for the main stages of the thermal decomposition of hexachloropropene is confirmed by the compositions and relative amounts of the reaction products. Owing to the absence of accurate kinetic data we cannot completely exclude the possibility of a chain mechanism for the reaction under consideration; below, however, we shall give our proposed radical non-chain scheme, which, in our opinion, is in fairly satisfactory agreement with experiment.

Let us pass to an examination of experimental results obtained in a flow system for a time of contact of 12-15 seconds. Results on the investigation of the pyrolysis of hexachloropropene are given in Table 2.

TABLE 2

Main Products of the Vapor-phase Pyrolysis of Hexachloropropene (yields in moles/mole of original C_3Cl_6)[1]

Temperature (°C)	CCl_4	C_2Cl_4	C_2Cl_6	C_6Cl_6
450-460	0.04	0.28	0.12	0.57
490-500	0.11	0.67	0.21	Traces
490-500	0.14	0.70	0.24	Traces
Mean for 490-500	0.125	0.685	0.225	

The authors of the paper cited [1] state that in the high-boiling fractions they identified considerable amounts of the crystalline compound C_6H_8 (which they considered to be 1,2,3,4,5-pentachloro-5-(trichloromethyl)-1,3--cyclopentadiene) and hexachlorobenzene. It was shown by special experiments that the hexachlorobenzene was formed by the thermal decomposition of C_6Cl_8*.

With the aid of Table 2 we may calculate the material balance sheet and determine the composition of the high-boiling residue. It is found that at 450-460° the composition of the residue corresponds to the formula $C_nCl_{1.29n}$, and at 490-500°, $C_nCl_{1.33n}$. Assuming that n = 6, we find that at 450-460° the formula of the residue is $C_6Cl_{7.74}$, and at 490-500°, C_6Cl_8. The yields (calculated for C_6Cl_8) are, respectively, 0.075 and 0.168 moles per mole of original C_3Cl_6.

Hexachloro-1,2-butadiene was not detected among the reaction products. This indicates that $\dot{C}_2Cl_3$ radicals are not formed in the thermal decomposition of hexachloropropene and that there is therefore an absence of C—C bond rupture in accordance with the equation:

$$Cl_3C{-}CCl{=}CCl_2 \longrightarrow Cl_3\dot{C} + \dot{C}_2Cl_3.$$

We therefore propose the following scheme for the mechanism of the reaction:

$$1.\ a\,C_3Cl_6 \rightarrow a\,C_3Cl_4 + 2a\,\dot{C}l.$$

$$2.\ a\,C_3Cl_4 \rightarrow \frac{a}{2}\,C_6Cl_8.$$

$$3.\ b\,C_3Cl_6 + b\,\dot{C}l \rightarrow b\,C_2Cl_4 + b\,\dot{C}Cl_3.$$

$$4.\ (2a-b)\,\dot{C}l + (2a-b)\,\dot{C}Cl_3 \rightarrow (2a-b)\,CCl_4.$$

$$5.\ (2b-2a)\,\dot{C}Cl_3 \rightarrow (b-a)\,C_2Cl_6.$$

$$(a+b)\,C_3Cl_6 \rightarrow \frac{a}{2}\,C_6Cl_8 + b\,C_2Cl_4 + (b-a)\,C_2Cl_6 + (2a-b)\,CCl_4$$

It follows from the overall equation for the process that the number of moles of hexachloropropene entering into reaction [we shall denote this by (C_3Cl_6)] equals the sum of the number of moles of tetrachloroethylene and the number of moles of C_6Cl_8, i. e., $(C_3Cl_6) = (C_2Cl_4) + 2(C_6Cl_8)$; also $(C_2Cl_6) = (C_2Cl_4) - 2(C_6Cl_8)$ and $(CCl_4) = 2(C_6Cl_8) - (C_2Cl_6)$.

Actually, these relationships hold very satisfactorily at 450-460°: 0.43 should equal 0.28 + 0.15; 0.12 should equal 0.28 − 0.15; 0.04 should equal 0.15 − 0.12. At 490-500°, however, there is a great departure from the second of these relationships (in the calculation we used average values from two experiments; see Table 2), and this makes it necessary to supplement the above mechanism scheme by the reaction between $\dot{C}Cl_3$ radicals and C_3Cl_6 molecules:

$$\dot{C}Cl_3 + C_3Cl_6 \rightarrow C_2Cl_4 + \dot{C}_2Cl_5;$$
$$2\dot{C}_2Cl_5 \rightarrow C_2Cl_4 + C_2Cl_6.$$

* These authors showed also that, under the conditions used, the chlorination of C_2Cl_4 to C_2Cl_6 did not occur to any appreciable extent, even at 400-500°.

To Equations 1-4 we must now add the following:

$$5a.\ c\,\dot{C}Cl_3 \rightarrow \frac{c}{2}\,C_2Cl_6.$$

$$6.\ (2b-2a-c)\,\dot{C}Cl_3 + (2b-2a-c)\,C_3Cl_8 \rightarrow$$

$$\rightarrow \left(3b-3a-\frac{3}{2}c\right)C_2Cl_4 + \left(b-a-\frac{c}{2}\right)C_2Cl_6.$$

$$(3b-a-c)\,C_3Cl_8 \rightarrow \frac{a}{2}\,C_6Cl_6 + \left(4b-3a-\frac{3}{2}c\right)C_2Cl_4 +$$
$$+ (b-a)\,C_2Cl_6 + (2a-b)\,CCl_4$$

Two relationships follow from the overall equation of the process:

a) (CCl_4) should equal $2(C_6Cl_6) - (C_2Cl_6)$;
b) $3(C_3Cl_8)$ should equal $2(C_2Cl_4) + (C_2Cl_6) + 8(C_6Cl_6)$.

It is easy to show that both of these relationships are true both at 450-460° and at 490-500°, which is a powerful argument in favor of the proposed mechanism scheme.

The same scheme enables us to explain also the results of experiments [1] on the chlorinolysis of hexachloropropene (Table 3).

TABLE 3
Products of the Chlorinolysis of Hexachloropropene (yields in moles/mole original C_3Cl_6)

Temperature (°C)	CCl_4	C_2Cl_4	C_2Cl_6	C_3Cl_6
300-310	0.08	0.09	0	0.88
350-360	0.62	0.69	0.02	0.26
400-410	0.92	0.96	0.04	0
490-500	0.90	0.90	0.12	0

TABLE 4
Products of the Pyrolysis of Octachloropentadiene in the Vapor Phase (moles/mole original C_5Cl_8)

Temperature (°C)	CCl_4	C_4Cl_6	C_5Cl_6	C_6Cl_6	C_5Cl_8
400-410	0.01	0.03	0.04	0	0.8
450-460	0.22	0.36	0.30	0.02	0.25
490-500	0.37	0.42	0.39	0.08	0

It is evident that the chlorinolysis of hexachloropropene proceeds by the chain reaction scheme:

1) $C_3Cl_6 + \dot{C}l \rightarrow C_2Cl_4 + \dot{C}Cl_3$;
2) $\dot{C}Cl_3 + Cl_2 \rightarrow CCl_4 + \dot{C}l$;
3) $\dot{C}Cl_3 + \dot{C}l \rightarrow CCl_4$ } chain termination
4) $2\dot{C}Cl_3 \rightarrow C_2Cl_6$ }

To a slight extent, there occurs also addition of chlorine to C_2Cl_4 according to the scheme:

5) $C_2Cl_4 + \dot{C}l \rightarrow \dot{C}_2Cl_5$.
6) $2\dot{C}_2Cl_5 \rightarrow C_2Cl_6 + C_2Cl_4$.

The occurrence of these two last reactions results in a reduction in the yield of C_2Cl_4 and an increase in the yield of C_2Cl_6 at 490-500° (Table 3).

Let us pass to an examination of data on the pyrolysis of octachloro-1,3-pentadiene (Table 4) [1].

On the basis of the above considerations, the mechanism of the process may be represented as follows:

$$1.\ a C_5Cl_8 \rightarrow a C_5Cl_6 + 2a \dot{C}l.$$

$$2.\ b C_5Cl_8 + b \dot{C}l \rightarrow b \dot{C}Cl_3 + b C_4Cl_6.$$

$$3.\ (2a - b) \dot{C}Cl_3 + (2a - b) \dot{C}l \rightarrow (2a - b) CCl_4.$$

$$4.\ (2b - 2a) \dot{C}Cl_3 \rightarrow (b - a) C_2Cl_6.$$

$$(a + b) C_5Cl_8 \rightarrow a C_5Cl_6 + b C_4Cl_6 + (2a - b) CCl_4 + (b - a) C_2Cl_6$$

It was actually found that the yield of CCl_4 at 450-500° was approximately equal to $2(C_5Cl_6) - (C_4Cl_6)$. The authors of this paper do not give the yield of C_2Cl_6, but it follows from the overall equation that this yield must be very low (only 0.03 mole per mole of original C_5Cl_8 at 490-500°).

TABLE 5

Products of the Chlorinolysis of Octachloro-1,3-pentadiene (moles per mole of original C_5Cl_8)

Temperature (°C)	CCl_4	C_4Cl_6	C_5Cl_6	C_5Cl_8
350-360	0.13	0.14	0.05	0.79
400-410	0.56	0.59	0.20	0.16
490-500	0.60	0.62	0.27	0.004

Data on the chlorinolysis of C_5Cl_8 (Table 5) [1] are in full accord with the above scheme. As can be seen from the data in Table 5, the yield of C_4Cl_6 is only slightly higher than that of CCl_4, i. e., almost all of the $\dot{C}Cl_2$ formed reacts with chlorine. The chain process develops in accordance with the scheme:

$$1.\ Cl_2C{=}CCl{-}CCl{=}CCl{-}\dot{C}Cl_2 + \dot{C}l \rightarrow CCl_2{=}CCl{-}CCl{=}{=}CCl_2 + \dot{C}Cl_2,$$

$$2.\ \dot{C}Cl_3 + Cl_2 \rightarrow CCl_4 + \dot{C}l.$$

It may be assumed that the scheme of destructive chlorination (chlorinolysis) proposed in this paper is fairly general in character.

SUMMARY

1. On the basis of data on the thermal decomposition of hexachloropropene and octachloro-1,3-pentadiene, some conclusions are drawn about the mechanism of these processes.

2. A mechanism scheme is proposed for the destructive chlorination of halogen-substituted unsaturated hydrocarbons containing a carbon-carbon single bond. The basis of the scheme is the concept of the addition of a chlorine atom at the double bond and subsequent breakdown of the resulting radical at the C—C bond.

CURRENT EVENTS

GENERAL MEETING OF THE DIVISION OF CHEMICAL SCIENCES OF THE ACADEMY OF SCIENCES OF THE USSR

A general meeting of the Division of Chemical Sciences of the Academy of Sciences of the USSR was held on April 25 and 26, 1956, under the chairmanship of Academicians I. I. Chernyaev and V. A. Kargin.

Academician V. A. Kargin read a paper entitled "Multichamber High Tension Electrodialysis". It is well known, said the speaker, that ordinary electrodialysis is a process for the purification of colloidal systems from electrolytes in which the latter are allowed to diffuse through semipermeable membranes, the rate of diffusion being increased by the application of an electric field. This process is often complicated by the presence of membrane potentials, which hinder the passage of some of the ions. These difficulties can be removed either by suitable choice of membrane or by the application of sufficiently high potential differences. New possibilities arise from the use of membranes prepared from ion-exchange resins, which permit the passage only of ions of one sign. Academician Kargin pointed out that, apart from the removal of electrolytes, the reverse process of diffusion of extracted substances into the substance being purified always occurs. When the rates of these processes become equal, an equilibrium is established and purification does not proceed further. Further purification or extraction of electrolytes requires the removal of the substances already extracted, which is usually achieved by changing the water in the side chambers of the electrodialyzer, in which the electrolytes are collected. This procedure complicates, and sometimes excludes, the use of electrodialysis for analytical purposes, and for the purification of substances very large amounts of very pure water are required. Instead of changing the water in the side chambers, we may cause it to circulate continuously through ion-exchange resins. Electrolytes are extracted in the form of the corresponding acids and bases, which are readily absorbed by the resins. This makes it possible to use no extra water at all and to speed up purification to such an extent that it is effective even for weak electrolytes. An example of this procedure is the purification of gelatin with isolation of the structure-forming part of the gelatin. A second method of extraction and concentration depends on the addition of two extra chambers of small volume connected to the side chambers by narrow channels. By the application of a further difference in potential the extracted electrolytes can be collected in a small volume of liquid for analytical purposes, or the purification can be carried out very rapidly and almost without consumption of water.

Apart from the purification of insoluble substances from electrolytes, the insoluble substances may be separated from one another by carrying out chemical reactions in the electrodialyzer itself which will selectively bring one or other substance into solution in the form of an electrolyte. The rates of such reactions in precipitates are dependent on the rates of diffusion determining the supply of the substances to be introduced and the removal of the substances formed. When these reactions are carried out in an electric field, the rates at which the ions move are correspondingly increased. Reacting electrolytes are introduced into the side chambers in such a way that the reacting ions pass through the mass of the substance to be purified. V. A. Kargin has called this method "purification in a stream of ions".

The high rates of purification in high tension electrodialysis make it possible to purify not only insoluble substances, but also solutions, and the use of a five-chamber electrodialyzer having thick membranes enables purification to be effected with small losses of the substance being purified. It is possible also to separate several solutes by the use of electrodialyzers having 10-20 chambers. In this case, under stationary conditions a definite pH is established in each chamber, and, on introduction of a mixture of salts, the metals are separated as oxides, which are precipitated in different chambers. Multichamber electrodialysis can be used also for the synthesis of substances formed from extremely dilute solutions. Several minerals were synthesized in this way, and crystalline

aluminosilicates were prepared by direct reaction between silicic acid and alumina in aqueous solutions at ordinary temperatures.

In illustration of his address, Academician Kargin gave demonstrations of various kinds of apparatus used by him in the laboratory. Corr. Member Acad. Sci. USSR B. V. Nekrasov, K. V. Chibisov, Doctor Chem. Sci., K. T. Poroshin, and R. P. Lastovsky, in discussing the paper, remarked on the great interest of the method and its high practical importance. In some of the works manufacturing chemical reagents high tension electrodialyzers were already in use for the removal of traces of impurities in the course of the preparation of chemically pure substances. The greatest obstacle to the extensive introduction of this method into practice is the lack of apparatus, which is not yet being manufactured.

Doctor of Chemical Sciences O. E. Zvyagintsev, (co-author E. F. Karandasheva) read a paper entitled "Rate of the Replacement of Ligands in Quadrivalent Platinum Complex Compounds as a Measure of the Trans Effect".

The trans effect, stated O. E. Zvyagintsev, is manifested in complex compounds in which the complex has a square or octahedral structure by the fact that the rate at which a ligand attached to the central atom is replaced is determined by the nature of the ligand occupying the trans position. An investigation into the kinetics of replacement in platinum compounds was undertaken with the object of characterizing the trans effect quantitatively.

The kinetics of replacement were studied for some reactions of bivalent platinum compounds, including:

$$K(PtNH_3Cl_3) + Py^* \rightarrow (PtNH_3ClPyCl) + KCl; \quad (1)$$
reaction coordinate Cl—Pt—Cl

$$K(PtNH_3ClBr) + Py \rightarrow (PtNH_3ClPyBr) + KCl; \quad (2)$$
reaction coordinate Br—Pt—Cl

$$K(PtNH_3ClNO_2Cl) + Py \rightarrow (PtNH_3ClPyNO_2) + KCl; \quad (3)$$
reaction coordinate NO_2—Pt—Cl

$$K[Pt(C_2H_4)Cl_3] + Py \rightarrow [Pt(C_2H_4)PyCl_2] + KCl; \quad (4)$$
reaction coordinate C_2H_4—Pt—Cl.

It was shown that the most reactive coordinate in platinous compounds is the coordinate (2). Replacement reactions on this coordinate are characterized by the highest rate constant and the lowest activation energy.

If the trans activity of a ligand is measured by the value of the rate constant, then the trans activity of a nitro group is ten times as high as that of chlorine, and the trans activity of bromine is three times as high as that of chlorine.

The kinetics of replacement in quadrivalent platinum compounds were investigated for the reactions:

$$[(NH_3)_3PtCl_3]Cl + Py \rightarrow [(NH_3)_3ClPtPyCl]Cl_2; \quad (5)$$
reaction coordinate Cl—Pt—Cl

$$[(NH_3)_3PtClBrCl]Cl + Py \rightarrow [(NH_3)_3ClPtPyBr]Cl_2; \quad (6)$$
reaction coordinate Br—Pt—Cl

$$[(NH_3)_3PtClNO_2Cl]Cl + Py \rightarrow [(NH_3)_3ClPtPyNO_2]Cl_2; \quad (7)$$
reaction coordinate NO_2—Pt—Cl

and also some other reactions, selected so as to permit investigations into the effect of a nitro group in the cis position relative to a chlorine that was undergoing replacement, the effect of the presence of a cyclic ethylenediamine group, and other factors.

The kinetic studies showed that replacement reactions are somewhat slower for the quadrivalent platinum compounds.

In quadrivalent platinum compounds the coordinate (7) is the least reactive, for it has the lowest rate constant and the highest activation energy.

The experiments on three of these compounds were repeated in acetone. It was found that the rates of re-

* Py = pyridine.

placement were almost identical in water and in acetone. A comparison of the rate constants for bi- and quadrivalent platinum compounds showed that the values for quadrivalent platinum are considerably lower than those for bivalent platinum compounds having the same reaction coordinates. The trans effect of bromine, as measured by the rate constant for the replacement of the opposite ligand, was found to be three times as great as that of chlorine both in bivalent and in quadrivalent platinum compounds. The nitro group behaves essentially differently in bivalent and in quadrivalent platinum compounds: its trans effect in compounds of bivalent platinum is very much greater than in compounds of quadrivalent platinum; in the latter it is considerably lower than that of chlorine and bromine.

As the speaker pointed out, the study of the kinetics of ligand replacement permits an estimation of the cis effects of various ligands, including cyclic ligands. The cis effect is very small in comparison with the trans effect.

From the results cited, said O. E. Zvyagintsev, we may conclude that the study of the kinetics of replacement in complex compounds of bi- and quadri-valent platinum makes it possible to make quantitative estimates of the trans activities of ligands.

Corr. Member Acad. Sci. USSR B. V. Nekrasov, Ya. K. Syrkin, and Doctor Chem. Sci. M. M. Yakshin, and others took part in the discussion on this paper and pointed out the importance of the investigation.

B. A. Dolgoplosk, Doctor Chem. Sci., read a paper entitled "Initiation of Free Radical Reactions in Aqueous and Hydrocarbon Media". He pointed out that the decomposition of many organic compounds into free radicals in hydrocarbon solutions usually proceeds at bonds between oxygen and oxygen, nitrogen and nitrogen, nitrogen and sulfur, carbon and nitrogen, sulfur and sulfur, etc. This process occurs particularly readily when such bonds are conjugated with an unsaturated bond or with an aromatic nucleus. Azo compounds, unlike peroxide, triazenes, hydroperoxides, and other substances, decompose in accordance with a unimolecular law, irrespective of their concentration in solution or the presence of reducing agents in the system. Aliphatic-aromatic triazenes are convenient sources of free radicals in hydrocarbon solutions.

Oxidation-reduction reactions leading to the formation of free radicals are energetically more advantageous than thermal dissociation. Oxidation-reduction systems, as sources of free radicals, were first investigated for the case of diazoaminobenzene (and hydrogen peroxide) with various reducing agents.

Discussing the reactions in aqueous and aqueous-hydrocarbon media, B. A. Dolgoplosk pointed out that the decomposition of aliphatic-aromatic triazenes under these conditions is brought about by the addition of water, with the quantitative formation of aniline and diazo-hydroxide (Reaction 1). The alkanediazo-hydroxide decomposes with elimination of nitrogen and formation of an alkyl radical and a free hydroxyl (Reaction 2); the radicals formed combine with formation of an alcohol (Reaction 3) or disproportionate with formation of unsaturated compounds (Reaction 4). Reaction 1 is greatly accelerated under the action of dienols, hydroquinone, pyrogallol, ferric sulfate, and other compounds, these substances being unaffected during the decomposition and playing the part of catalysts. In presence of acceptors for free radicals, Reactions 3 and 4 are suppressed. In this system water is utilized for the formation of OH radicals.

The author stated that the inhibiting effect of hydroquinone on chain reactions involving radicals is due to the formation of benzoquinone and stable semiquinone radicals. The reaction between hydroperoxides and hydroquinone in aqueous media may be effectively used for the initiation of radical processes at low temperatures when substances that can reduce quinonoid forms to benzenoid are introduced into the system. This part can be played by sulfites and bisulfites. A system of this type has found industrial application for the initiation of polymerization in an emulsion at a temperature of +5°.

Discussing reactions in hydrocarbon media, B. A. Dolgoplosk stated that oxidation-reduction systems in which peroxides and hydroperoxides take part can be used for the initiation of polymerization in an anhydrous hydrocarbon medium. In absence of monomer, all oxidation-reduction systems cause cross-linking and degradation processes to develop in polymers at low temperatures. Similar effects are shown by various reversible systems containing peroxides, ferric naphthenate, and substances that can reduce ferric iron to ferrous and also by systems containing peroxides and thiols, peroxides and sulfur dioxide, sulfur dioxide and thiols, etc. In the last case sulfur dioxide plays the part of an oxidizing agent. It was stated that various systems containing oxygen which initiate the oxidative degradation of polymers in hydrocarbon media had been studied in detail.

The speaker said that the work had established the possibility in principle of using oxidation-reduction systems for the initiation of chain oxidative processes at low temperatures. The reduction of iron and chromium naphthenates by hydrocarbons can be used for the initiation of polymerization processes at 100°. In these experiments it was shown that the dehydrogenation of a hydrocarbon chain by chromium and iron compounds passes through the stage of free radicals. At 100° various olefins have reducing properties. The decomposition of aliphatic-aromatic triazenes in hydrocarbon media in presence of organic acids proceeds at room temperature with quantitative formation of aniline and formation of an intermediate diazo ester, which then decomposes into acyl and alkyl radicals with formation of nitrogen. In absence of acceptors for free radicals, the reaction proceeds quantitatively in the direction of radical combination, with formation of an ester. In absence of water the reaction can be used for the quantitative alkylation of carboxy and dienol groups (in dihydroxymaleic and ascorbic acids).

Corr. Member Acad. Sci. USSR I. A. Kazarnovsky, S. S. Medvedev, and Academician V. A. Kargin joined in the discussion and pointed out the great importance of this work and its interest for those working on polymerization processes.

A paper entitled "Kinetics and Chemistry of the Polycondensation of Esters of α-Amino Acids" was read by K. T. Poroshin, Doctor Chem. Sci. (co-authors: T. D. Kazarenko and Yu. I. Khurgin). The speaker pointed out the great importance of the synthesis of polymers derived from α-amino acids for the study of natural polypeptides and some of the simple proteins. Synthetic polypeptides provide models for use in the elucidation of the structure of insulin, corticotropine, oxytocin, and vasopressin, and they are widely used in the chromatographic separation of hydrolyzates as models of the corresponding fragments of the protein under investigation. The discovery of physiological activity in some of the poly-α-amino-acids, e. g. polyornithine, polylysine, and polyglutamic acid, and the successful synthesis of these by the polymerization of suitable derivatives show the great importance of developing new, simpler, and more accessible methods for the synthesis of poly-α-amino-acids. The investigation had the object of developing in detail one of the known, but rarely used, methods for the synthesis of polypeptides — the polycondensation of esters of α-amino acids. Glycine ethyl ester, being a convenient object for the study of the polycondensation reaction, was selected for investigation.

The speaker pointed out that the polycondensation process is accompanied by the formation of linear poly-α-amino-acids varying in molecular weight and by the formation also of a six-membered cyclic dimer, 2,5-piperazinedione. The polycondensation reaction can be initiated by carbon dioxide and various other substances. When an exact dosage of initiator is used, reproducible results can be obtained. In order to study the compositions of the polycondensation products, methods were developed for the determination of free monomer, piperazinedione, and the tripeptide.

The variation of the composition of the polycondensation products with time was studied under constant conditions (40°, 2 moles percent of initiator on the amount of monomer). It was found that the rate of formation of piperazinedione was very great in the early stages of the reaction. Simultaneously, linear-polycondensation products accumulated, in the first place tripeptides, which gradually disappeared as the chain grew with formation of products of higher molecular weight. K. T. Poroshin showed that tetrapeptides and still longer peptides are already to be found in the first stage of the reaction. The monomer reacts according to a first-order law. The variation with time of the relative concentration of peperazinedione in the polycondensation products also corresponds to a reaction of the first order. Increase in initiator concentration results in an increase in the reaction rate, and the amount of piperazinedione in the condensation products simultaneously diminishes. As the speaker pointed out, these facts make it possible to advance important hypotheses on the nature of the polycondensation reaction of esters of α-amino acids and the effect of carbon dioxide on the suppression of the cyclization reaction.

Corr. Member Acad. Sci. USSR V. V. Korshak, Doctor Chem. Sci. E. D. Kaverzneva, Academician V. A. Kargin, and others joined in the discussion. Speakers remarked on the significance of the study of the polycondensation of esters of α-amino acids for the eventual synthesis of polypeptides of various structures and for the solution of important biological problems concerned with the relationship between the composition of a compound, the geometric arrangement of various groups in its carbon chain, and its biological activity.

FROM THE CHEMICAL NOMENCLATURE COMMISSION OF THE DIVISION OF CHEMICAL SCIENCES OF THE ACADEMY OF SCIENCES OF THE U S S R

The Division of Chemical Sciences of the Academy of Sciences of the USSR has set up a Chemical Nomenclature Commission, and this body collects and studies material in various languages on the nomenclature of organic and inorganic compounds with a view to the development of scientific nomenclatures for chemical compounds in the various languages of the peoples of the USSR and their introduction into practice.

The Commission is now working on several schemes of nomenclature, and it is intended to publish these, so that they may be discussed at a conference representing a wide range of interests. This conference is to be held by the Division of Chemical Sciences in the first quarter of 1957, and it is desirable that it should be preceded by extensive informal discussion of the projected schemes.

Among documents of cardinal importance, the Commission has received:

A. Documents on the nomenclature of organic compounds

1) The 1892 Geneva rules and modifications of these introduced in the fourth edition of Beilstein's Handbuch. 2) Rules adopted by the International Union of Pure and Applied Chemistry during 1930-1953. 3) Scheme for the systematic naming of organic compounds in Russian. 4) Scheme for the systematic nomenclature of hydrocarbons and fundamental heterocyclic nuclei (International Union of Pure and Applied Chemistry, 1955). 5) New proposals of Dyson, Taylor, and Patterson for the naming of polycyclic structures (1955).

B. Documents on the nomenclature of inorganic compounds

1) Material discussed by the Nomenclature Commissions of Mendeleev Congresses, compiled by A.Kh. Bork. 2) Rules of the International Union of Pure and Applied Chemistry.

The first three items of Group A were published in "Nomenclature of Organic Compounds" by A.P. Terentyev and others (Acad. Sci. USSR Press, Moscow, 1955). For the first item of Group B see Progr. Chem. 6, 605-621 (in which a detailed bibliography is given), 924, 1251, 1732 (1937). The rest of the material will be published by the Commission.

The Commission invites industrial organizations, research institutes, higher-education establishments, publishers of books and journals, and individual chemists to send in suggestions and comments on matters relating to the nomenclature of organic and inorganic compounds.

Correspondence should be addressed to the Nomenclature Commission, Division of Chemical Sciences, 14 Bolshaya Kaluzhskaya, Moscow, or direct to the chairman of the Commission, A.P. Terentyev, Corresponding Member of the Academy of Sciences of the USSR (Moscow B-234, Chemistry Department, Moscow State University).

Recommendations of the Commission

The Commission recommends that, for Russian publications and for teaching conducted in the Russian language, the names and symbols used for the chemical elements should be those given in the official table (below). This table gives also the values of atomic weights confirmed by the International Commission on Atomic Weights in 1953 and remaining valid for 1956 [Union internationale de Chemie pure et appliquee, Comptes rendus de la XVII Conference. J Am. Chem. Soc. 76, 2033 (1954)].

For some radioactive elements, the mass number of the most stable isotope is given (in square brackets),

TABLE OF THE RUSSIAN NAMES AND SYMBOLS OF THE CHEMICAL ELEMENTS

Name	Symbol	Atomic number	Atomic weight	Name	Symbol	Atomic number	Atomic weight
Azot	N	7	14.008	Neon	Ne	10	20.183

Publisher's Note: The symbols are as in the original; the names are transliterated. The Consultants Bureau convention of transliterating the Russian letters "i" as "y" at the end of a word has not been followed in this translation.

instead of the atomic weight. These values are derived from data available in the literature on January 1, 1956. Some values confirmed by the International Commission have been altered as follows.

Berkli (berkelium). Previous value 245, half-life 4.95 days. Recommended value 249, half-life 290 days. This is adopted on the basis of the data of Diamond, Magnusson, et al. [Phys. Rev. 94, 1083 (1953); 96, 1576 (1953)].

Kalifornii (californium). Previous value 248, half-life 250 days. Recommended value 249, half-life 470 ± 100 years. This is adopted on the basis of the data of Diamond, Magnusson, et al. [Phys. Rev. 94, 1083 (1953); 96, 1576 (1953)].

The table gives also elements No. 99, 100, and 101, which were obtained in 1951-1955 by Seaborg and others. These investigators proposed the names: No. 99, einshteinii (einsteinium, E); No. 100, fermii (fermium, Fm); No. 101, mendeleevii (mendelevium, Mv) [Phys. Rev. 98, 1518 (1955); Progr. Chem. 25, 133 (1956)].

While accepting these names, the Commission recommends the symbol En for einshteinii (einsteinium) and Md for mendeleevii (mendelevium), in accordance with traditional practice for the derivation of the symbols of the elements.

For isotopes occurring in natural radioactive series — as also for the isotopes of other elements — it is recommended that obsolescent historical names should no longer be used: the symbols given in the official list should be used, and the mass number of the isotope should be indicated by an index.

For isotopes of hydrogen and radon (No. 86) it is permissible to use the following names and symbols when necessary, in addition to those recommended: deiterii (deuterium) D; tritii (tritium) T; aktinon (actinon) An; toron (thoron) Tn.

PART OF THE FIVE-COMPONENT SYSTEM NICKEL-CHROMIUM-TUNGSTEN-TITANIUM-ALUMINUM

I. I. Kornilov, L. I. Pryakhina and O. V. Ozhimkova

Success in the task of finding new alloys of practical value demands the investigation of the ways in which metals interact in multicomponent systems. Modern technical requirements are most satisfactorily met by alloys of complex chemical composition.

Fig. 1. Phase diagram for part of the five-component system Ni-Cr-W-Ti-Al.

Until recently phase-diagram studies were mainly devoted to binary and ternary metal systems; there have been very few investigations of four-component systems, and only isolated studies of the alloys of five-component and still more complex systems. One of the causes of the lack of progress in this field is the lack of knowledge of methods of investigation of these complex systems and of methods of representing the results on the interaction of metals in the form of phase diagrams. The geometric representation of systems containing more than four components requires that we should pass from three-dimensional measurement to the methods of multi-dimensional

geometry [1], which are less accessible and more difficult to understand than methods of representation within the limits of three-dimensional space. In this connection, we have proposed and described a method of representing parts of multicomponent (more than four components) metal systems within the limits of three dimensions [2]. The application of this method is simplest for metals that tend to give continuous or limited solid solutions with many elements. These metals include many of practical importance, e.g. aluminum, copper, iron, nickel, and titanium. Such systems are of the greatest practical interest.

Using this method, we are making a systematic investigation of metal systems having five, six, and more (up to ten) components.

In this paper we give the results of an investigation of part of the five-component system nickel-chromium-tungsten-titanium-aluminum. The basis for our study of the interactions of these five metals and the construction of a phase diagram of part of the system is provided by experimental material obtained by various authors on the corresponding binary and ternary systems that form part of the five-component system. Following our proposed method of representing the compositions of alloys [2], as our point of origin we took the binary alloy of nickel (80%) and chromium (20%), which is a homogeneous solid solution (Fig. 1). From this point as origin, the contents of the third, fourth, and fifth components (in this case, tungsten, aluminum, and titanium) are plotted along three axes of coordinates (x, y, and z), the chromium content always being constant at 20%. In this way, the compositions in the corresponding sections of ternary systems of nickel, chromium, and third component are plotted along the three axes (x, y, and z) (Fig. 1). On the basis of data in the literature or our experimental data, limiting concentrations of solid solutions and the points at which new phases begin to separate are plotted along these axes. On the planes corresponding to the sides of our solid figure, plots are made of compositions of quaternary alloys of nickel, chromium, and two other components (tungsten and aluminum, tungsten and titanium, and aluminum and titanium). Having determined the limiting concentrations of solid solutions and the points at which new phases begin to separate (Fig. 1) in the quaternary systems, we may pass to the investigation of alloys of the five-component system.

Fig. 2. Polythermal section of the five-component system Ni-Cr-W-Ti-Al for variation in the aluminum content.

This may be done by considering suitable sections in which the contents of some components are maintained constant and the contents of one or more components are varied. We studied sections for variable contents of titanium, tungsten, and aluminum, which are shown in Fig. 1, in the form of straight lines having points on the corresponding planes. Sections for a variable content of aluminum were studied for constant contents of chromium (20%), titanium (2%), and tungsten (6% and 9%). It was first shown that quaternary nickel alloys in these two sections (20% chromium, 2% titanium, and 6 or 9% of tungsten) are quaternary solid solutions.

Alloys in these two sections of the five-component system were prepared with aluminum contents varying from zero to 8 or 16%. The compositions of these alloys covered a region of five-component solid solutions based on nickel with separation of a second phase. With variable aluminum content and limiting saturation with aluminum, the basis of the separating phase was a nickel-aluminum compound – very probably Ni_3Al. If we assume that the compound Ni_3Al is able to dissolve excess of nickel and, to some extent, chromium, tungsten, and titanium, it may be considered that in this phase all these elements will be present in the form of solid solutions in the compound Ni_3Al.

A series of polythermal sections was constructed for alloys of the system Ni-Cr-W-Ti-Al, and some of the properties of the alloys were studied (microstructure, hardness, specific resistance, and heat-resistance). By way of example, in Fig. 2 we give one of our polythermal sections for alloys of variable aluminum content and constant contents of chromium (20%), tungsten (9%), and titanium (2%).

In this figure we have constructed from our own data the fusion diagram for alloys of this section and the

Fig. 3. Composition-property diagram of alloys of the system Ni-Cr-W-Ti-Al having a variable aluminum content: 1) hardness of alloys after aging at 700° for 100 hours; 2) electrical resistance at 20°.

solubility-temperature curve for aluminum, determined by the method of microstructure analysis. As will be seen from the diagram, in the five-component alloys addition of aluminum brings about a lowering of the liquidus curve. At aluminum contents of more than 7-8%, a second halt occurs on the cooling curves, possibly corresponding to crystallization of the eutectic. Fig. 3 shows curves for the variation of hardness (1) and of specific resistance (2) for alloys tempered from 1150° and aged at 700° for 100 hours.

With increase in the aluminum content, the hardness of the alloys increases continuously from 185 to 328 kg/mm². With increase in the aluminum content from 0.5 to 2.8%, the specific resistance of the alloys increases from 1.22 to 1.35 ohm mm²/m and has a maximum of 1.37 ohm mm²/m at an aluminum content of 3.4-5.1%. Further increase in the aluminum content from 5.1 to 7.9% causes a sharp reduction in the specific resistance from 1.37 to 1.02 ohm mm²/m; this is to be explained by the appearance of a second phase, which takes the form of coagulated particles, in alloys containing more than 5% of aluminum. Hence, the hardness and specific resistance curves in Fig. 3 indicate regular changes in properties, which, as in the case of binary and tertiary systems [3-5], can be related to changes in the compositions and phase structures of the alloys.

In conclusion it may be stated that by the use of this method of representation it will be possible to investigate partial phase diagrams of many complex (having more than four components) metal systems, based not only on nickel, but also on other metals of great practical importance.

SUMMARY

1. An investigation was made of part of the five-component system nickel-chromium-tungsten-titanium-aluminum in the region of nickel solid solutions. Use was made of a method of representing parts of multicomponent (having more than four components) metal systems within the limits of three dimensions.

2. Polythermal sections were constructed for alloys of the system nickel-chromium-tungsten-titanium-aluminum having variable contents of aluminum, titanium, and tungsten; and various properties of these alloys were studied (microstructure, hardness, specific resistance, and heat-stability).

3. The investigation of the partial phase diagram (in the region of solid solutions) of the system nickel-chromium-tungsten-titanium-aluminum enabled us to find alloys having high strength properties.

THERMAL ANALYSIS OF THE SYSTEM BENZENE-STANNIC BROMIDE

A. F. Kapustinsky and Yu. M. Kessler

Kapustinsky and Drakin [1,2] have previously studied some systems consisting of benzene and halogen-substituted methanes, and they have advanced some views on the chemistry of the formation of compounds in these systems and the structures of these compounds, the formation of compounds between benzene and carbon tetrahalides being explained by the unsaturated character of halogens in tetrahalides and the presence of three oscillating double bonds in the benzene molecule. Confirmation of this view can be found in recently published work by Andrews [3]. Kapustinsky and Drakin [1,2] found that the possibility of compound formation diminishes as the size of the tetrahalide molecule increases, this effect being attributed to steric hindrance.

Stannic halides are analogous in structure to carbon tetrahalides, i.e., the molecule has the form of a regular tetrahedron having a tin atom in the center. However, tin is more electropositive than carbon, and the halogens in stannic halides should therefore be more saturated than those in the corresponding carbon tetrahalides. Also, the size of a stannic halide molecule is considerably greater than that of the corresponding carbon tetrahalide molecule, in fact the size of the molecule of the most compact stannic halide - stannic chloride (we have no data for stannic fluoride) – is greater than that of the carbon tetraiodide molecule: the Sn - Cl distance is 2.30 A, whereas the C-I distance is 2.12 A [4]. On the basis of these considerations and the nature and structure of crystalline benzene-addition compounds, as described in the papers cited [1,2], we may expect that benzene will not form compounds with stannic halides.

Actually, with benzene, stannic chloride forms a system having a simple eutectic [5]. This result is in accord with data on other properties of this system. Absence of chemical interaction between the components is indicated by the viscosity isotherms, determined at 25° and 70° [6]. The refractive index shows a feeble positive departure from additivity [7]. The vapor pressures of mixtures show only very slight departures from Raoult's law [8]. Schultze and Hock found that mixing of the components was accompanied by appreciable cooling and increase in volume and that positive departures of the vapor pressures of mixtures from Raoult's law increase as the temperature falls (measurements were made at 30°, 100°, and 125°) [9].

Fig. 1. Heating curve for a mixture containing 72.2 moles % of $SnBr_4$.

EXPERIMENTAL

For the construction of fusion diagrams of the system benzene-$SnBr_4$ we determined heating curves of mixtures by the method of constant temperature differences. This method, wich was devised by Kapustinsky and Barsky [10] for the determination of heat capacities and heats of reactions and transformations, was more suitable for our purpose than other methods, since the heating curves obtained by this method are more prolonged and have more clearly defined horizontal sections corresponding to isothermal effects and more clearly defined points of inflection at the termination of non-isothermal effects than those found on heating curves obtained by other methods.

The curves are completely reproducible. This ensures that the determination of the transformation temperatures will be reliable. A typical heating curve for our mixtures is given in Fig. 1. We are the first to use this method for the study of fusion diagrams.

The apparatus in which the freezing and subsequent heating of the samples were carried out is shown in Fig. 2. It consists of a thin-walled brass jacket 1, which serves for the better equalization of the temperature over the height of the vessel containing the sample, the glass test tube 2. The test tube is fixed in the stopper 3, which is held in the neck of the jacket 1. The tube is further centered by means of the Plexiglas ring 4, which is cemented to the inside of the jacket. The ring 4 serves also as a support for the differential thermopile 5, which consists of 13 pairs of copper-constantan junctions arranged at various heights around the circumference of the test tube. In this way a constant temperature difference is maintained between the inner surface of the jacket 1 and the outer surface of the test tube 2; the standard envelope regulating the inflow of heat is the layer of air, about 5 mm in the thickness, between these two surfaces. The test tube is firmly closed by the stopper 6, which carries the holder 7 for the capillary jacket 8 of the simple copper-constantan couple 9. This holder serves also as a guide for the electromagnetic reciprocating platinum-ring stirrer 10, which is operated from the coil 11 mounted directly on the test tube; the stirrer works at three periods per second. For heating, this apparatus is placed in a Dewar vessel, in which it is supported by the stopper 3. The Dewar vessel contains an open heating element of nickeline wire (diameter 0.15 mm, 10 turns/cm on a special mounting consisting of six copper rods covered with insulating lacquer and fixed cylinder-fashion by means of Plexiglas rings).

Fig. 2. Apparatus for the determination of heating curves.

Checks for constant difference were carried out continuously from the readings of a mirror galvanometer, and readings of simple and differential galvanometers were made every 30 seconds at the signal from a buzzer working from a Warren SD-2 motor. The heating was regulated with three rheostats of resistance 260, 2000, and 4000 ohm, and, for a heater resistance of 1100 ohm, it was then possible to maintain a constant difference accurately within 0.5%.

The calibration curve of the simple galvanometer was constructed from the transformation temperature and melting point of Kahlbaum carbon tetrachloride, which was dried further with amalgamated aluminum, from the melting point of ice from doubly distilled water, and from the melting point of cryoscopic benzene. The relation between the galvanometer readings and the temperature was linear. Temperatures could be read accurately within 0.1°. The rate of heating was 1.5-1.8° per minute.

Benzene was purified by the method given in Beilstein's Handbuch [11]. The product was dried with sodium and kept over sodium in a bottle having a ground-in stopper. Its melting point, determined with a certified normal thermometer graduated in 0.1° intervals, was 5.58° (the literature [12] gives 5.58°).

Stannic bromide was synthesized by Vanino's method [13] from Kahlbaum tin and "pure grade" liquid bromine. The product was distilled twice from a Wurtz flask having a receiver adapter directly attached to the outlet through a ground joint. It was kept in a flask with a ground-in stopper in a desiccator over calcium chloride. The purity of the product was established from its melting point, which was determined directly in our apparatus: the value found was 29.40° (the literature [14] gives 29.45°).

The mixtures were prepared directly in the test tube with exclusion of moisture. All weighings were carried out accurately within 0.0001 g on a microanalytical balance. The fusion diagram that we obtained is shown in Fig. 3. It will be seen that no compounds are formed between the components. The eutectic is at a point

corresponding to 9.9° and 65.9 moles % of benzene. On the heating curves of mixtures containing 87.4, 88.0, and 94.8% of stannic bromide, halts were noted at 15.7°, 15.6°, and 15.3°, respectively. On the heating curve of pure stannic bromide there is also a halt at 15.3°. At this temperature the liquidus curve has a point of inflection. This behavior indicates that stannic bromide undergoes a polymorphous transformation at 15.3°.

In the literature there is only one reference to the existence of two modifications of stannic bromide. Biltz and Jeep [15], in a study of the system $SnBr_4$ – bromine by the thermoanalysis method, observed halts on the heating curves of mixtures rich in stannic bromide at −6° and an inflection at this temperature on the corresponding branch of the liquidus, but on the heating curves of the pure substance they obtained only one halt, which corresponded to melting. Biltz and Jeep observed the transformation in pure stannic bromide visually – by the change in the appearance of the crystals when cooled – and dilatometrically – by the reduction in volume between −6° and −7°.

The results of our experiments indicate the absence of any transformation in the neighborhood of −6°, both in the pure substance, and also in its mixtures with benzene. When we consider that, on one hand a transformation occurring with change in the appearance of the crystals and a considerable change in volume must be accompanied by an appreciable thermal effect, which could not remain undetected at the sensitivity characteristic of our method, and, on the other hand, we did not succeed in observing any change in the appearance of the crystals at −6°, either in the heating, or in the cooling of stannic bromide, although we did observe such a change at about 15° we are compelled to regard the results of Biltz and Jeep as erroneous. It should be noted also that on the liquidus branch of stannic bromide as studied by de Carli [16] in the system $SnBr_4$-nitrobenzene (simple eutectic) there is an inflection at about 18°, for which the author gives no explanation.

Fig. 3. Fusion diagram of the system benzene-$SnBr_4$.

The establishing of a simple eutectic from the fusion diagram does not in itself make it possible to estimate the interaction between molecules of the components. This can be done by determining the heat of mixing. The method of thermoanalysis that we used enabled us to determine the heats of isothermal processes directly from the heating curves of mixtures with a probable error of not more than 5% by use of the following equation [10]:

$$Q = \frac{k}{m} \Delta t \Delta z, \qquad (1)$$

in which Q is the thermal effect, k is the coefficient of heat transfer, Δt is the temperature difference as determined by the readings of the differential galvanometer, Δz is the duration of the halt, and m is the mass of the sample. From this equation we determined the heat of mixing of the components at the eutectic temperature. With the simplified arrangement for regulating the heating which we used in these experiments, it was impossible to avoid departures from the standard value of the difference at the beginning and at the end of a halt, and we therefore used Equation 1 in the form:

$$Q = \frac{k}{m} \int_1^2 \Delta t \, dz, \qquad (2)$$

and, after constructing the curve $\Delta t = f(z)$, we determined the integral graphically, taking the beginning and end of the halt as limits. The coefficient of heat transfer k was determined from the heats of fusion of stannic bromide, cyclohexane, nitrobenzene, and benzene. The maximum departure from the average value was 3.7%. As the investigated range of temperatures was only 40° and the maximum departure of the difference from the standard value was not greater than 20% and occurred for only short times in comparison with the duration of the halts, we neglected the variation of k with temperature.

The heat of fusion of the eutectic Q may be represented as the sum of the heats of fusion of the components ΔH_A and ΔH_B and the heat of mixing them Q_m:

$$Q = n_A \Delta H_A + n_B \Delta H_B + Q_{cm}, \qquad (3)$$

in which n is the number of moles of the given component in a mixture of eutectic composition. In view of the absence of data in the literature on the heat capacity of stannic bromide in the liquid state, we took the heats of fusion of the pure components for our calculation. In view of the small temperature range, the error introduced was less than the experimental error; its effect would be to make the determined value too low, for in our case $(cp)_l - (cp)_s > 0$ for both components. The value of Q_m was determined as the mean of 22 determinations for mixtures on both sides of the eutectic. Q_m was found to be a quantity having about one-tenth the value of Q, so that an error of 5% in the determination of Q will result in a 50% error in the determination of Q_m. Hence, we can speak with confidence only of the order of Q_m. We obtained the value of $Q_m = 256 \pm 125$ cal per mole of mixture, which indicates absence of chemical interaction. When we compare this value with the almost temperature-independent heat of mixing of carbon tetrachloride and cyclohexane (35.5 cal per mole of mixture at 20° [17]), between which there are also no compounds formed, it becomes obvious that not even signs of chemical affinity between benzene and stannic bromide molecules are to be found. Hence, the behavior of stannic halides in mixtures with benzene falls within the scope of the concepts discussed above, and it may be considered that these are valid for all the tetrahalides of Group IV.

Actually, with increase in the size of the tetrahalide molecule, the formation of a compound by the orientation of three halogens of the molecule toward the three double bonds of the benzene molecule becomes impossible on geometric grounds. Moreover, the orientation of a tetrahalide molecule with one halogen atom associated with a double bond of benzene cannot result in compound formation owing to the increased electrosaturation of the halogens, a property that increases with increase in the electropositivity of the central atom of the tetrahalide as we pass from carbon to the other elements of Group IV.

By the same method we have determined also the heat of the polymorphous transformation of stannic bromide at 15.3° ($[SnBr_4]_I \rightleftharpoons [SnBr_4]_{II}$), which we found to be $\Delta H = 304 \pm 15$ cal/mole.

SUMMARY

1. A study was made of the fusion diagram of the system benzene-stannic bromide. A simple eutectic was established at −9.9° and 34.1 moles percent of stannic bromide.

2. The heat of mixing of the components at the eutectic composition and temperature was estimated and found to be 256 ± 125 cal per mole of mixture.

3. It was shown that structural concepts which explain the interaction of benzene and carbon tetrahalides are applicable also to binary systems of benzene and stannic halides.

4. It was shown that stannic bromide undergoes a polymorphous transformation at 15.3°. The heat of transformation was determined and found to be 304 ± 15 cal/mole.

SOLUBILITY OF SILICIC ACID

Yu. V. Morachevsky and M. M. Piryutko

The first investigation on the solubility of silicic acid was carried out more than one hundred years ago by Fuchs [1]. The matter was reexamined subsequently by various investigators, and an indication of the results obtained is given in Table 1.

TABLE 1

Author	Year	Value of solubility found ($g/ml\ SiO_2$)	Temperature of solution	Attainment of equilibrium	Form of material investigated	Method of determining concentration of silicic acid in solution
Fuchs [1]	1852	$13 \cdot 10^{-3}$	Not stated	Not stated	Gel	Gravimetric
Maschke [2]	1855	$90 \cdot 10^{-3}$	"	"	"	"
Struckman [3]	1855	$21 \cdot 10^{-3}$	"	"	"	"
Graham [4]	1864	$10—20 \cdot 10^{-3}$	"	"	"	"
Seeman [5]	1905	$7.7 \cdot 10^{-3}$	18°	"	"	"
		$27 \cdot 10^{-3}$	100°	"	"	"
Lenher and Merrill [6]	1917	$16.1 \cdot 10^{-3}$	25°	Equilibrium	"	"
		$42.7 \cdot 10^{-3}$	90°	"	"	"
Antipov-Karataev and Ryub [7]	1936	$12.3 \cdot 10^{-3}$	Room temp.	"	"	Colorimetric
Correns [8]	1940	$24 \cdot 10^{-3}$	"	"	"	Gravimetric
Alexander [9]	1954	$10—14 \cdot 10^{-3}$	25°	"	"	Colorimetric

As will be seen from Table 1, the results of different authors vary considerably. The probable causes of this are insufficient attention to the attainment of equilibrium between the phases and to other experimental conditions (temperature, nature of the material) and insufficient attention to the form in which the silicic acid passes into solution. The gravimetric method of determining the concentration gives the overall silicic acid content, irrespective of the form in which it occurs in the solution, and it therefore does not enable us to distinguish clearly between true dissolution of silicic acid and its passage into solution as the result of the peptization of a gel. The process is complicated by the polymerization of silicic acid during its treatment with water. The colorimetric method determines the content of only a relatively small amount of the polymerized form of silicic acid (it determines only the component known as the α-form in Egorova's classification [10]).

Many investigations have been reported on the passage of silicic acid into solution (leaching) when various silicates are treated with water or various aqueous solutions. Such passage of silicic acid into solution is often incorrectly referred to as its solubility. We shall not cite this literature because these investigations do not characterize the solubility of silicic acid, solid phase being not silicic acid, but always a silicate of some kind, or quartz.

The question of the solubility of silicic acid in water and dilute solutions of certain salts has recently attracted great interest in connection with hydroconstruction. In various cases it is of practical importance to establish the limiting concentration of silicic acid in water and in salt solutions of various composition. For example, such data are essential for the calculation of the limiting rate of removal of silicic acid in true solution from rocks through which waters of some particular composition are filtering. The present paper gives the results of an investigation of the solubility in pure water of a silicic acid gel prepared in various ways and dehydrated to various degrees.

EXPERIMENTAL

1. Solubility of Silicic Acid Gels Dried at Room Temperature

Experimental Procedure. Silicic acid gels prepared by two methods were investigated.

Gel "a" was prepared by decomposing sodium silicate with acid. Pure silica was fused with six times its weight of sodium carbonate. The product was decomposed with dilute hydrochloric acid, the solution was evaporated to dryness, and the residue was moistened with hydrochloric acid and leached with water. The silicic acid gel so obtained was washed with hot water on a Buchner funnel until the washings were free from chloride ion. It was dried in the air at room temperature and kept in a jar having a ground-in stopper. Analysis of gel "a" gave the following results: SiO_2 – 77.52%; H_2O – 22.42%; impurities – 0.06%.

Gel "b" was prepared by hydrolyzing freshly distilled silicon tetrachloride. After the hydrolysis the solution was evaporated to dryness and the residue was given the treatment described above. Analysis of gel "b" gave the following results: SiO_2 – 66.72%; H_2O – 33.26%; impurities – 0.02%. Gel "b", therefore, was considerably more hydrated than gel "a". Also, whereas gel "a" was a light powder, gel "b" was a much denser product.

The solubility determination was carried out as follows.

Distilled water (200 ml) was poured on a sample of the gel (corresponding in weight to 1 g of anhydrous silica) contained in a stainless-steel beaker. The beaker was contained in a water thermostat maintained at 25.9 ± 0.2° by means of a thermoregulator; the thermostat and beaker were provided with stirrers. Stirring was continued for eight hours, after which the thermostat and stirrer were switched off until the next morning, when they were switched on again for eight hours, and so on. The temperature of the solution fell somewhat during the breaks.

Samples for the determination of the silicic acid concentration were taken at set intervals and always after a long period of stirring at 25.9°. The samples were taken by pipet through a No. 3 porous glass filter with the aid of a water pump. Two test samples were taken: one for the determination of the α-form (silicate ions that are not polymerized or only slightly polymerized), and another for the determination of the silicic acid present both as simple and as highly polymerized ions that no longer give a color with molybdic acid. Simple calculation gave the contents of both of the forms of silicic acid that were of interest to us.

For the silicic acid that could be determined colorimetrically, 2 ml of the solution was diluted with water in a 25-ml measuring flask and acidified by the addition of 0.6 ml of 4 N HCl; 1 ml of 10% ammonium molybdate solution was then added, and the solution was diluted with water to the 25-ml mark. The solution was stirred for 15-20 minutes, and the intensity of the yellow color was then determined with the aid of an FEK-M photoelectric colorimeter.

For the total content of silicic acid, 2 ml of the solution was placed in a tall platinum thimble and diluted to about 10 ml; 1 ml of 3 N Na_2CO_3 was added. The solution was heated for 5-10 minutes in a boiling water bath; this resulted in the depolymerization of the silicic acid and its conversion into a form capable of giving a colored compound with molybdic acid. The solution was cooled, acidified with 1.4 ml of 4 N HCl, and transferred to a 25-ml measuring flask. Ammonium molybdate was added, the solution was made up to volume, and the colorimetric determination was carried out as above.

Results for Solubility of Silicic Acid at 25.9°. The results of the solubility experiments on the silicic acid gels "a" and "b" are given in Table 2. The total concentration of silicic acid and the concentration of colorimetrically determinable silicic acid (α-form) are given in separate columns.

It follows from Table 2 that 1) almost the whole of the silicic acid in the solution is in the α-form, i.e., in the form of simple ions that give a colored heteropoly acid with molybdic acid, the observed differences being within the limits of experimental error; 2) the equilibrium solubility of silicic acid gel does not depend on the method by which it is prepared and has an average value of $12.5 \cdot 10^{-5}$ g/ml SiO_2; 3) the method of preparation affects only the rate of dissolution, equilibrium being attained considerably more rapidly for the gel "b" than for the gel "a".

Results for the Solubility of Silicic Acid at 97°. The only difference in the experimental procedure was that the dissolution was carried out in a silver beaker and the temperature of the thermostat was maintained

at 97 ± 0.5°. The solution was stirred continuously; as the rate of dissolution increases rapidly with rise of temperature, experiments could be completed within one day without breaks. The results are given in Table 3.

These results show that equilibrium is attained at 97° within two hours. The equilibrium solubility is $41.5 \cdot 10^{-5}$ g/ml SiO_2. It is notable that in the hot solution the whole of the silicic acid is in the α-form.

The hot saturated solution of silicic acid was allowed to cool and then left at room temperature (18-20°). Periodically, it was stirred and test samples were taken for the determination of silicic acid concentration. The results of these experiments are shown in Table 4.

As Table 4 shows, when a solution saturated at 97° is cooled, the concentration of silicic acid gradually falls and finally attains a value close to that obtained previously at 25.9°, i.e., $11.0 \cdot 10^{-5}$ g/ml SiO_2. This value is a little lower than that obtained at 25.9° ($12.5 \cdot 10^{-5}$ g/ml), which is readily explained by the lower temperature to which the solution was cooled. It is very interesting that the whole of the silicic acid is in the form of simple colorimetrically determinable particles. Hence, when a solution, saturated at 97°, is cooled, silicic acid is precipitated from the solution into the solid phase; only the amount corresponding to the solubility at the given temperature remains in solution. It should be noted that, in the process of cooling, the solution corresponding to the gel "b" passes more rapidly into a state of equilibrium than the solution corresponding to the gel "a".

Experiments were carried out on the evaporation of a saturated solution of silicic acid at 97°. When the evaporation was carried out without the removal of the solid phase (gel), only in the first minutes was increase in silicic acid concentration (supersaturation) observed, and, if evaporation was stopped and the solution maintained

at the same temperature, the silicic acid concentration fell until, after one hour, it attained the equilibrium value corresponding to the given temperature, i.e., 97°. When, after saturation at 97°, the solid phase was removed, it was found to be possible greatly to increase the silicic acid concentration without precipitation of a solid phase or even visible turbidity in the solution. It was found that in this case most of the silicic acid was in the form that is not determinable colorimetrically, i.e., in the form of relatively highly polymerized particles, possibly attaining the size of colloidal particles. Thus, for a total silicic acid content of $113 \cdot 10^{-5}$ g/ml SiO_2 we found only $17.5 \cdot 10^{-5}$ g/ml colorimetrically, $95.5 \cdot 10^{-5}$ g/ml being more highly polymerized (β- and perhaps also some γ-silicic acid, as described in Egorova's classification).

It was considered to be of interest also to carry out an experiment on the cooling of a solution saturated at 97°, the solid phase being first removed. This experiment gave the results given in Table 5. It will be seen that, as a solution saturated with silicic acid at 97° is kept in absence of solid phase, the concentration of simple particles (α-form) falls toward the equilibrium solubility for the given temperature, whereas the total silicic acid content of the solution remains almost constant, i.e., much of the silicic acid is present in the solution in the form of more highly polymerized, possibly colloidal, particles.

In the next series of experiments, 400 ml of water was heated with the gel "b" for three hours. The solution, saturated at 97°, was separated from the solid phase and divided into five parts, each of which was kept in a flask coated on the inside with paraffin wax. Some silicic acid gel was introduced into the first flask immediately. Gel was introduced into the second after 67 hours, into the third after 140 hours, and into the fourth after 188 hours; no solid phase was introduced into the fifth flask. Test samples were taken from all these solutions periodically, and both forms of silicic acid were determined. The results of this series of experiments are given in Table 6.

The following conclusions can be drawn from these experiments. 1) In absence of solid phase there is a slow fall in the concentration of simple forms of silicic acid, which tends to its equilibrium value, while the total silicic acid content of the solution remains almost constant; this confirms the results of the experiment described above (Table 5). 2) Introduction of solid phase (gel) into the solution accelerates the lowering of the concentration of simple forms of silicic acid and causes also a gradual fall in the total silicic acid concentration, i.e., a gradual

passage of highly polymerized forms into the precipitate.

Hence, in a solution in equilibrium with a silicic acid gel there are only very simple silicic acid particles that are able to react with molybdic acid; the concentration of these particles depends on the temperature. Solutions of higher silicic acid content can be prepared 1) by the evaporation of solutions not containing solid phase, or 2) by the cooling of solutions that have been saturated at a higher temperature and then separated from the solid phase. These solutions of higher silicic acid content contain simple particles at a concentration corresponding to the solubility and more complex, more highly polymerized particles, the concentration of which can be so high in absence of solid phase that it cannot be referred to as the saturation concentration.

2. Solubility of Silicic Acid Dehydrated to a Varied Extent

In order to determine the effect of the water content of the gel and of its preliminary thermal treatment on the solubility of silicic acid, gels "a" and "b" were maintained at a given temperature – varying from 100° to 1120° in different experiments – until constant weight was attained. The effects of these treatments on the extent of the dehydration of the gel are shown in Table 7.

The treated gel was placed in a beaker containing water at 25.9°, and the subsequent procedure was identical with that described above. In these experiments the solid phase was silicon dioxide hydrated to various extents, and the process of its passage into solution had to proceed via a hydration stage.

The experiments showed that, when silicic acid dried at 105° or calcined at 200, 500, 800, 900, or 1000° was treated with water, silicic acid gradually passed into solution; moreover, 1) the equilibrium concentration was the same as that found for the air-dried gel, i.e., $12.5 \cdot 10^{-5}$ g/ml SiO_2 at 25.9°; 2) all the silicic acid passing into solution was in the form of simple particles, capable of reacting with molybdic acid; 3) the rate of dissolution was lower the higher the calcination temperature of the gel, i.e., the lower the water content of the calcined material. Thus, for the gel dried at 105°, the equilibrium silicic acid concentration was attained in the solution

TABLE 7

No.	Composition / Treatment conditions	Gel "a"			Gel "b"

1	Dried in the air at room temperature	77.52	22.42	$SiO_2 \cdot H_2O$	66.72	33.26	$SiO_2 \cdot 1.7H_2O$
2	Dried at 105°	95.33	4.67	$6.1\,SiO_2 \cdot H_2O$	95.80	4.20	$6.8\,SiO_2 \cdot H_2O$
3	" 200°	96.74	3.26	$9.2\,SiO_2 \cdot H_2O$	96.76	3.24	$9.2\,SiO_2 \cdot H_2O$
4	Calcined at 500°	99.13	0.87	$34.5\,SiO_2 \cdot H_2O$	98.68	1.32	$22.5\,SiO_2 \cdot H_2O$
5	" 800°	99.64	0.36	$83\,SiO_2 \cdot H_2O$	99.32	0.68	$43.6\,SiO_2 \cdot H_2O$
6	" 900°	99.75	0.25	$119\,SiO_2 \cdot H_2O$	99.30	0.70	$43.6\,SiO_2 \cdot H_2O$
7	" 1000°	100	—	SiO_2	99.84	0.16	$185\,SiO_2 \cdot H_2O$
8	" 1120°	100	—	SiO_2	100	—	SiO_2

under our experimental conditions in 125 hours, whereas for the gel calcined at 900° the equilibrium concentration was attained only after 816 hours, and for the gel calcined at 1000° the silicic acid concentration attained only $10 \cdot 10^{-5}$ g/ml SiO_2, i.e., somewhat lower than that attained for gels calcined at a lower temperature, even after 1824 hours; in all cases, for the gel "b" equilibrium solubility was attained more rapidly than for gel "a".

The gel calcined at 1120° was found by analysis to be quite free from water, and it differed greatly from the others with respect to solubility. For this form of silica the amount that passed into solution was negligibly small. A sample was placed in water in a stainless-steel beaker and left at room temperature with periodic stirring for 7128 hours. For the gel "a" the silicic acid concentration was then only $0.1 \cdot 10^{-5}$ g/ml SiO_2, and for the gel "b" it was only $0.6 \cdot 10^{-5}$ g/ml SiO_2.

SUMMARY

1. The solubilities of silicic acid gels in water at 25.9° and 97° were studied.

2. It was shown that the silicic acid that passed into solution was present entirely in the form of simple molecules and ions capable of reacting with molybdic acid. The equilibrium concentration was attained slowly at 25° ($12.5 \cdot 10^{-5}$ g/ml SiO_2) and rapidly at 97° ($41.5 \cdot 10^{-5}$ g/ml SiO_2).

3. A study was made of the behavior of silicic acid during the evaporation of its solutions and during the cooling of solutions saturated at 97°.

4. A study was made of the effect of prior heat treatment of a silicic acid gel on its solubility. It was shown that prior heating at 100, 200, 500, 800, or 900° has no effect on the solubility of silicic acid, but the rate of dissolution falls as the temperature of the previous heat treatment is raised. The solubility of silicic acid calcined at 1120° is very greatly reduced.

REACTION BETWEEN THE ETHER COMPLEX OF BORON TRIFLUORIDE AND LITHIUM HYDRIDE

COMMUNICATION 1. PREPARATION OF PURE DIBORANE

V. I. Mikheeva and E. M. Fedneva

The simplest boron hydride – diborane – is one of the most stable compounds of this class and is one of the least active in its attack on the grease in joints and taps. Until recently, most of the methods for its synthesis gave complex mixtures of volatile substances containing relatively little diborane, and its isolation from these mixtures was a very difficult task.

Stock, the pioneer in the systematic investigation of the boron hydrides, obtained diborane by prolonged fractionation of the hydrolysis products of so-called magnesium boride [1-4]. Later, Schlesinger and Burg [5] and Stock [6] obtained diborane by passing a mixture of boron halides and hydrogen through an electric discharge, but the yield did not exceed 6%. Hurd [7] prepared diborane by the reduction of boron halides with hydrogen in presence of metals and metal hydrides at high temperatures, and the product was again a difficultly separable mixture having a relatively low diborane content. In 1947 Schlesinger and coworkers [8] made use of the reaction of lithium aluminum hydride with boron trichloride for the preparation of diborane.

With the object of preparing diborane, at the end of 1949 we carried out a systematic study of the reduction of simple inorganic boron compounds with lithium hydride. For this purpose we used boron halides and sulfides, alkali-metal fluoborates, and other compounds. We found that, apart from boron trifluoride in ether solutions, all these substances react with lithium hydride with deflagration and the separation of elementary boron. After a considerable induction period lithium hydride reacted with a dilute ethereal solution of boron trifluoride at room temperature with separation of diborane; when the ether complex of boron trifluoride ("boron trifluoride etherate", a liquid, b.p. 126°) was used, reaction set in very quickly. The gas evolved was almost pure diborane, free from impurities apart from ether vapor. However, the reaction was found to be very capricious, giving yields that varied over the range 20-60%, and systematic work was necessary in order to ensure a reproducible yield.

Since we began this work some patents and papers have been published on the preparation of diborane by reaction between boron trifluoride and lithium hydride in an ether medium. Two patents were published in 1951 on the preparation of diborane by heating a mixture of lithium hydride and boron trifluoride in ether with simultaneous removal of diborane by distillation [9,10]. In a paper by Schapiro and coworkers in 1952 [11] a method is described for the preparation of diborane by reaction between boron trifluoride etherate and lithium aluminum hydride, and in a paper by Elliott, Boldebuck, and Roedel [12] its preparation by reaction of lithium hydride and boron trifluoride etherate is described. In this last investigation numerous experiments were carried out under various conditions, and the results were examined from the point of view of the possibility of the occurrence of two reactions:

$$6LiH + 2BF_3 \xrightarrow{\text{activator}} B_2H_6 + 6LiF$$

$$6LiH + 8BF_3 \rightarrow B_2H_6 + 6\,LiBF_4.$$

In presence of sufficient activator, the reaction proceeds in stages:

$$6LiH + 1.5BF_3 \xrightarrow{\text{activator}} 1.5LiBH_4 + 4.5LiF$$

$$1.5\ LiBH_4 + 0.5\ BF_3 \rightarrow B_2H_6 + 1.5\ LiF.$$

The authors point out the great complexity of the reaction and state that the presence of an ether-soluble activator ($LiBH_4$ or $LiBH(OCH_3)_3$) results in preferential conversion to $LiBH_4$, whereas in absence of an activator the reaction proceeds in the direction of the formation of B_2H_6 and $LiBF_4$. High pressures and the use of a tetrahydrofuran medium, in which diborane is highly soluble [13], favor the formation of lithium borohydride. The inconsistency of the yields is particularly emphasized in this paper. In a paper by Schlesinger and coworkers [14] it is stated that boron trifluoride etherate reacts with lithium hydride according to Equation 1 at a rate that depends on the degree of grinding of the lithium hydride, and the maximum yields that they give are not greater than 40-60% with respect to boron. The following intermediate stages are indicated in this paper:

$$3\ LiH + 3\ BF_3 \cdot O(C_2H_5)_2 \rightarrow 3\ LiBHF_3 + 3\ (C_2H_5)_2O;$$

$$3\ LiBHF_3 + BF_3 \cdot (C_2H_5)_2O \rightarrow \frac{1}{2}\ B_2H_6 + 3\ LiBF_4 + (C_2H_5)_2O.$$

It is pointed out that successive additions of the etherate react progressively less vigorously, in spite of the presence of excess of lithium hydride in the reaction mixture. The authors regard this reaction as difficult and non-quantitative, and they prefer the reaction of boron trifluoride with $NaBH(OCH_3)_3$, which gives more consistent yields of diborane. In all the published investigations, therefore, references are made to the complexity of the reaction and the inconsistency of the yields of diborane. For this reason we considered it desirable to publish our results on the reaction of boron trifluoride with lithium hydride, which were verified in numerous experiments under laboratory conditions.

EXPERIMENTAL

Original Substances. Lithium hydride LiH was the commercial quality, a fused crystalline mass containing 90-98% of LiH. It was ground as finely as possible in a mortar, sieved, and used immediately in the reaction. The use of hydride powder that has been kept for a long time results in a long period of induction with subsequent violent reaction.

Boron trifluoride BF_3 was prepared by reaction of boric anhydride with potassium fluoborate and concentrated sulfuric acid [15]. In order to remove hydrogen fluoride and water vapor impurities, the gas was passed through a trap containing concentrated sulfuric acid saturated with boric anhydride in the cold.

Boron trifluoride etherate $BF_3 \cdot (C_2H_5)_2O$ was prepared by saturating absolute ether with boron trifluoride and then distilling at atmospheric pressure; b.p. 126°. When kept, the etherate darkens in color; freshly distilled material must be used in the reaction.

Diethyl ether was first dried with calcined calcium chloride and then distilled and kept over sodium for a long time.

Investigation of Solid Reaction Products. After the reaction, during which gaseous diborane was removed, and removal of ether, a white solid remained in the reaction vessel. In order to determine the exact yield of the reaction with respect to the reactants consumed, it was necessary to determine the composition of this solid.

A test for $LiBH_4$ was carried out by adding 3-4 drops of water or dilute acid to a small amount of an ether extract of the solid. The presence of $LiBH_4$ was indicated by vigorous evolution of hydrogen. Lithium borohydride was isolated quantitatively from the solid by repeated washing with ether on a glass funnel with a porous bottom, filtration under a pressure of dry nitrogen, removal of ether from the filtrate under atmospheric pressure, and drying of the product in a vacuum at 90-100°. The active-hydrogen content of the lithium borohydride was determined by decomposing a sample with a weakly acid solution of a nickel salt [16].

In order to test for the presence of $LiBF_4$, an aqueous solution of a little of the solid was neutralized to methyl orange with hydrochloric acid and mixed with concentrated calcium chloride solution. In presence of $LiBF_4$ the reaction

$$LiBF_4 + 2CaCl_2 + 3H_2O \rightarrow H_3BO_3 + LiCl + 3HCl + 2CaF_2.$$

occurred; there was an indicator change to pink, which became bright red with simultaneous precipitation of CaF_2, when the solution was heated.

For the quantitative determination of $LiBF_4$, a sample of the solid weighing 0.2-0.3 g was dissolved in the least possible amount of water, the solution was neutralized to methyl orange, a strong neutral solution of calcium chloride was added, and the solution was brought almost to the boil, at which it was maintained for 10-15 minutes. The hot solution was titrated with 0.1 N NaOH until almost neutral, and it was then again heated almost to the boil and again titrated. Heating and titration were continued until 1-2 ml of alkali was required for neutralization. The solution was then boiled again for 30 minutes, cooled to room temperature, and titrated for the last time. At this point the hydrolysis of the BF_4^- ion would be practically complete [17]. The calculation of the lithium fluoborate concentration was carried out on the basis of the above equation.

Determination of unchanged lithium hydride in the solid was carried out after removal of lithium borohydride by ether extraction and removal of ether under vacuum. A sample weighing 0.02-0.03 g was decomposed with water, and the hydrogen evolved was collected in a gas buret. The volume was adjusted to normal conditions, and the LiH content of the solid was calculated.

Determination of boron was carried out on the solution after determining the BF_4^- ion and filtering off the precipitate of potassium fluoride. The solution was made up to 250 ml in a measuring flask. An aliquot of this was neutralized to methyl red, mannitol was added, and the solution was titrated to phenolphthalein with 0.1 N NaOH.

For the determination of total fluorine, the precipitate of CaF_2 remaining after the determination of fluorine bound in the form of $LiBF_4$ was filtered off, carefully washed with water, and placed together with the filter paper in a platinum crucible. After being dried and then ignited at 500-600°, the precipitate was weighed. A simple calculation gave the fluorine content.

Lithium was determined gravimetrically in the form of Li_2SO_4, boron being first removed in the form of trimethyl borate and fluorine by repeated evaporation to dryness with sulfuric acid and methanol, the latter being added periodically.

Experiments with Stoichiometric Proportions and with Excess of One or Other Reactant. In the first series of experiments on the preparation of diborane (Table 1), the reaction vessel was a three-necked flask fitted with mercury-sealed mechanical stirrer, dropping funnel, an arrangement for scattering the lithium hydride, and a very efficient reflux condenser, the free end of which was connected to traps cooled with solid carbon dioxide for trapping ether vapor. The yield of diborane in these experiments was determined by absorbing the gas evolved in 20-30% caustic potash solution, acidifying the solution, and determining the boric acid content [18,19], from which the yield of diborane was calculated. In the experiments in which diborane was actually isolated, for the complete removal of ether vapor it was first passed through traps containing concentrated sulfuric acid and then through traps cooled with a mixture of solid carbon dioxide and acetone; it was collected in receivers cooled with liquid nitrogen. In these experiments air was first displaced from the apparatus with dry hydrogen.

In some experiments lithium hydride powder was added to boron trifluoride etherate (Experiments 1 and 3). In most of the experiments, after displacement of air with dry hydrogen or nitrogen, the whole of the amount of finely ground lithium hydride required for the reaction was placed in the reactor and made into a suspension with the minimum amount of ether, and 25-30% of the amount of etherate necessary for reaction in accordance with Equation 1 was added rapidly. The temperature of the mixture then rose to 40°, the mixture boiled, and evolution of diborane set in immediately. The remainder of the etherate was then added gradually. The diborane formed was carried away by a current of dry hydrogen or nitrogen.

An examination of Table 1, which gives the conditions and results of experiments with stoichiometric proportions of reactants (Equation 1), with excess of lithium hydride, and with excess of boron trifluoride, reveals certain regularities. Considerable dilution of the boron trifluoride etherate with ether (Experiment 1) delays the start of the reaction, whereas the addition of small amounts of ether to the lithium hydride at the beginning and in the course of the reaction facilitates mixing and the evolution of diborane. The best yields of diborane with respect to boron are attained with an excess of lithium hydride of 25% and more. The use of a considerable excess of the etherate lowers the yield of diborane with respect to boron to 20% (Experiment 13); moreover, in spite of the excess of etherate, much of the lithium hydride (as much as 50% or higher) does not react. The probable cause of this is the envelopment of hydride particles by solid reaction products – first lithium fluoride, and then lithium fluoborate – which make the particles incapable of further reaction with

the etherate. For the best utilization of the boron, therefore, it is necessary to take excess of lithium hydride over the amount required according to Equation 1.

Experiments on the preparation of diborane from reaction mixtures containing small additions of lithium borohydride, lithium aluminum hydride, sodium hydride, or trimethyl borate showed that lithium borohydride and trimethyl borate are highly active, particularly the former. The addition of lithium borohydride, even in small amounts, causes the initiation of the reaction and practically eliminates the induction period.

The effect of temperature can be derived from comparisons between various experiments. For example, in 2 reaction was between 12.7 g (0.09 mole) of $BF_3 \cdot (C_2H_5)_2O$ and 4.55 g (0.57 mole) of LiH (BF_3 : LiH = 1 : 6) at 18°, and 2.6 g of lithium borohydride etherate was isolated. When reaction between the same amounts of reactants was carried out at the boiling point of ether, $LiBH_4$ was completely absent from the ether layer. At 0° (Exp. 15) formation of diborane was at a minimum and reaction proceeded preferentially in the direction of $LiBH_4$ formation.

Comparison between Experiments 4 and 5 shows the effect of the order of addition of reactants: alternation of the addition of etherate and hydride improves the yield of diborane, but gradual addition of etherate to the whole amount of the hydride as a suspension in ether (Experiment 16) gives the best yields of diborane.

Fig. 1. Laboratory apparatus for the preparation of diborane.

Experiments with Excess of Boron Trifluoride Etherate.* The next series of experiments, for which reaction balance sheets were calculated, was based on an analysis of the results of the first series (Table 1) with the object of improving the yield of diborane, both with respect to boron and with respect to lithium hydride. The yield calculated on the amount of lithium hydride taken is very important, for excess of hydride in the solid reaction product is difficult to utilize or recover, whereas unchanged boron trifluoride can be recovered by distillation during the course of the calcination of the precipitate. In this series of experiments the apparatus used consisted of a reactor A containing a magnetic stirrer (Fig. 1) and fitted with a dropping funnel B, a tube with a tap for introduction of nitrogen, and a reflux condenser C attached to traps. A suspension of the whole of the lithium hydride in a little ether was prepared in the reactor, and 15-25% of the total amount of etherate was added rapidly. A uniform stream of liberated diborane was then maintained by the addition of fresh portions of etherate. In these experiments the diborane was absorbed in dry pyridine, with which it formed the complex $C_5H_5N \cdot BH_3$ [20]. The active hydrogen in the pyridine solution was subsequently determined.

Table 2 gives the amounts of the reactants and products for some experiments of this series. For Experiments 3 and 4 curves showing the time-dependence of the liberation of diborane are given (Fig. 2). In order to indicate the procedure, we describe one of these experiments below. In most of the experiments, not only the gaseous, but also the solid reaction products were investigated, so that the actual equation of the reaction could be given (last column of Table 2).

These equations were obtained by multiplying the numbers of moles of lithium hydride and boron trifluoride etherate brought into reaction by a factor that brings the number of moles of lithium hydride to six, so that a comparison can be made with Equation 1. As lithium borohydride was not found in any of the experiments and the lithium hydride was utilized almost quantitatively, we regarded the yield of diborane as almost quantitative. This is in satisfactory agreement with results on the determination of the yield of diborane when correction is made for unavoidable leakage; Experiment 1 is exceptional, since a considerable loss of the diborane occurred.

Description of Experiment 4 (Table 2). Boron trifluoride etherate (21.3 g) was added rapidly to an electromagnetically stirred suspension of 6.4 g (0.8 mole) of lithium hydride in 15 ml of absolute ether. The remainder of the etherate was added gradually in such a way that uniform liberation of diborane was maintained.

* Excess of etherate is to be understood as referring to the stoichiometry of Equation 1.

In all, 42.3 g (0.30 mole) of etherate was added. Further addition of etherate did not result in liberation of more diborane. As necessary, more ether was added to the reaction mixture (three 15-ml portions). The diborane evolved was absorbed with dry pyridine. The pyridine traps were changed periodically so that the course of the liberation of diborane could be followed (Fig. 2). The yield of diborane with respect to boron trifluoride etherate (according to Equation 1) was 83.4%, and with respect to lithium hydride it was 94.6%. Other experiments of this series were carried out in a similar way. By this procedure, therefore, all the lithium hydride can be caused to react without an appreciable reduction in the yield of diborane calculated on a boron basis.

Fig. 2. Time-dependence of liberation of diborane: 1) Experiment 3; 2) Experiment 4.

Fig. 3. Diagram of vacuum apparatus for the refining of diborane and the determination of its constants.

Determination of the Purity of the Diborane. The diborane obtained by the reaction investigated contains only ether vapor as impurity. The solutions obtained by absorption of the diborane in traps containing water gave no reaction for fluorine with saturated calcium chloride solution. Passage of the diborane through traps containing

concentrated sulfuric acid and traps cooled with a mixture of solid carbon dioxide and acetone (-78°) freed it from ether vapor. In order to establish the purity of the diborane, it was fractionated by the fractional-condensation method and the physical constants of the fractions were determined, this being carried out in a special vacuum apparatus (Fig. 3) constructed in accordance with Stock's recommendations [4], in which the diborane came into contact only with glass and mercury. The fractionation showed that the gas consisted of one fraction only, this being collected at -170° in the form of a white crystalline mass.

Fig. 4 Heating curve of diborane.

The substance was characterized by vapor-pressure and melting-point determinations. The vapor pressure, which was determined by Stock's method [4] using a gas thermometer (filled with ethylene), was found to be 166.5 mm at -119° (m.p. of diethyl ether), whereas Stock obtained a value of 167.5-168 mm for the same temperature. Heating curves for samples of diborane in the range from -195° to -100° (Fig. 4) have only one halt, corresponding to the endothermic process of fusion; the start of this was at -165°, both for "crude", and also for carefully fractionated diborane (Stock obtained -165.5°). The diborane obtained by the method described was therefore almost completely pure.

DISCUSSION OF RESULTS

An unsatisfactory feature of the preparation of diborane by reaction between boron trifluoride etherate and lithium hydride is the great variation in yield, which varies from 20% to 90% with respect to boron under what appear to be extremely similar conditions. Sometimes the reaction has a long period of induction and then proceeds at an uncontrollable rate. Among the causes of this great variation in yield there is, in the first place, the effect of the presence of moisture in the ether, which results in the formation of films of oxide on the lithium hydride particles. Hence, the quality of the ether and lithium hydride is subject to very exacting requirements. After carrying out several series of experiments with complete analysis of the gaseous, liquid, and solid phases, we were able to discover also other factors that affect the yield of diborane. Our investigation showed that the reaction of lithium hydride with boron trifluoride etherate cannot be described by any one equation, but consists in a series of parallel reactions having successive stages.

Apart from the reactions described by Equations 1 and 2, if the intermediate stages are not counted, the following reactions are also possible:

$$4\,LiH + BF_3 \cdot (C_2H_5)_2O \rightarrow LiBH_4 + 3\,LiF. \quad (3)$$

$$BF_3 + LiF = LiBF_4. \quad (4)$$

$$BF_3 + 3\,LiBH_4 = B_2H_6 + 3\,LiF. \quad (5)$$

The transformation of boron trifluoride goes in three directions: formation of diborane, of lithium borohydride, and of lithium fluoborate. Taking into account the solubilities of the compounds obtained in ether [12] (B_2H_6 - 1.1 g/100 g; $LiBF_4$ - 1.9 g/100 g; $LiBH_4$ - 3.0 g/100 g; LiF - 0.05 g/100 g) and our experiments showing that only diborane is present in the gas phase, we may suppose that the solid phase remaining after distillation of ether may contain, apart from unchanged lithium hydride, lithium fluoride and the boron-containing compounds lithium fluoborate and lithium borohydride. Depending on temperature, dilution with ether, proportions of reactants, and the order of their addition, the reaction may proceed in the direction of a higher or lower relative yield of diborane.

When reaction is brought about at room temperature with an excess of lithium hydride, the temperature of

3	60.3 (0.425)	6.4 (0.8)	1 : 2	57.0	88.1	Nil	37.5	Dimer
4	42.3 (0.30)	6.4 (0.8)	1 : 2.7	83.45	94.6	Nil	11.1	$6LiH + 2.25BF_3 \cdot (C_2H_5)_2O \rightarrow B_2H_6 + 5.75LiF + 0.25LiBF_4 + 2.25 \cdot (C_2H_5)_2O$

of the mixture rises to 25-35° and there is preferential formation of diborane; under these conditions lithium borohydride does not accumulate in the ether solution. However, much of the boron remains in the precipitate in the form of $LiBF_4$ and the lithium hydride is not utilized fully. When there is a considerable excess of lithium trifluoride, not only is the yield with respect to boron lowered, but the yield with respect to lithium hydride is lowered also. An incomparably better procedure is that carried out in the second series of experiments (Table 2) with a ratio of boron trifluoride to lithium hydride greater than that corresponding to Equation 1 and with gradual addition of the boron trifluoride etherate to the whole of the lithium hydride under vigorous stirring. No lithium borohydride is then formed in the overall reaction, and the yield of diborane is raised both with respect to the utilization of boron, and also with respect to lithium hydride. Under these conditions, the reaction proceeds neither by Equation 1 nor by Equation 2, but by an equation in which the number of moles of boron trifluoride etherate varies over the range 2.25-2.8.

The curve for the time-dependence of the liberation of diborane has a well defined point of inflection A (Fig. 2). This shows that, with gradual addition of etherate, the reaction proceeds in two stages. In the first stage, in which there is a large excess of lithium hydride, the comparatively slow liberation of diborane is associated with the accumulation of active intermediate reaction products – possibly also lithium borohydride – without appreciable formation of lithium fluoborate. The second stage consists in the reaction of fresh portions of etherate with the remaining lithium hydride and with the accumulated active intermediaries, including lithium borohydride. Most of the diborane is obtained at this stage, and there is a corresponding sharp rise in the curve for the liberation of diborane (Fig. 2).

At both stages the reaction probably has a multistage mechanism with formation of the intermediaries $LiHBF_3$, $LiBH_2F_2$, and $LiBH_3F$. The last two compounds may give diborane, since their molecules contain a "ready-made" borine group BH_3:

$$2\,LiBH_3F \rightarrow B_2H_6 + 2\,LiF$$

or

$$2LiBH_3F + 2BF_3 \cdot (C_2H_5)_2O \rightarrow B_2H_6 + 2LiBF_4,$$
$$3\,LiBH_4 + BF_3 \cdot (C_2H_5)_2O \rightarrow 2\,B_2H_6 + 3\,LiF.$$

Simultaneously, particularly in the first stage, a reaction occurs between diborane and excess of lithium hydride:

$$2\,LiH + B_2H_6 \rightarrow 2\,LiBH_4$$

and there is also the reaction (4) in the case of excess

of boron trifluoride. Moreoever, in the initial stage of the reaction, while the temperature of the reaction mixture is rising to 40°, disproportionation reactions are possible for the intermediate reduction products:

$$2\ LiHBF_3 \rightarrow LiBH_2F_2 + LiBF_4;$$

$$3\ LiBH_2F_2 \rightarrow B_2H_6 + LiBF_4 + 2\ LiF;$$

$$4\ LiBHF_3 \rightarrow LiBH_4 + 3\ LiBF_4 \text{ etc.}$$

The reactions that we have cited here give some idea of the complexity of the process studied.

From these considerations we may conclude that, for maximum yields of diborane, the initial stage of the reaction must be carried out in presence of excess of lithium hydride, and that, for the best utilization of the hydride, the amount of boron trifluoride etherate taken must be greater than that corresponding to the stoichiometry of Equation 1. These conditions are attained by the procedure used in Experiment 4 (Table 2). Carrying out the reaction in accordance with our description of this experiment ensures the preparation of highly pure diborane in consistent and almost quantitative yield with respect to lithium hydride and to the boron trifluoride etherate that reacts.

SUMMARY

1. The reaction of lithium hydride with boron trifluoride etherate has a complex mechanism, which probably includes various parallel and successive reactions leading to the formation, as the ultimate boron-containing products, of diborane, lithium borohydride, and lithium fluoborate. The yield of diborane is dependent on reaction temperature, relative amounts of reactants, degree of agitation of the reaction mixture, and order of addition of reactants.

2. An almost quantitative yield with respect to both reactants is attained by carrying out the reaction at somewhat raised temperature (25-30°) in the initial stage, at a BF_3 : LiH ratio of 1 : 2.4-2.8, and with gradual addition under constant stirring of lithium trifluoride etherate to lithium hydride.

3. The reaction studied is the simplest and most economical method for the preparation of highly pure diborane under laboratory conditions, and it opens up wide possibilities for the further study of the chemistry of boron hydrides and their derivatives.

MECHANISM OF THE DEACTIVATION OF NICKEL CATALYSTS BY STEAM UNDER PRESSURE

L. Kh. Freidlin, A. A. Balandin, N. V. Borunova, and A. E. Agronomov

Water is one of the most frequently encountered impurities in catalytic reduction and hydrogenation processes; it is formed by the reduction of metal oxides and oxygen-containing organic compounds. Water is a reaction component in transformations of hydrocarbons and carbon monoxide; it is used as a solvent and diluent. However, the effect of water vapor on nickel hydrogenation catalysts has been inadequately investigated.

Tsutsumi and coworkers [1] noted that small amounts of water greatly reduce the activity of a nickel catalyst in fat-hydrogenation reactions. Slovokhotova and Ivanov [2] found that the rate of dehydrogenation of cyclohexane at 250-300° over a nickel-alumina catalyst was reduced by a factor of five in presence of water vapor. Arnold and Atwood [3] state that nickel deposited on a complex mixture of oxides is of low stability as a catalyst for the transformation of hydrocarbons by means of steam.

In an investigation of the properties of nickel catalysts prepared by reduction with hydrogen at a pressure of 500 atm, we concluded that the cause of their low activity was the presence of water vapor in the sphere of the reduction reaction. In this connection we studied the effect of water vapor purposely introduced into the reduction zone in the treatment of nickelous oxide with hydrogen under pressure. It was found that steam under pressure brings about a far-reaching irreversible change in the catalyst components, namely their recrystallization. Our results make it possible to approach the question of the mechanism of the deactivation of of metal catalysts with water vapor from a new viewpoint.

EXPERIMENTAL

Experimental Procedure

The catalysts were prepared by coprecipitation from a mixture of molar nitrate solutions with 30% sodium hydroxide. The product was decomposed to give a mixture of oxides corresponding to 35% NiO and 65% Al_2O_3 (or 65% MgO).

The reduced catalyst or carrier-supported nickelous oxide was placed in a stainless-steel beaker and treated for five hours at 350° with a mixture of steam (100 atm) and hydrogen (700 atm) in a special high-pressure reactor. The treated mass was removed from the cooled reactor and reduced with electrolytic hydrogen at 350° and normal pressure. The activity of the catalyst was characterized by the degree of hydrogenation of benzene (at 120° and at a space velocity of 0.3 $hour^{-1}$) or the degree of dehydrogenation of cyclohexane (at 300° and at a space velocity of 0.3 $hour^{-1}$), determined in continuous-flow apparatus. The degree of hydrogenation of benzene and the degree of dehydrogenation of cyclohexane were determined refractometrically [4].

Effect of a Mixture of Steam and Hydrogen under Pressure on the Activity of a Nickel-Alumina Catalyst

Experiments 1 and 2 were carried out with commercial nickel-alumina catalyst containing 50% of nickel. Over this catalyst benzene was hydrogenated to the extent of 97% at 120°. It will be seen from Table 1 that, after the steam-hydrogen treatment, the degree of hydrogenation of benzene was only 14.4%. The catalyst was then reduced with hydrogen for five hours at 350° and normal pressure. Its activity then increased

considerably: the degree of hydrogenation of benzene was 56.2%. After a further reduction with hydrogen for six hours under the same conditions, the activity of the catalyst was almost completely recovered. It is thus possible to regenerate a reduced catalyst that has been deactivated by treatment with steam. However, the deactivated catalyst must be treated with hydrogen for a fairly long time.

TABLE 1

Effect of Treatment with a Steam-Hydrogen Mixture Under Pressure on the Activity of a Nickel-Alumina Catalyst. Conditions of treatment: hydrogen pressure 700 atm; steam pressure 100 atm; duration five hours; temperature 350°

Expt. No.	Sample of $Ni\text{-}Al_2O_3$	Duration of reduction with hydrogen * (hours)	Degree of hydrogenation of benzene (%)
1	Untreated	6	97.4
2	Treated	–	14.4
		5	56.2
		6	94.0

* At 350° under normal pressure.

Effect of Treatment of Carrier-supported Nickelous Oxide with a Mixture of steam and Hydrogen under Pressure

Nickelous oxide on a carrier was treated for five hours at 350° with a mixture of steam and hydrogen. It will be seen from Table 2 that sample No. 7 of nickelous oxide on alumina, treated in this way and then reduced with hydrogen for five hours at 350° and normal pressure, was almost completely inactive as a catalyst: the degree of hydrogenation of benzene at 120° was only 6.4%. After further reduction with hydrogen for eight hours, the activity of the catalyst did not increase. After a third reduction with hydrogen for eight hours, the activity of the catalyst was still low: the degree of hydrogenation of benzene at 180° was 9.5% (Experiment 4). For a catalyst prepared from the same sample without treatment with steam, the degree of hydrogenation of benzene was 91.6% and the degree of dehydrogenation of cyclohexane was 63% (Experiment 3).

Similar results were obtained with sample No. 8. The catalyst prepared from this sample and not subjected to the action of steam was very active: the degree of hydrogenation of benzene was 98.8%, and the degree of dehydrogenation of cyclohexane was 78.8%. The sample was treated with a mixture of steam and hydrogen under pressure at 350°, and subsequent reduction with hydrogen at atmospheric pressure at 350° gave an inactive catalyst: the degree of hydrogenation of benzene at 120° was 1.2%. After further reduction with hydrogen at ordinary pressure and 350° for eight hours and then at 425° for five hours, it remained almost inactive (Experiments 5 and 6).

Similar results were obtained when the catalyst was prepared from nickelous oxide and magnesia, subsequently treated with a mixture of steam and hydrogen under pressure. Reduction with hydrogen for five hours at 350° and ordinary pressure gave an inactive catalyst: the degree of hydrogenation of benzene was 0.2% at 120° and 8.8% at 180°. After further reduction with hydrogen for eight hours under similar conditions, the degree of hydrogenation of benzene attained 19%. The catalyst prepared from the same sample of nickelous oxide on magnesia, but not subjected to the action of steam, hydrogenated benzene to the extent of 91.6% and dehydrogenated cyclohexane to the extent of 46.4% (Experiments 7 and 8).

The results obtained with three samples of nickelous oxide on alumina or magnesia show that, when reduced with hydrogen in presence of steam, carrier-supported nickelous oxide suffers an irreversible change. An active catalyst was not obtained from the nickelous oxide even after reduction with hydrogen for 13-21 hours at 350° and ordinary pressure.

Similar results were obtained when nickelous oxides on carriers were treated with a mixture of steam and nitrogen under pressure. However, they were somewhat more active than samples treated with a mixture of steam and hydrogen (Experiments 9 and 10) (Table 3).

Effect of Treatment of Alumina-supported Nickelous Oxide with Steam

In order to determine the effect of treating nickelous oxide with steam in absence of hydrogen or nitrogen, a series of experiments was carried out in which the following procedure was adopted. Nickelous oxide on alumina was heated in an autoclave with a definite volume of distilled water. The temperature was measured with a thermocouple placed in the pocket of the autoclave. At the end of the experiment, the contents were unloaded, dried at 100°, formed into shape, and reduced with hydrogen at 350°. The activity of the catalyst was then tested for the hydrogenation of benzene or the dehydrogenation of cyclohexane by the usual method.

* At 350° under normal pressure.

It will be seen from Table 4 (Experiment 11) that nickelous oxide on alumina, treated for five hours at 350° with steam under a pressure of 100 atm and then reduced with hydrogen, becomes quite inert as a catalyst. A

similar result was obtained with the same sample of nickelous oxide on alumina treated with steam for two hours (Experiment 12). The two catalysts from Experiments 11 and 12 were then mixed and further reduced with hydrogen for 20 hours at 350° at normal pressure, the total duration of the hydrogen treatment then being 25-33 hours. Even then, however, the catalyst was found to be quite inactive (Experiment 13). It follows from Experiment 14 that, when the temperature of the steam treatment of nickelous oxide on alumina in the autoclave was lowered to 300°, a catalyst was obtained which was again of low activity: the degree of hydrogenation of benzene in its presence was 3.4%. In Experiment 15 no water was added. It was found that even the very small amount of water vapor that is liberated during dehydration at 350° is sufficient to reduce the activity of the catalyst appreciably (Table 4).

* At 350° and normal pressure.
** Duration of steam treatment two hours.
*** Treated with steam at 300°
**** No water was added.

The results given in Table 2 and 4 show that a catalyst prepared from carrier-supported nickelous oxide treated with steam is just as inactive as a nickelous oxide preparation treated with a mixture of steam and hydrogen.

Effect of Treatment of Nickelous Oxide Alone with Steam

The above-described results refer to nickelous oxide supported on a carrier. It was essential to determine the effect of steam treatment of nickelous oxide alone, in absence of carrier. With this object, nickelous oxide prepared by precipitation of a molar solution of the nitrate with sodium hydroxide was taken in an amount of 4.2 g (10 ml) and reduced with hydrogen for ten hours at 350°. Another portion of the same sample of nickelous oxide was pretreated for five hours at 350° with steam at 180 atm, and some of the product (4.2 g, i.e., 2.5 ml) was reduced for ten hours at 350°. Activity tests showed that, with the catalyst prepared from nickelous oxide not treated with steam, benzene was hydrogenated to the extent of 93.4%, and cyclohexane was dehydrogenated to the extent of 37.8%. The activity of the catalyst prepared from the steam-treated nickelous oxide was considerably lower: degree of hydrogenation of benzene 52-60% and degree of dehydrogenation of cyclohexane 20-21%. As will be seen, the effect of steam under given conditions on nickelous oxide without carrier is much less than on nickelous oxide supported by a carrier. This shows the very close association between the nickelous oxide and the carrier in the coprecipitated mixture.

Effect of Steam on the Activity of Nickel Catalysts

Investigations were made also on the effect of steam treatment on the activities of Raney nickel and of a catalyst prepared by the reduction of nickelous oxide.

a) Effect on the Activity of Nickel Prepared by the Reduction of Nickelous Oxide. A catalyst prepared by the reduction of 4.2 g (10 ml) of nickelous oxide with hydrogen (ten hours at 350°) was treated for five hours at 350° with steam at atmospheric pressure. The space velocity of passage of water was 0.5-0.6 hour^{-1}, and the total amount of water passed was 30 ml. After steam treatment, the catalyst was reduced with hydrogen for five hours at 350°. There was little change in activity: before steam treatment the degree of hydrogenation of benzene was 93.8%; after steam treatment it was 87.6%. It will be seen that treatment of reduced nickel with steam at ordinary pressure has only a slight effect on catalytic activity.

b) Effect on the Activity of Raney Nickel Catalyst. Samples of catalyst were prepared by leaching 50% nickel-aluminum alloy with 20% caustic alkali at 100°. The activity of the catalyst before and after steam treatment was characterized by the rate of hydrogenation of 0.25 g of phenyl vinyl ether in alcohol at 20°. A paste of the catalyst (10 g) was placed in a glass tube filled with nitrogen. The tube was heated in an electric furnace

* 12 ml of water passed.

** 1 g of catalyst.

provided with a thermoregulator. During the warming-up period and throughout the experiment, a slow stream of oxygen-free nitrogen was passed through the tube. Water was admitted to the tube at a uniform space velocity of 0.6 hour^{-1}. The steam-treated catalyst was cooled in a stream of nitrogen and emptied out into water. It will be seen from Table 5 that treatment of the catalyst with steam for two hours at 150-200° did not lower the activity. Only steam treatment at 250-300° lowered the activity of the catalyst to an appreciable extent. Our results are in conflict with Aubry's assumption [5] concerning the interaction of Raney nickel and water at room temperature.

c) Effect of Treatment of Raney Nickel Catalyst with Steam at High Pressure. The catalyst was placed together with a definite volume of water in a 200-ml autoclave. The autoclave was hermetically sealed, blown out three times with nitrogen, and heated to the temperature of the experiment. At the end of the experiment the autoclave was cooled to room temperature. It was then opened rapidly, and water was poured over the catalyst. It will be seen from Table 6 that, when 10 g of catalyst was heated under pressure with 6-12 ml of water at only 150°, its activity was reduced by a factor of 3-4. Even the small amount of water contained in the moist Raney nickel paste was sufficient to deactivate the catalyst at 150° (Experiments 25 and 26). It is interesting to note that heating of the catalyst at 150° under pressure in presence of a large amount of water (100 ml) scarcely reduced the activity (Experiment 23). In this case the catalyst was covered with a layer of water, which probably protected it from the deactivating effect of steam. Steam, therefore, is more aggressive in its action than water in the liquid state.

Effect of Steam on the Specific Surface of a Mixture of Nickelous Oxide and Alumina

The effect of water vapor on the reduction of nickelous oxide by hydrogen at normal pressure has been studied by several investigators. It was established that water vapor retards the reduction of nickelous oxide, lengthens the induction period, raises the temperature at which reduction begins, and increases the time necessary for complete reduction [6-8]. The inhibiting effect of water vapor on the reduction of metal oxides has been explained by investigators by the formation of a firmly adsorbed film on the metal surface, the oxide surface, or the interface

Fig. 1.

Fig. 2

between the metal and oxide phases. As the degree of reduction of metal oxides (under given conditions of temperature and pressure) depends on the relative concentrations of hydrogen and water vapor in the system, the effect of the latter tends to be equivalent to a change in the thermodynamic conditions of the process, thus resulting in a displacement of equilibrium.

However, this cannot explain the almost complete inertness of nickel prepared by the reduction of steam-tested carrier-supported nickelous oxide. The processes of forming films of adsorbed water vapor, and also oxide films or phases, are reversible. Water vapor may be desorbed, and a metal oxide may be reduced. However, as the results of our experiments show, treatment of nickelous oxide on a carrier with steam under pressure has an irreversible effect on the activity of the catalyst prepared from it.

Our results led us to the view that, in the course of steam treatment, nickelous oxide undergoes extensive recrystallization. In order to verify this we investigated the effect of steam treatment on the specific surfaces of samples No. 7 and 8 of alumina-supported nickelous oxide. A 30-40 mg sample was placed in a high-vacuum apparatus containing a quartz spring balance, and it was freed from adsorbed gases and vapors by treating it for many hours at 250° at a residual pressure of the order of 10^{-5}–10^{-6} mm. Adsorption isotherms were then determined for benzene vapor at 0°. The benzene was first freed from traces of thiophene and moisture and had b.p. 79.7-80° (755 mm) and n_D^{20} 1.5035. The benzene was freed from dissolved air and was thoroughly dried over magnesium perchlorate in the apparatus itself. The pressure of benzene vapor in the system was measured with a mercury manometer accurately within 0.01 mm. The extension of the spirals was measured with a microcatheto-meter accurately within 0.01 mm, which made it possible to determine changes in weight accurately within $1 \cdot 10^{-5}$ g. The surface area was calculated by the Brunauer, Emmett, and Teller method [9] on the assumption that the area of the benzene molecule is 46.5 A^2 [10]. The isotherms for the adsorption of benzene on samples No. 7 and 8 are shown in Figures 1 and 2.

Sample No. 8 of nickelous oxide on alumina was found to be nonporous, and its specific surface was 170 sq.m/g. The specific surface of the same sample after treatment for five hours at 350° with a mixture of steam and hydrogen at pressure of 700 atm was only about 10 sq.m/g; the volume of benzene adsorbed by the sample at saturation was reduced to about one-third by the treatment. The specific surface of sample No. 7 of nickelous oxide on alumina was reduced from 80 to 30 sq.m/g by treatment for five hours at 350° with a mixture of steam and nitrogen. The specific surface of alumina, treated with steam under similar conditions, was reduced by a factor of almost three (from 355 to 125 sq.m/g) [11].

These results confirmed that steam treatment brings about extensive recrystallization both of carrier-supported nickelous oxide and of the carrier itself. They are in accord with the results of van Eyk van Voorthuijsen and Franzen, which show that steam treatment facilitates the perfection of the crystal structure of nickel hydrosilicate [12].

Discussion of Experimental Results

Our results show that catalysts prepared by the reduction of steam-treated nickelous oxide supported on a carrier (Al_2O_3, MgO) are almost completely inactive for the hydrogenation of benzene at normal-pressure; they catalyze the hydrogenation of an ethylene bond (3-octene, styrene) at ordinary pressure, and they will hydrogenate

also an aromatic bond at high pressure [13]. Even after long treatment with hydrogen, the extent to which the nickelous oxide in these catalysts is reduced does not exceed 20-30%. This, however, is does not explain the low activity of catalysts prepared in this way. In our experiments, catalysts (prepared from carrier-supported nickelous oxide which had not been subjected to the action of steam) in which the nickelous oxide was reduced to the extent of, for example, 40-50%,were very active for the hydrogenation of benzene. It is known also that benzene can be readily and completely hydrogenated over a catalyst containing only 1-4% of nickel supported on charcoal [14].

Our adsorption measurements showed that, when treated with steam at high temperature and pressure, a mixture of nickelous oxide and carrier, as also the carrier itself, undergoes far-reaching recrystallization. It appears that the main cause of the inactivity of our catalysts is the low dispersity of the nickel obtained by the reduction of recrystallized nickelous oxide. Lachinov [15] suggested that, owing to the presence of water vapor during reduction with hydrogen under pressure, the iron catalyst for the ammonia synthesis undergoes alternate oxidation and reduction with recrystallization of metal particles and reduction of the activity of the catalyst.

The results that we have obtained on the effect of steam treatment of carrier-supported nickelous oxide on the activity of the catalyst prepared from it enable us to examine the mechanism of the deactivation of metal catalysts by steam in a new light. It was found that steam treatment had the greatest effect on carrier-supported nickelous oxide, and not on reduced nickel. Steam treatment of a prepared nickel catalyst under similar conditions lowered the activity of the catalyst to a much lower extent. When the steam treatment was at ordinary pressure, the difference was difficult to detect, but at high pressure the difference was great. Treatment of carrier-supported nickelous oxide with steam alone had an even greater effect, than treatment with a mixture of steam and hydrogen.

It is clear that the deactivation of the catalyst is due to the recrystallization not of the metal, but of its lower oxide (film or phase), which is formed by the action of steam at high temperature, particularly when the pressure is also high. The subsequent reduction of the coarsely dispersed particles of recrystallized oxide proceeds with great difficulty, being slower and requiring a higher temperature. The metal particles obtained after the reduction of the recrystallized oxide are also of low dispersion and of low activity. We consider that the mechanism that we have proposed is applicable also to the deactivation of iron catalysts by steam.

Kamzolkin and Livshits [16] stated that a few hundredths of a percent of water vapor in the gas mixture lower the productivity of an ammonia-synthesis column by hundreds of kilograms per hour. It is known that it is exceptionally important to have a small admixture of alumina for lasting activity in the iron catalyst of the ammonia synthesis [17]. It may be assumed that, under the action of steam at high temperature, alumia will recrystallize and its promoting effect will be lost. In this lies one of the causes of the deactivation of an iron catalyst by steam.

Shurmovskaya and Bruns [18] consider that in this process at low concentrations of water vapor it is impossible to expect that an iron oxide phase will appear. Reaction of iron is here of a purely surface character. The results of our work show that the deactivating effect of small amounts of water vapor on an iron catalyst can be explained by the formation of a recrystallized, and therefore difficultly reducible, surface film of oxide. The work of Bashkirov and coworkers [19] shows that one of the causes of the irreversible deactivation of an iron catalyst in the synthesis of hydrocarbons from carbon monoxide and hydrogen under pressure is reaction between the water vapor liberated and the catalyst with formation of an iron oxide phase. This conclusion requires supplementation by a demonstration of the occurrence of recrystallization in the metal oxide phase formed by the action of water vapor in a high-pressure system.

SUMMARY

1. An investigation was made into the deactivating effect of steam on nickel catalysts in the course of their preparation by reduction with hydrogen under pressure.

2. It was shown that pretreatment of a mixture of nickelous oxide and carrier (Al_2O_3, MgO) with steam under pressure results in the formation of catalysts of low activity. Similar treatment of a reduced carrier-supported nickel catalyst has a very much smaller effect on activity.

3. It was shown that steam treatment of a coprecipitated mixture of nickelous oxide and alumina (or magnesia) under pressure results in a far-reaching irreversible change, namely recrystallization with great reduction in specific surface.

4. It is evident that the deactivation of reduced nickel catalysts by steam in the course of their use is due to the formation of nickelous oxide films or phases that rapidly recrystallize and are reduced with difficulty with formation of coarsely dispersed nickel. It is probable that the mechanism here proposed is applicable also to the deactivation of iron catalysts by water vapor.

DERIVATIVES OF UNSATURATED PHOSPHONIC ACIDS

COMMUNICATION 19. 2-CHLORO-3-BUTENYL- AND 1,3-BUTYADIENYL-PHOSPHONIC ESTERS

K. N. Anisimov and N. E. Kolobova

We have previously effected the addition of phosphorus pentachloride to vinyl ethers and to ethylenic and acetylenic hydrocarbons. From the addition products so obtained acid chlorides were prepared by treatment with sulfur dioxide, and these were converted further into other derivatives of unsaturated phosphonic acids [1,2,3]. It was considered to be of interest to investigate the addition reaction between phosphorus pentachloride and dienic hydrocarbons (butadiene, isoprene, piperylene, and 2,3-dimethylbutadiene).

In the present paper we report the synthesis and reactions of 2-chloro-3-butenylphosphonic dichloride. This substance was prepared as follows:

$$CH_2=CH-CH=CH_2+2PCl_5\rightarrow CH_2=CH-CHCl-CH_2PCl_4PCl_5;$$
$$CH_2=CH-CHCl-CH_2PCl_4\cdot PCl_5+2SO_2\rightarrow CH_2=CH-CHCl-CH_2POCl_2+$$
$$+POCl_3+2SOCl_2.$$

From the ozonization products of the acid chloride obtained, formic acid was isolated. This gave us reason to believe that addition of phosphorus pentachloride to butadiene occurs at the 1,2-position. 2-Chloro-3-butenylphosphonic dichloride is a colorless liquid having the characteristic odor of an acid chloride. It readily reacts with alcohols and is soluble in all organic solvents. By the use of the very vigorous reaction of 2-chloro-3-butenylphosphonic dichloride with alcohols, we were able to synthesize 2-chloro-3-butenylphosphonic esters by the method of Milobendzski and Sachnowski [4]:

$$CH_2=CH-CHCl-CH_2POCl_2+2ROH+2C_5H_5N\rightarrow$$
$$\rightarrow CH_2=CH-CHCl-CH_2PO(OR)_2+2C_5H_5N\cdot HCl.$$

In this way we prepared the methyl, ethyl, propyl, isopropyl, butyl, isobutyl, allyl, hexyl, 2-methoxyethyl, and 2-ethoxyethyl esters of 2-chloro-3-butenylphosphonic acid.

2-Chloro-3-butenylphosphonic esters are colorless mobile liquids, readily distilled under reduced pressure, and soluble in the usual organic solvents. They decolorize bromine water and give a positive Beilstein test for chlorine. The constants of these esters are given in Table 1.

When the 2-chloro-3-butenylphosphonic esters were treated with alcoholic potash, hydrogen chloride was eliminated and the corresponding 1,3-butadienylphosphonic esters were formed in accordance with the reaction

$$CH_2=CH-CHCl-CH_2PO(OR)_2+\xrightarrow[C_2H_5OH]{KOH}CH_2=CH-CH=CHPO(OR)_2+$$
$$+KCl.$$

* According to a patent [5], diethyl 1,3-butadienylphosphonate, b.p. 100-124° (11 mm), was prepared by reaction between phosphorus pentachloride and butadiene with subsequent treatment of the tetrachloride with alcohol, the product being then dehydrochlorinated with alcoholic potash.

In this way we prepared and characterized the methyl, ethyl, propyl, isopropyl, butyl, isobutyl, allyl, hexyl, 2-methoxyethyl, and 2-ethoxyethyl esters of 1,3-butadienylphosphonic acid. All these esters are colorless liquids that can be readily distilled under reduced pressure. They combine with bromine with formation of thick sirups, which do not crystallize and which decompose when vacuum-distilled. Constants of 1,3-butadienylphosphonic esters are given in Table 2.

EXPERIMENTAL

2-Chloro-3-butenylphosphonic Dichloride $CH_2=CH-CHCl-CH_2-POCl_2$. A mixture of 208 g of phosphorus pentachloride and 250 ml of absolute benzene was prepared in a three-necked flask fitted with mechanical stirrer, condenser, and tube for the passage of gas. The mixture was cooled with ice and stirred while 85-90 g of 1,3-butadiene was passed in. A yellowish crystalline mass formed and was left overnight. On the next day the crystalline butadiene-PCl_5 addition product was treated with sulfur dioxide until complete dissolution occurred. After removal of solvent, thionyl chloride, and phosphoryl chloride by distillation, the residue was vacuum-fractionated at a residual pressure of 2 mm.

The yield of acid chloride, m.p. 103-105° (2 mm), n_D^{20} 1.5200; d_4^{20} 1.4452 was 114 g (90%).

Found %: C 23.05, 23.14; H 2.83, 2.94; P 14.85, 14.82; Cl 51.48, 51.20. $C_4H_6POCl_3$. Calculated %: C 23.13; H 2.89; P 14.93; Cl 51.32.

Ozonization of 2-Chloro-3-butenylphosphonic Dichloride. A solution of 10 g of 2-chloro-3-butenylphosphonic dichloride, b.p. 103-105° (2 mm), in chloroform was treated with ozone at 0° for 12 hours (ozone concentration 5%). Water (25 ml) and 5% hydrogen peroxide (7 ml) were added to the solution of ozonide. The mixture was heated for nine hours at 65°, and was then neutralized with 10 g of sodium carbonate. After the separation of chloroform, the solution of water-soluble salts was vacuum-evaporated to dryness. The residue was decomposed with 5% hydrochloric acid and extracted several times with ethyl ether. After removal of ether, formic acid, b.p. 98-100° and n_D^{20} 1.3720, was isolated (the literature [6] gives b. p. 100.8° and n_D^{20} 1.3714). There was a positive calomel reaction for formic acid. The formic acid was distilled from the mixture of water-soluble acids, and a dark-brown resin remained. This did not crystallize, even after a long time, and it decomposed when attempts were made to distil it in a vacuum. Nothing could be isolated from the chloroform solution.

Dimethyl 2-Chloro-3-butenylphosphonate $CH_2=CH-CHCl-CH_2PO(OCH_3)_2$. A mixture of 75 ml of of benzene, 12.8 g of absolute methanol, and 31.6 g of pyridine was prepared in a three-necked flask fitted with stirrer, reflux condenser, and dropping funnel. The mixture was cooled with ice water and stirred while 41.5 g of 2-chloro-3-butenylphosphonic dichloride was added gradually. When the whole of the acid chloride had been added, the reaction mixture was set aside overnight. On the next day the mixture was heated for two hours at 75-80° and then cooled. Pyridine hydrochloride was filtered off, and the filtrate was dried over sodium sulfate. After removal of solvent, the residue was vacuum-fractionated and gave 20 g (50%) of the ester, b.p. 112-114° (2 mm), n_D^{20} 1.4770, and d_4^{20} 1.2365.

Found %: P 15.59, 15.45. $C_6H_{12}PO_3Cl$. Calculated %: P 15.61.

All the other 2-chloro-3-butenylphosphonic esters were prepared in the same way.

Dimethyl 1,3-Butadienylphosphonate $CH_2=CH-CH=CHPO(OCH_3)_2$. A solution of 1.8 g of caustic potash in 20 ml of absolute alcohol was placed in a flask fitted with stirrer, condenser, and dropping funnel. The solution was stirred while 6.5 g of dimethyl 2-chloro-3-butenylphosphonate was added. After the addition of the whole of the ester, the reaction mixture was heated for two hours at 70°. When the mixture was cool, potassium chloride was filtered off and alcohol was distilled from the filtrate. Vacuum fractionation of the residue gave 3.5 g of dimethyl 1,3-butadienylphosphonate, b.p. 77-78.5° (3 mm), n_D^{20} 1.4835, and d_4^{20} 1.1021.

Found %: P 18.97, 18.85. $C_6H_{11}PO_3$. Calculated %: P 19.13.

The other 1,3-butadienylphosphonic esters were synthesized in a similar way.

SUMMARY

1. With the aid of the addition reaction between phosphorus pentachloride and 1,3-butadiene, 2-chloro-3-butenylphosphonic dichloride was prepared.

2. The methyl, ethyl, propyl, isopropyl, butyl, isobutyl, allyl, hexyl, 2-methoxyethyl, and 2-ethoxyethyl esters of 2-chloro-3-butenylphosphonic acid were prepared by the action of alcohols on 2-chloro-3-butenylphosphonic dichloride, and some of their properties were determined.

3. By reaction between alcoholic potash and esters of 2-chloro-3-butenylphosphonic acid, the methyl, ethyl, propyl, isopropyl, butyl, isobutyl, allyl, hexyl, 2-methoxyethyl, and 2-ethoxyethyl esters of 1,3-butadienylphosphonic acid were synthesized.

DERIVATIVES OF UNSATURATED PHOSPHONIC ACIDS

COMMUNICATION 20. 2-CHLORO-3-METHYL-3-BUTENYL- AND 3-METHYL-1,3-BUTADIENYL-PHOSPHONIC ESTERS

K. N. Anisimov and N. E. Kolobova

In the preceding communication [1] we described the addition of phosphorus pentachloride to 1,3-butadiene. With the aid of this reaction we prepared 2-chloro-3-butenylphosphonic dichloride, 2-chloro-3-butenylphosphonic esters, and 1,3-butadienylphosphonic esters. In continuation of our investigations on the addition of phosphorus pentachloride to dienic hydrocarbons, we have studied the addition of phosphorus pentachloride to isoprene.

The process was carried out under the conditions described in the preceding paper [1], the reactions occurring being

$$CH_2=\underset{\displaystyle CH_3}{\overset{|}{C}}-CH=CH_2+2PCl_5\rightarrow CH_2=\underset{\displaystyle CH_3}{\overset{|}{C}}-CHCl-CH_2PCl_4\cdot PCl_5;$$

$$CH_2=\underset{\displaystyle CH_3}{\overset{|}{C}}-CH-CH_2\cdot PCl_4\cdot PCl_5+2SO_2\rightarrow CH_2=\underset{\displaystyle CH_3}{\overset{|}{C}}H-CHCl-CH_2POCl_2+POCl_3+2SOCl_2$$

The position at which the addition of phosphorus pentachloride to isoprene occurred was determined by ozonization of the acid chloride obtained. Formic acid was isolated from the ozonolysis products, which gave us reason to believe that addition to isoprene occurred at the 1,2-position, so that the product was 2-chloro-3-methyl-3-butenylphosphonic dichloride.

Treatment of this substance with alcohols gave diesters of 2-chloro-3-methyl-3-butenylphosphonic acid, in accordance with the reaction [2]:

$$CH_2=\underset{\displaystyle CH_3}{\overset{|}{C}}-CHCl-CH_2POCl_2+2ROH+2C_5H_5N\longrightarrow$$

$$\longrightarrow CH_2=\underset{\displaystyle CH_3}{\overset{|}{C}}-CHCl-CH_2PO(OR)_2+2C_5H_5N\cdot HCl$$

Constants of the esters obtained are given in Table 1.

2-Chloro-3-methyl-3-butenylphosphonic esters are readily dehydrochlorinated by alcoholic potash with formation of 3-methyl-1,3-butadienylphosphonic esters:

$$CH_2=\underset{\displaystyle CH_3}{\overset{|}{C}}-CHCl-CH_2PO(OR)_2+\xrightarrow[C_2H_5O]{KOH}$$

$$\rightarrow CH_2=\underset{\displaystyle CH_3}{\overset{|}{C}}-CH=CHPO(OR)_2+KCl$$

Properties of 3-methyl-1,3-butadienylphosphonic esters are given in Table 2.

EXPERIMENTAL

Preparation of 2-Chloro-3-methyl-3-butenylphosphonic Dichloride $CH_2=C(CH_3)-CHCl-CH_2POCl_2$. A mixture of 500 ml of benzene and 417 g (2 moles) of phosphorus pentachloride was prepared in a three-necked flask fitted with mechanical stirrer, dropping funnel, and reflux condenser. The mixture was cooled with ice water and stirred well while 74.8 g (1.1 moles) of isoprene was added gradually. The crystalline addition product formed was left ovemight and then treated with sulfur dioxide until it was converted completely into a liquid. Solvent, thionyl chloride, and phosphoryl chloride were distilled off. Vacuum fractionation of the residue gave 200 g (90%) of 2-chloro-3-methyl-3-butenylphosphonic dichloride, b.p. 107-108° (2 mm), n_D^{20} 1.5230; d_4^{20} 1.3918.

Found %: C 27.19, 27.25; H 3.81, 3.72; P 13.92, 13.98; Cl 47.82, 47.73. $C_5H_9POCl_3$. Calculated %: C 27.08; H 3.61; P 13.99; Cl 48.08.

Synthesis of Dimethyl 2-Chloro-3-methyl-3-butenylphosphonate $CH_2=C(CH_3)-CHCl-CH_2PO(OCH_3)_2$. A mixture of 150 ml of benzene, 16 g (0.5 mole) of methanol, and 39.5 g (0.5 mole) of pyridine was prepared in a three-necked flask fitted with stirrer, reflux condenser, and dropping funnel. The mixture was cooled with ice water and stirred while 55.3 g (0.25 mole) of 2-chloro-3-methyl-3-butenylphosphonic dichloride was added gradually. On the next day the reaction mixture was heated for two hours at 70°, and then cooled. The precipitate of pyridine hydrochloride was filtered off, and the filtrate was washed with 3% sodium carbonate solution and dried over magnesium sulfate. The solvent was distilled off, and vacuum fractionation of the residue gave 27.4 g (50%) of product, b.p. 119-121° (3 mm), n_D^{20} 1.4805; d_D^{20} 1.1971.

Found %: P. 14.84, 14.76. $C_7H_{14}PO_3Cl$. Calculated %: P 14.58.

All the other 2-chloro-3-methyl-3-butenylphosphonic esters were prepared by this method.

Preparation of Dimethyl 3-Methyl-1,3-butadienylphosphonate $CH_2=C(CH_3)-CH=CHPO(OCH_3)_2$. A solution of 5.4 g (0.1 mole) of caustic soda in 50 ml of absolute ethanol was placed in a three-necked flask fitted with stirrer, condenser, and dropping funnel. The solution was stirred while 21.2 g (0.1 mole) of dimethyl 2-chloro-3-methyl-3-butenylphosphonate was added slowly. The reaction mixture was then heated at 80° for three hours. The potassium chloride that was precipitated was filtered off, alcohol was distilled off, and vacuum distillation of the residue gave 13 g (74%) of the ester, b.p. 95-96° (2 mm), n_D^{20} 1.4868; d_4^{20} 1.1015.

Found %: P 17.42, 17.46. $C_7H_{13}PO_3$. Calculated %: P 17.61.

The other 3-methyl-1,3-butadienylphosphonic esters listed in Table 2 were prepared similarly.

SUMMARY

1. With the aid of the reaction between isoprene and phosphorus pentachloride, 2-chloro-3-methyl-3-butenylphosphonic dichloride was prepared.

2. The methyl, ethyl, propyl, isopropyl, butyl, isobutyl, allyl, hexyl, 2-methoxyethyl, and 2-ethoxyethyl esters of 2-chloro-3-methyl-3-butenylphosphonic and 3-methyl-1,3-butadienylphosphonic acids were prepared and characterized.

ALKYLAMIDES OF ORGANIC DERIVATIVES OF PHOSPHORUS ACIDS

B. A. Arbuzov, P. I. Alimov and O. N. Fedorova

In the preceding communication [1] we described the synthesis of organic derivatives of bis[phosphoric acid] amide of general formula

in which R^1 is C_2H_5O or $(CH_3)_2N$, R^2 is C_2H_5O or $(CH_3)_2N$, and R is CH_3, C_2H_5, C_4H_9, or C_6H_5. Tests on toxicity to the corn weevil showed that these compounds have insecticidal properties, their activities being determined both by the radicals attached to phosphorus and by the radicals attached to nitrogen.

In order to extend the range of these organic compounds of phosphorus and nitrogen, improve the method of preparation, study their physical and chemical properties and also physiological activity, we synthesized amides of phosphorus acids, analogous to the above, but with different groups on the phosphorus and nitrogen atoms. These substances were synthesized by reaction of phosphorochloridic esters and their thiono analogs with N-alkyl-N-sodiophosphoramidic esters and their thiono analogs in accordance with the equation.

in which R is C_3H_7, i-C_3H_7, C_4H_9, or i-C_4H_9, and R^1 is CH_3 or C_2H_5; OR may be replaced by $(CH_3)_2N$. N-Alkyl-N-sodiophosphoramidic esters are readily soluble in organic solvents (ether and gasoline).

Apart from the structure given above, the following could be proposed for the compounds synthesized:

This structure, however, is less probable.

Table 1 gives the formulas, physical constants, yields, and results of the elementary analysis of the alkylamides prepared in this way. The compounds listed in this table are colorless mobile liquids having a feeble ethereal odor. They are readily soluble in organic solvents, but sparingly soluble in water. In tests on the corn weevil they showed rather low insecticidal activity. For example, compound No. 4 – the tetraisopropyl ester of bis[phosphoric acid] methylamide – gave a mortality figure of 8% of the beetles in one day for a concentration of 0.2%.

TABLE 1

No.	Formula of compound	B.p. in °C (p in mm)	n_D^{20}	d_4^{20}	MR found	MR calculated	Phosphorus content (%) found		Phosphorus content (%) calculated	Yield (%)

By reaction between N-alkyl-N-sodiophosphoramidic esters and phosphorochloridous esters, alkylamides containing residues of phosphoric and phosphorous diesters were obtained:

in which R is C_2H_5, i-C_3H_7, or C_3H_7, and R^1 is CH_3 or C_2H_5. The constants of substances synthesized in this way are given in Table 2.

Tetraalkyl esters of mixed alkylamides of phosphoric and phosphorous acids, being compounds containing a tervalent phosphorus atom, are able to undergo addition reactions and rearrangement of ester groupings at the tervalent phosphorus atom. Thus they readily combine with sulfur with formation of mixed alkylamides of phosphoric and phosphorothionic acids:

When treated with alkyl halides, the alkylamides isomerize or undergo rearrangement into compounds containing two quinquevalent phosphorus atoms:

(1)

(2)

The last compound is assigned its structure by analogy with the structure of the substance obtained by reaction of chloral with triethyl phosphite [2]:

The constants of substances obtained by these isomerization and rearrangement reactions are given in Table 3.

EXPERIMENTAL

I. Synthesis of Tetraalkyl Esters of Bis[phosphoric acid] Alkylamides

Tetrapropyl Ester of Bis[phosphoric acid] Methylamide. Dipropyl Phosphorochloridate (26.06 g, i.e. 0.13 mole) was added to a cooled stirred solution of dipropyl N-methyl-N-sodiophosphoramidate prepared from 25.35 g (0.13 mole) of the N-methylphosphoramidic ester and 3 g (0.13 g-atom) of sodium in 120 ml of gasoline, b.p. 70-120°. When addition was complete, the mixture was heated for one hour at 55-65° and then left overnight. Sodium chloride was removed by centrifugation, and gasoline was distilled off under reduced pressure. The residue, which amounted to 38.5 g (82.4%), was distilled at 2 mm from an Arbuzov flask, and the following fractions were obtained:

Fraction I, b. p. 95-165°; 10.2 g
Fraction II, b.p. 165-171°; 18.2 g
Residue 9.0 g

Redistillation of Fraction II gave 14.2 g (30.4%) of a substance having b.p. 159-160° (1 mm); n_D^{20} 1.4365; d_4^{20} 1.0867; found MR 86.46; calculated $C_{13}H_{31}O_6P_2N$ MR 86.77.

Found %: P 17.33, 17.18. $C_{13}H_{31}O_6P_2N$. Calculated %: P 17.22.

The product was a colorless mobile liquid, readily soluble in organic solvents. Compounds No. 2, 3, 4, 5, 6, 7, 8, 11, and 12 in Table 1 were prepared under similar conditions.

II. Synthesis of Tetraalkyl Esters of Mixed Alkylamides of Phosphoric and Phosphorous Acids

Tetraisopropyl Ester of the Mixed Methylamide of Phosphoric and Phosphorous Acids. This compound was prepared by the action of 10.3 g (0.056 mole) of diisopropyl phosphorochloridite on diisopropyl N-methyl-N-sodiophosphoramidate, prepared from 10.9 g (0.056 mole) of the N-methylphosphoramidic ester and 1.28 g (0.056 g-atom) of sodium in 100 ml of gasoline. The crude product, amounting to 17.5 g (91.3%), was distilled at 2 mm, and the following fractions were obtained:

Fraction I, b.p. 45-110°; 2.5 g
Fraction II, b.p. 110-115°; 12.5 g
Residue 1.5 g

Redistillation of Fraction II gave 8.6 g (44.8%) of a substance having b.p. 107-109° (1 mm); n_D^{20} 1.4330; d_4^{20} 1.0179; found MR 87.58; calculated $C_{13}H_{31}O_5P_2N$ MR 87.91.

Found %: P 18.04, 18.00. $C_{13}H_{31}O_5P_2N$. Calculated %: P 18.07.

This substance is a colorless mobile liquid having a feeble odor reminiscent of a phosphorous ester; it is readily soluble in organic solvents. Compounds No. 1 and 3 in Table 2 were prepared similarly.

III. Synthesis of Tetraalkyl Esters of Mixed Alkylamides of Phosphoric and Phosphorothionic Acids

Addition of Sulfur to the Tetraisopropyl Ester of the Mixed Methylamide of Phosphoric and Phosphorous Acids. A mixture of 5.6 g of the methylamide (b.p. 107-109° (1 mm)), 0.52 g of sulfur (1 g-atom per mole of amide), and 25 ml of benzene was heated at the boiling point of benzene for 20 minutes. Solvent was distilled off, and the residue was vacuum-distilled. The main fraction, amounting to 3.9 g (64.2%), had b.p. 126-127.5° (1 mm); n_D^{20} 1.4535; d_4^{20} 1.0786; found MR 94.08; calculated $C_{13}H_{31}O_5P_2NS$ MR 94.28. Compounds No. 9 and 10 in Table 1 were prepared similarly.

Found %: P 16.76, 16.5; S 8.32, 8.29. $C_{13}H_{31}O_5P_2NS$. Calculated %: P 16.53; S 8.53.

IV. Action of Halogen Compounds on the Tetraethyl Ester of the Mixed Methylamide of Phosphoric and Phosphorous Acids

Isomerization of the Tetraethyl Ester of the Mixed Methylamide of Phosphoric and Phosphorous Acids with Ethyl Iodide. A mixture of 7 g of the amide (b.p. 104-106° (1 mm)) and 1 g of ethyl iodide was sealed in a glass tube and heated for six hours at 120-130°. Distillation of the contents of the tube gave a main

fraction amounting to 4.5 g (64.3%) and having b.p. 132-133° (1 mm), n_D^{20} 1.4430; d_4^{20} 1.1394; found MR 66.78; calculated $C_9H_{19}O_5P_2N$ MR 66.67.

Found %: P 21.82, 21.73. $C_9H_{19}O_5P_2N$. Calculated %: P 21.60.

The substance was a colorless liquid, readily soluble in organic solvents.

Action of Ethyl Bromoacetate on the Tetraethyl Ester of the Mixed Methylamide of Phosphoric and Phosphorous Acids. The amide (10 g, i.e. 0.035 mole) was heated to 120°, and 5.8 g (0.035 mole) of ethyl bromoacetate was added from a dropping funnel. The mixture was heated for one hour at 120-130°. Distillation gave a main fraction amounting to 6.5 g (67.6%) and having b.p. 161-163° (1 mm); n_D^{20} 1.4490; d_4^{20} 1.1878; found MR 77.92; calculated $C_{11}H_{25}O_7P_2N$ MR 78.06.

Found %: P 17.71, 18.00. $C_{11}H_{25}O_7P_2N$. Calculated %: P 17.97.

The product was a feebly smelling colorless liquid, soluble in organic solvents.

Action of Chloral on the Tetraethyl Ester of the Mixed Methylamide of Phosphoric and Phosphorous Acids. Chloral (4.7 g, i.e. 0.032 mole) was added from a dropping funnel at room temperature to 9.18 g (0.032 mole) of the amide. Reaction was accompanied by rise in temperature and liberation of ethyl chloride. When reaction was complete, the crude product was vacuum-distilled. A fraction, amounting to 7.8 g (65.5%), came over at 152-153° (1 mm); it had n_D^{20} 1.4606; d_4^{20} 1.3077; found MR 77.56; calculated $C_9H_{19}O_6P_2NCl_2$ MR 77.56.

Found %: P 17.11, 17.10. $C_9H_{19}O_6P_2NCl_2$. Calculated %: P 16.76.

SUMMARY

1. By reaction of phosphorochloridic esters (and their thiono analogs) and of phosphorochloridous esters with N-alkyl-N-sodiophosphoramidic esters (and their thiono analogs), organic compounds of phosphorus and nitrogen of the following general formulas were synthesized:

I) $(RO)_2P(O(S))-N(R^1)-P(O(S))(OR)_2$,

in which R is C_3H_7, i-C_3H_7, C_4H_9, or i-C_4H_9, and R^1 is CH_3 or C_2H_5; OR may be replaced by $(CH_3)_2N$;

II) $(RO)_2P(O)-N(R^1)-P(OR)_2$,

in which R is C_2H_5, C_3H_7, or i-C_3H_7, and R^1 is CH_3 or C_2H_5.

2. Physical constants of these products were determined, some of their chemical properties were investigated, and they were examined for insecticidal activity.

ACYL DERIVATIVES OF 1-HYDROXYALKYLPHOSPHONIC ESTERS

P. I. Alimov and I. V. Cheplanova

In studying the properties of mixed anhydrides derived from diethyl hydrogen phosphite and a carboxylic acid $RCOOP(OC_2H_5)_2$ [1], we found that these compounds readily react with aldehydes with formation of acyl derivatives of 1-hydroxyalkylphosphonic esters:

As organophosphorus compounds of this series were not known previously, in the present paper we give data on their properties and describe a more convenient method for their preparation. Synthesis by the second method is effected by reaction of acid chlorides in presence of triethylamine with 1-hydroxyalkylphosphonic esters having a hydrogen on the 1-carbon atom:

The reaction was carried out in gasoline solution at room temperature and it was completed by heating the mixture at 50-60° for 60-90 minutes. 1-Hydroxyalkylphosphonic esters in which the hydrogen on the 1-carbon was replaced by a radical were found to be much less active toward the acid chloride. Under the conditions described above, acyl derivatives of these esters are either not formed at all, or are formed in very low yield. Reaction under more severe conditions gives somewhat higher yields. Thus, when a xylene solution of acetyl chloride, diethyl 1-hydroxy-1-methylethylphosphonate, and triethylamine was heated at 80-90° for 13 hours, the product was a mixture, b.p. 95-96° (0.5 mm), consisting of the acetyl derivative of diethyl 1-hydroxy-1-methylethylphosphonate (43%) and unchanged hydroxy ester.

The diethyl 1-hydroxyalkylphosphonates were prepared by Abramov's method [2]. The table gives constants and yields of the 1-(acyloxy)alkylphosphonic esters that we synthesized.

The substances listed in the table are colorless or yellowish liquids which can be distilled in a vacuum without decomposition. When boiled with 10% caustic soda they are hydrolyzed with formation of carboxylic and 1-hydroxyalkylphosphonic acids:

TABLE

No.	Formula of compound	B.p. in °C (p in mm)	n_D^{20}	d_4^{20}	MR found	MR calculated	Phosphorus content (%) found	Phosphorus content (%) calculated	Yield (%)
1		93—93.5 (0.5)	1.4271	1.1083	51.9	51.67	13.94; 13.87	13.83	76.8
2		111—112 (2)	1.4312	1.0649	61.28	60.9	12.53; 12.51	12.30	50.9
3		158—160 (2)	1.4917	1.1540	71.86	71.15	11.00; 11,19	10.8	55.6
4		168—169 (3)	1.4933	1.1333	76.97	75.77	10.33; 10,23	10.33	64
5		129—130 (0.5)	1.4694	1.1946	64.39	64.60	11.21; 11.18	11.23	39.1
6		150—151 (1.5)	1.4637	1.1387	73.62	73.83	10.36; 10,07	10.2	67
7		156—157 (0.5)	1.4640	1.1088	82.65	83.07	9.36; 9.09	9.33	37.5

In an alkaline medium the decomposition of 1-hydroalkylphosphonic acids probably proceeds further [3]. The organic acids were determined by titration with alkali after they had been liberated from their salts with sulfuric acid and separated from the other hydrolysis products by distillation.

EXPERIMENTAL

Action of Acetyl Chloride on Diethyl 1-Hydroxybutylphosphonate

Acetyl chloride (6.4 g, i.e. 0.081 mole) was added from a dropping funnel to a stirred mixture of 17 g (0.081 mole) of diethyl 1-hydroxybutylphosphonate (b.p. 141-142° (3 mm)), 8.2 g (0.081 mole) of triethylamine, and 150 ml of gasoline (b.p. 70-120°). The reaction mixture was maintained at 65-70° for one hour. After separation of triethylamine hydrochloride and removal of solvent under reduced pressure, the residue, amounting to 20.4 g (100%), was distilled from an Arbuzov flask at a residual pressure of 3 mm. The fractions obtained were:

Fraction I, b.p. 110-117°; 1.5 g
Fraction II, b.p. 117-120°; 18 g

Redistillation of Fraction II gave 10.4 g (50.9%) of a substance having b. p. 111-112° (2 mm); n_D^{20} 1.4312; d_4^{20} 1.0649; found MR 61.28; calculated for $C_{10}H_{21}PO_5$ MR 60.9.

Found %: P 12.53, 12.51. $C_{10}H_{21}PO_5$. Calculated %: P 12.30.

Determination of the Acetyl Group. A solution of a 0.5346-g sample of the sample of the substance in 15 ml of 10% caustic soda was boiled for one hour. The mixture was acidified with sulfuric acid, and solvent was distilled off until an almost dry residue was obtained. Water was added to the residue, and the mixture was again distilled, and the whole of this operation was repeated. The distillates were titrated with alkali.

Acetyl content found 17.21% . $C_{10}H_{21}PO_5$. Acetyl content calculated : 17.06%.

Diethyl 1-acetoxybutylphosphonate is a colorless mobile liquid of feeble odor; it is soluble in organic solvents. Compounds No. 1, 3, and 4 were prepared similarly.

Action of the Mixed Anhydride of Diethyl Hydrogen Phosphite and Acetic Acid on Butyraldehyde

A mixture of 8.77 g (0.034 mole) of tetraethyl pyrophosphite and 2.04 g (0.034 mole) of acetic acid was heated for ten minutes at 110-115°. The mixed anhydride of diethyl hydrogen phosphite and acetic acid so obtained [1] was mixed with 2.45 g (0.034 mole) of butyraldehyde, and the mixture was heated for 45 minutes at 130-140°. Distillation at 4 mm from an Arbuzov flask gave the fractions:

Fraction I, b.p. 47-80°; 4.5 g
Fraction II, b.p. 80-137°; 6 g
Residue 1.5 g

Redistillation of Fraction II gave 2.2 g (25.6%) of a substance having b.p. 123-125° (5 mm); n_D^{20} 1.4318; d_4^{20} 1.0672; found MR 61.23; calculated for $C_{10}H_{21}PO_5$ MR 60.9.

Found %: P 12.68, 12.64. $C_{10}H_{21}PO_5$. Calculated %: P 12.3.

Acetyl content found: 17.29%. $C_{10}H_{21}PO_5$. Acetyl content calculated: 17.06%.

Action of Isobutyryl Chloride on Diethyl α-Hydroxyfurfurylphosphonate

Several drops of a saturated solution of sodium methoxide in methanol were added to a mixture of 13.8 g (0.1 mole) of diethyl hydrogen phosphite and 9.6 g (0.1 mole) of 2-furaldehyde [2]. The temperature of the mixture then rose to 73°. The mixture was heated for one hour at 95-100° and then cooled.

The resulting crude diethyl α-hydroxyfurfurylphosphonate was dissolved in 150 ml of gasoline (b.p. 70-125°), and 10.1 g (0.1 mole) of triethylamine was stirred in. Isobutyryl chloride (10.65 g, i.e. 0.1 mole) was then added from a dropping funnel to the stirred mixture. The temperature was maintained at 65-70° for one hour. After separation of triethylamine hydrochloride and removal of solvent under reduced pressure, the residue, which amounted to 28 g (93.3%), was distilled at 1 mm. The following fractions were obtained:

Fraction I, to 143°; 1.5 g
Fraction II, b.p. 143-147°; 22.6 g

Redistillation of Fraction II gave 20.1 g (67%) of a substance having b.p. 150-151° (1.5 mm); n_D^{20} 1.4637; d_4^{20} 1.1383; found MR 73.62; calculated for $C_{13}H_{21}O_6P$ MR 73.83.

Found %: P 10.36, 10.07. $C_{13}H_{21}O_6P$. Calculated %: P 10.2.

The substance was an odorless viscous yellow liquid, readily soluble in organic solvents, but sparingly soluble in water. Compounds No. 5 and 7 were prepared similarly.

SUMMARY

1. By the action of acetyl, butyryl, and isobutyryl chlorides on some 1-hydroxyalkylphosphonic esters having a hydrogen on the 1-carbon, the corresponding acyl derivatives of the esters were obtained. Some of their physical constants were determined.

2. It was shown that similar compounds can be prepared by reaction of aldehydes with esters of mixed anhydrides of phosphorous acid and various carboxylic acids.

MECHANISM OF REACTIONS BETWEEN DIAZO COMPOUNDS AND METALS WITH FORMATION OF ORGANOMETALLIC COMPOUNDS*

O. A. Reutov

In 1929 Nesmeyanov [1] discovered the diazo method of synthesizing organometallic compounds, which consists in the decomposition of double diazonium salts with metal powders:

$$ArN_2X \cdot MeX_n \xrightarrow{Me'} Ar_mMeX_{p-m} \text{ or } Ar_nMe'X_{q-n}$$

(p and q are the valencies of metals Meand Me'). The Nesmeyanov reaction has been applied in the synthesis of organic compounds of mercury [2-6], tin [7,8], lead [9,10], arsenic [11-13], antimony [14-22], bismuth [23], and thallium [24].

It has been generally ackowledged that the Nesmeyanov reaction is a homolytic process, proceeding through the stage of neutral radicals. This view, which receives its support mainly from the investigations of Waters [25], is based on the fact that the Nesmeyanov reaction is accompanied by the formation of byproducts which could arise only from the reactions of the neutral radicals Ar· and Cl· (hydrocarbons ArH and products of the chlorination of solvents). Such products, however, could arise in side reactions, whereas the main reaction, in which the organometallic compound is formed, might be heterolytic.

Markovskaya [26] showed that, under the conditions of the Nesmeyanov reaction, double diazonium salts can dissociate with formation of free arenediazonium chloride. The decomposition of the arenediazonium chloride (under the action of the metal, or thermally) naturally results in the formation of free radicals, which react with the solvent. This side reaction, however, is unlikely to have any direct bearing on the reaction between the double diazonium salt and the metal, which results in the formation of an organometallic compound.

We investigated [27] the relation between the rate of the reaction

$$p\text{-}XC_6H_4SbCl_4 \cdot C_6H_5N_2Cl + Fe \rightarrow XC_6H_4(C_6H_5)SbCl_2 + N_2 + FeCl_2$$

and the character of the substitutent X.

It was found that, with respect to increasing reaction rate, substitutents X fall in the same order as they do with respect to increasing electron-donating power:

$$O_2N < Cl < H < CH_3 < C_2H_5O$$

As electron density is not a determining factor in radical reactions (see, for example, [28]), such a simple relation between reaction rate and the electronegative properties of the substituent is incomprehensible if the reaction is homolytic.

On the other hand, the observed relation can be explained on the assumption that the decomposition of the double salts by, for example, iron prowder is heterolytic in character and may proceed as follows:

* Communication from A. N. Nesmeyanov's department.

It is clear that the heterolytic decomposition of the intermediately formed double salt B (addition of $C_6H_5^+$ at the free electron pair of the antimony atom) will be facilitated by substituents of the first kind and rendered more difficult by substituents of the second kind.

The relation found between the rates of decomposition of the salts $C_6H_5SbCl_4 \cdot p\text{-}YC_6H_4N_2Cl$ and the character of the substituent Y [26] is again in accord (see below) with the hypothesis of a heterolytic mechanism for the reaction (with increase in the electron-donating powers of the substituents, the reaction rate falls:

$$H > CH_3 > C_2H_5O^*).$$

* When Y is a substituent of the second kind (NO_2, $COOC_2H_5$), the double diazonium salt is appreciably dissociated in acetone solution and iron powder brings about two reactions: decomposition of double salt and decomposition of free arenediazonium.

A parallel may be drawn between the tendency of the double salts $C_6H_5SbCl_4 \cdot p\text{-}YC_6H_4N_2Cl$ (and probably also any of the double salts $MCl_n \cdot p\text{-}YC_6H_4N_2Cl$) (Y is a substituent of the second kind) to undergo ready dissociation and the tendency of the diazo compounds $p\text{-}YC_6H_4-\overset{+}{N}\equiv NCl^-$ (Y is a substituent of the second kind) to enter readily into the azo-coupling reaction. The causes of the two phenomena are probably analogous.

As is well known, p-nitrobenzenediazonium chloride, for example, readily undergoes azo-coupling because the nitro group in attracting electrons creates a partial positive charge on the end nitrogen of the diazo group:

Reversible dissociation, to which all double diazonium salts are to some extent prone, is to a certain extent analogous to the reaction of azo-coupling, for example:

In both reactions the diazonium cation becomes covalently bound with an atom (carbon in the first case and chlorine in the second) by the acceptance of an electron pair. It is clear that the dissociation of a double salt, which consists essentially in the removal of a chlorine anion from an antimony atom by means of a diazonium cation, must resemble azo coupling in being facilitated by substituents of the second kind:

These considerations enable us to understand why 2,4-dinitrobenzenediazonium chloride – one of the most energetic azo-coupling reactants – is quite unable to form double diazonium salts.

Similar conclusions follow from a study of the stability of double diazonium salts of the type $ArSbCl_3 \cdot Ar'N_2Cl$*, which are generally readily decomposed in acetone or ethyl acetate according to the equation:

$$ArSbCl_3 \cdot Ar'N_2Cl \rightarrow ArAr'SbCl_3 + N_2$$

The table lists double diazonium salts of arylantimony dichlorides, which were prepared by the reaction:

$$ArSbCl_2 + Ar'N_2Cl \cdot FeCl_3 \rightarrow ArSbCl_2 \cdot Ar'N_2Cl + FeCl_3.$$

As will be seen from the table, salts of the type $ArSBCl_2 \cdot Ar'N_2Cl$ vary in stability according to the identities of Ar' and Ar [29]. Substituents of the first kind lower the stability of the double salt when they are in the radical of the organoantimony component and raise it when in the radical of the diazo component. On the other hand, substituents of the second kind raise the stability of the double salt when they are in the radical of the organoantimony component and lower it when in the radical of the diazo component.

TABLE

Relation of the Stability of the Double Salt X—C$_6$H$_4$—$SbCl_2 \cdot Y$—C$_6$H$_4$—N_2Cl to the Characters of X and Y

No.	Substituent Y	Substituent X**			
		p-O$_2$N—	p-H$_2$NO$_2$S—	p-H—	p-CH$_3$—
1	p-O$_2$N—	—	—	—	—
2	m-O$_2$N—	—	—	—	—
3	p-C$_2$H$_5$OOC—	—	—	—	—
4	p-CH$_3$—C(=O)—	+	—	—	—
5	p-H—	+	+	+	—
6	p-CH$_3$—	+		+	+
7	p-CH$_3$O—	+		+	+
8	p-C$_2$H$_5$O—		+	+	
9	p-(CH$_3$)$_2$N—	+	+	+	+

** The sign + denotes that a double salt is obtained, and the sign − that the salt cannot exist (decomposes). When no sign appears, the corresponding salt was not investigated.

* In the scheme given above it is assumed that double salts of this type (B) are formed as intermediate compounds.

Many salts, particularly those containing a substituent of the second kind in the radical of the diazo component and a substituent of the first kind in the radical of the organoantimony component, are unable to exist, and in all attempts to prepare them they immediately decompose with formation of a diarylantimony trichloride. It does not appear that this phenomenon can be explained on the basis of the view generally held at present, according to which the decomposition of double diazonium salts is a radical reaction:

If, however, we suppose that it is a heterolytic reaction:

then the dependence of the stability of the salt $ArSbCl_2 \cdot Ar'N_2Cl$ on the characters of Ar and Ar' can be explained.

The instability of double diazonium salts having substituents of the second kind in the radical of the diazo component is probably due to interaction between the anion of the organoantimony compound and the arenediazonium cation, and this interaction, in its turn, is the result of the presence of a free electron pair on the antimony atom, on the one hand, and a partial positive charge on the carbon atom of the benzene ring attached to nitrogen (due to attraction of electrons by a substituent of the second kind), on the other. For example:

The introduction of a substituent of the second kind into the ortho or para position of phenylantimony dichloride should result in the displacement of the free electron pair of the antimony atom in the direction of the benzene ring, so that the interaction of the antimony atom with the carbon atom of the diazonium radical will be reduced, and the stability of the double salt consequently increased. This is probably the explanation of the ability of p-nitrophenylantimony dichloride to form stable double salts with arenediazonium halides even when the latter contains a substituent of the second kind (acetyl):

In the light of the data considered above we are compelled to reexamine the now generally accepted view of the homolytic character of the synthesis of organometallic compounds via double diazonium salts (particularly the Nesmeyanov reaction) and to advance the hypothesis that these reactions have a heterolytic character.

In conclusion, we shall consider the relationship between the Nesmeyanov reaction and the Waters reaction. According to Waters [25], in the reduction of the double diazonium salt in the course of the Nesmeyanov reaction, free metal is formed and reacts with the arenediazonium halide by the radical mechanism, for example:

$$ArN_2Cl \cdot HgCl_2 + 2Cu \longrightarrow ArN_2Cl + Hg + CuCl_2$$

$$Ar\dot{N}_2 + Cl + \cdot Hg \cdot \longrightarrow Ar-Hg-Cl + N_2$$

This hypothesis, however, is not in accord with various facts.

1) In the decomposition of the double salt $C_6H_5N_2Cl \cdot HgCl_2$ by silver powder, phenylmercury chloride is formed [30], as in the case of decomposition by copper powder:

$$C_6H_5N_2Cl \cdot HgCl_2 + 2Ag \rightarrow C_6H_5 - HgCl + 2AgCl + N_2.$$

In this case, however, the reaction certainly cannot pass through the stage of free-mercury formation, for silver cannot displace mercury from mercuric chloride. The completely analogous decompositions of the double salts

$$(ArN_2Cl)_n \cdot SnCl_4,\ (ArN_2Cl)_n \cdot PbCl_4,\ (ArN_2Cl)_n \cdot PbCl_2 + ArN_2Cl \cdot SbCl_3$$

by copper powder cannot pass through the stage of free-metal formation, though they yield organo-tin, -lead, and -antimony compounds, respectively.

2) If the Nesmeyanov reaction passes through the stage of the formation of free metal, then its field of application should not differ from that of the Waters reaction. However, some organometallic compounds, for example those of bismuth, thallium, and lead, can be prepared only by the first reaction.

3) Finally, the reactions covered by the hypothesis of the intermediate formation of free metal do not include decomposition by metal powders of double salts of the type

$$ArSbCl_4 \cdot ArN_2Cl,\ Ar_2SbCl \cdot ArN_2Cl,\ ArSbCl_4 \cdot ArN_2Cl \rightleftarrows Ar_2SbCl_3 \cdot ArN_2Cl,$$

which results in the formation of new carbon-metal linkages. The intermediate formation of free metal is here excluded entirely, although these reactions are completely analogous, with respect to character and conditions, to the decomposition reactions of double salts of the type $ArN_2Cl \cdot MeCl)_n$.

On the other hand, if we assume that the Waters reaction proceeds, completely or predominantly, through the stage of intermediate formation of double diazonium salts of the metal chlorides:

$$n\,ArN_2Cl + Me \rightarrow n\,Ar\cdot + n\,N_2 + MeCl_n$$

$$ArN_2Cl + MeCl_n \rightarrow ArN_2^+ [MeCl_{n+1}]^-$$
$$\downarrow Me$$
$$Ar - MeCl_{n-1}$$

then the characteristic features of the two reactions (Nesmeyanov and Waters) – which have hitherto been obscure – can be readily understood.

1) It becomes clear why the formation of $ArHgCl$ from ArN_2Cl and Hg will proceed, as McClure and Lowry showed [31], in an aqueous medium, whereas organoantimony and organoarsenic compounds are not formed under these conditions. The reason for this lies in the fact that the $SbCl_3$ and $AsCl_3$ formed by reaction of ArN_2Cl with Sb and As, respectively, are hydrolyzed by water and cannot give the double diazonium salts $ArN_2Cl \cdot SbCl_3$ and $ArN_2Cl \cdot AsCl_3$. In the reaction of ArN_2Cl with mercury, however, the mercuric chloride formed is not hydrolyzed and can give the double salt $ArN_2Cl \cdot HgCl_2$. As it is known that the reaction

$$ArN_2Cl \cdot HgCl_2 + Cu \rightarrow Ar - HgCl + N_2 + CuCl_2$$

can occur in an aqueous medium [32], it is natural to suppose that the decomposition of $ArN_2Cl \cdot HgCl_2$ by finely divided mercury in an aqueous medium will also lead to the formation of ArHgCl:

$$ArN_2Cl \cdot HgCl_2 \xrightarrow[(H_2O)]{Hg} Ar-HgCl$$

Experiments carried out in collaboration with Yu. G. Bundel confirm this view.*

2) One can imagine why the Waters reaction, unlike the Nesmeyanov reaction, does not give organic compounds of bismuth and thallium. The cause probably lies in the fact that the reaction of ArN_2Cl does not go in the cold. At a raised temperature the equilibrium

$$ArN_2Cl \cdot MeCl_3 \rightleftarrows ArN_2Cl + MeCl_3,$$

may be greatly displaced to the right, and the metal will bring about not the decomposition of the double diazonium salt, but the decomposition of the free arenediazonium halide, which does not yield an organometallic compound in the case of these metals.

It is not surprising also that, although ArN_2Cl reacts slowly with Pb in the cold, organolead compounds are not formed in the cold by the Waters reaction, for only very slight yields of organolead compounds are obtained from the double salts $(C_6H_5N_2Cl)_2 \cdot PbCl_2$ and $C_6H_5N_2Cl \cdot PbCl_2$ by the Nesmeyanov reaction.

3) When double diazonium salts of zinc chloride are used instead of free diazonium salts for the synthesis of organoantimony compounds [33], the reaction appears to go according to the scheme:

a) $3(C_6H_5N_2Cl)_2 \cdot ZnCl_2 \xrightarrow{2Sb} 2SbCl_3 + 6C_6H_5\cdot + 3N_2 + 3ZnCl_2$,

b) $(C_6H_5N_2Cl)_2 \cdot ZnCl_2 + 2SbCl_3 \rightleftarrows 2C_6H_5N_2Cl \cdot SbCl_3 + ZnCl_2$,

c) $C_6H_5N_2Cl \cdot SbCl_3 \xrightarrow{Sb}$ organoantimony compounds.

If the formation of organoantimony compounds by the action of antimony on the double diazonium salt of zinc chloride does proceed through the intermediate formation of the double diazonium salt of antimony trichloride $C_6H_5N_2Cl \cdot SbCl_3$, then it is clear that the decomposition of $C_6H_5N_2Cl \cdot SbCl_3$ by antimony under the same conditions should give a higher yield of organoantimony compounds.

Makin and Waters [33] state that in the decomposition of $(C_6H_5N_2Cl)_2 \cdot ZnCl_2$ organoantimony compounds are formed in 26% yield (on the amount of amine taken), whereas in the decomposition of $C_6H_5N_2Cl \cdot SbCl_3$ the yield is only 11%. These results are in conflict with our hypothesis. A repetition of Makin and Waters' experiments showed, however, that they separated only a part of the organoantimony compounds formed in the reaction (namely, triarylantimony dichloride) and therefore gave values that did not correspond to the total yield of organoantimony compounds. Actually, $(C_6H_5N_2Cl)_2 \cdot ZnCl_2$ gives organoantimony compounds in 36% yield, and $C_6H_5N_2Cl \cdot SbCl_3$ gives them in 46% yield.

These results are in accord with the above reaction scheme. It can be understood also why the addition of excess of zinc chloride to the reaction mixture in our experiments was found to reduce the yield of organoantimony compounds.

Returning to the Nesmeyanov reaction, we may point out that the dissociation of the double diazonium salt

$$ArN_2Cl \cdot MeCl_n \rightleftarrows ArN_2Cl + MeCl_n$$

* McClure and Lowry's reaction can be represented as a chain reaction, as follows:

$$2ArN_2Cl + Hg \rightarrow HgCl_2 + 2Ar\cdot + 2N_2;$$
$$ArN_2Cl + HgCl_2 \rightarrow ArN_2Cl \cdot HgCl_2;$$
$$ArN_2Cl \cdot HgCl_2 + Hg \rightarrow Ar-HgCl + N_2 + HgCl_2 \text{ etc.}$$

with formation of free arenediazonium chloride – which increases with rise in temperature – should lower the yield of organometallic compound. It is clear, therefore, why the optimum conditions for most Nesmeyanov reactions are obtained when the decomposition of the double salt is carried out under cooling. An exception is found in the synthesis of organoantimony compounds, which is carried out at about 75° (the total yield of organoantimony compounds attains 80%), but in the decomposition of $ArN_2Cl \cdot SbCl_3$ at 0° with iron powder, still higher yields of organoantimony compounds are obtained [21]. As a substituent of the second kind increases the degree of dissociation of double diazonium salts $XC_6H_4N_2Cl \cdot MeCl_n$, the synthesis of organomercury compounds $XC_6H_4 - HgCl$ (in which X = NO_2, SO_3H, COOH, etc.) requires the use of cooling to a temperature of from −10° to −70° [4] in order to depress this dissociation.

Finally, it must be pointed out that the view that the Waters reaction proceeds through the stage of the formation of double diazonium salts can apply only to metals (Hg, Sb, Sn, etc.). For nonmetals (S, Se, Te), whose chlorides do not give stable double salts with arenediazonium chlorides, the mechanism of reaction with ArN_2Cl will doubtless be different, namely the radical mechanism. There must also be some borderline elements, which can form heteroorganic compounds with ArN_2Cl reacting via two different routes simultaneously: a) by the free-radical reaction of ArN_2Cl with the element, E, and b) by the heterolytic reaction of the element E with intermediate formation of the salt $ArN_2Cl \cdot ECl_n$. It is possible that an example of such a borderline element may be arsenic, whose chloride gives only unstable double salts with ArN_2Cl.

SUMMARY

1. The decomposition of double salts of diazonium and metal chlorides by means of metal powders with formation of organometallic compounds (the Nesmeyanov reaction) is heterolytic in character.

2. The synthesis of organometallic compounds by reaction of arenediazonium chlorides with metal powders (the Waters reaction) proceeds through intermediate formation of a double salt of diazonium and metal chlorides.

STEREOCHEMISTRY OF CYCLIC COMPOUNDS

COMMUNICATION 12. STEREOCHEMISTRY OF LACTONES OF 1,2,3,5,6,7,8,8a-OCTAHYDRO-1,2-NAPHTHALENEDICARBOXYLIC ACIDS

I. N. Nazarov, V. F. Kucherov and V. M. Andreev

It has already been established [1] that the lactonization of unsaturated cyclic o-dicarboxylic acids is greatly dependent on the steric configuration of these compounds and that the reaction is of great interest for the study of the stereochemistry of cyclic compounds. We have therefore made a detailed study of the lactonization of the four isomeric 1,2,3,5,6,7,8,8a-octahydro-1,2-naphthalenedicarboxylic acids (I), (X), (XIII), and (XIX) described in previous papers [2]. As we had the isomeric monoesters corresponding to the acids (I) and (XIII) at our disposal, we were able not only to prove the structures of the lactones formed, but also to establish their precise steric configurations.

It was found that, under the action of hydrogen chloride in glacial acetic acids, the syn-cis dicarboxylic acid (I) was readily converted in good yield into the previously described [3] syn-cis γ-lactone acid (II). With diazomethane this gave the crystalline syn-cis γ-lactone ester (III), which can be readily prepared also by the lactonization of the syn-cis monoester (IV) with a free carboxyl at C-1.

These data prove without doubt that only the carboxyl at C-1 takes part in the formation of a lactone from the syn-cis acid (I), so that the syn-cis γ-lactone acid (II) obtained must have a γ-lactone structure. The syn-cis γ-lactone ester (III), in which the carboxyl at C-2 is disposed equatorially, was found to be incapable of undergoing isomerization with sodium methoxide; under these conditions it is merely hydrolyzed into the original syn-cis γ-lactone acid (II).

As was to be expected, the isomeric syn-cis monoester (V) having an esterified carboxyl at C-1 was found to be quite incapable of undergoing lactonization; when treated with hydrogen chloride in acetic acid, it was merely isomerized with displacement of the double bond into the intercycle position, as we have noted previously in other similar cases [1]. The new monoester (VI) formed in this way gives the diester (VII) with diazomethane and can be hydrolyzed to the cis-dicarboxylic acid (VIII), which is converted into the cis anhydride (IX) when boiled with acetyl chloride. The fact that the cis acid (VIII) is not hydrogenated in presence of a platinum catalyst under normal conditions shows that it has the structure 1,2,3,4,5,6,7,8-octahydro-1,2-naphthalenedicarboxylic acid, the double bond being between the rings.

In the above scheme (e) denotes an equatorial disposition of the substituent, and (p) denotes a polar disposition.

The spatial configuration of syn-cis acid (I) is such that the only carboxyl that can take part in lactonization is the polar carboxyl at C-1, which is directed toward the double bond; the product is the syn-cis γ-lactone acid (II), in which the equatorial position of the carboxyl at C-2 is preserved, so that the corresponding syn-cis γ-lactone ester (III) is incapable of isomerization under the influence of sodium methoxide. For the same reason, the isomeric syn-cis monoester (V) having an esterified carboxyl at C-1 cannot undergo lactonization, with the result that the double bond is displaced into the intercycle position with formation of the dicarboxylic acid (VIII). Owing to its flatter structure, this substance is also incapable of lactonization, the carboxyls being considerably removed from the intercycle double bond.

In accordance with the molecular models, the syn-trans acid (X) having a diequatorial (e–e) arrangement of carboxyls is more difficult to lactonize than the isomeric syn-cis acid (I): it gives the syn-trans γ-lactone acid (XI) having a polar carboxyl at C-2 in a yield of only about 40%. As the models show, the lactonization of the syn-trans acid (X) can again occur only at the 1-carboxyl, but in this case the reaction is accompanied by

bending of the cyclohexane ring and corresponds to the lactonization of the unstable form of the syn-trans acid (Xa) having a dipolar (p− p) arrangement of carboxyls. It is very probable that it is this fact that explains the difficult lactonization of the syn-trans acid (X) referred to above .

Under the action of diazomethane the syn-trans γ-lactone acid (XI) gives the corresponding lactone ester (XII) having a polar disposition of the methoxycarbonyl group at C-2 so that it is readily isomerized by sodium methoxide into the above-described syn-cis γ-lactone acid (II).

All these results, which support the γ-lactone structure of the syn-cis and syn-trans γ-lactone acids (II) and (XI), were confirmed by infrared-spectrum measurements. The spectra of the γ-lactone esters (III) and (XII), determined in carbon tetrachloride solution, both contained the same two carboxyl bands at 1740 and 1780 cm^{-1}. The first of these bands corresponds to the presence of a free carboxyl, whereas the band at 1780 cm^{-1} indicates that the γ-lactone esters (III) and (XII) contain a γ-lactone ring that is somewhat more highly strained than in simple γ-lactones [4].

Quite different behavior was found in the lactonization of the isomeric anti-cis and anti-trans 1,2,3,5,6,7,8,8a-octahydro-1,2-naphthalenedicarboxylic acids (XIII) and (XIX). It was found that treatment of the anti-cis acid (XIII) with hydrogen chloride in glacial acetic acid resulted in the formation of a mixture of equal amounts of the anti-cis δ-lactone acid (XIV) and the chlorine-containing dicarboxylic acid (XV), which were readily separated by crystallization.

The chloro dicarboxylic acid (XV), which corresponded in composition to the product of the addition of hydrogen chloride at the double bond, contained mobile chlorine at C-4a: when boiled with water it readily gave the lactone acid (XIV). When hydrolyzed with 5% caustic soda solution, the chloro dicarboxylic acid (XV) was converted in good yield into the above-described unsaturated dicarboxylic acid (VIII) having an intercycle double bond (prepared from the syn-cis monoester (V)). The formation of one and the same dicarboxylic acid (VIII) from the isomeric syn-cis and anti-cis acids (I) and (XIII) confirms previous results [2] showing that these acids are epimers with respect to hydrogen at C-8a, for only in this case can the elimination of a common center of asymmetry lead to a single 1,2,3,4,5,6,7,8-octahydro-1,2-naphthalenedicarboxylic acid (VIII).

On the basis of a study of the chemical reactions of the anti-cis monoester (XVII) and of an examination of the molecular model of the anti-cis acid (XIII) it was found possible to resolve the question of the structure of the anti-cis δ-lactone acid (XIV). It was found that treatment of the monoester (XVII) with hydrogen chloride in glacial acetic acid did not give the possible lactone ester, but gave a good yield of pure anti-cis δ-lactone acid (XIV), converted by diazomethane into the anti-cis δ-lactone ester (XVI), which is not isomerized by sodium methoxide. This shows that, as in the case of the acids (I) and (Xa), in the lactonization of the anti-cis acid (XIII) the polar carboxyl (at C-2) takes part, so that the lactone acid (XIV) must have a δ-lactone ring.

These results are fully in accord with the molecular model of the anti-cis acid (XIII).

As can be seen from the model, in the anti-cis acid (XIII) the equatorial disposition of the carboxyl at C-1 excludes the formation of a γ-lactone, and lactonization can proceed only at the polar carboxyl at C-2 with formation of the anti-cis δ-lactone acid (XIV). In accordance with this, the lactone ester (XVI) has an equatorial methoxycarbonyl group at C-1 and should not therefore be isomerized by sodium methoxide, but the lactonization of the monoester (XVII) should proceed with formation of the lactone acid (XIV) owing to the ready acidolysis of the ester group at C-2.

All these results concerning the δ-lactone structure of the anti-cis lactone acid (XIV) are in accord with facts that we have previously established with regard to the lactonization of anti-cis-1,2,3,5,6,7,8,8a-octahydro-1-methyl-1,2-naphthalenedicarboxylic acid [1] and were confirmed by a study of the infrared spectrum of the anti-cis δ-lactone ester (XVI). It was found that this lactone ester has a carbonyl absorption band at 1765 cm^{-1} characteristic for δ-lactones; it differs greatly from the absorption band of the γ-lactone esters (III) and (XII). The fact that this band is appreciably displaced toward the shorter waves as compared with simple δ-lactones [4] can be explained by the presence of appreciable strain in the bicyclic δ-lactone acid (XIV), which results in a highly distorted chair form for the B ring.

As indicated by molecular models, the anti-trans acid (XIX) should not be capable of lactonization, owing to the diequatorial (e–e) arrangement of carboxyls. This was confirmed experimentally, for it was found that, when heated with hydrogen chloride in acetic acid, this acid was recovered unchanged in almost quantitative yield.

EXPERIMENTAL

syn-cis γ-Lactone Acid (II)

To 30 ml of a saturated solution of dry hydrogen chloride in glacial acetic acid, 2.7 g of the syn-cis dicarboxylic acid (I), m.p. 172° [2], was added, and the mixture was heated at 60° for one hour. Acetic acid was distilled off under reduced pressure, and the crystalline residue was washed on the filter with ether. Crystallization from 10% aqueous acetone gave 2.2 g of the syn-cis γ-lactone acid (II), m.p. 175-176°, which gave a phenacyl ester of m.p. 132-133° (from 60% alcohol). A lactone acid having the same constants was obtained earlier by Cook and Lawrence [3] by hydrolysis of the maleic anhydride adduct of vinylcyclohexene.

syn-cis γ-Lactone Ester (III)

a) A suspension of 2 g of the syn-cis γ-lactone acid (II) in ether was treated with ethereal diazomethane, ether was distilled off, and the crystalline product was washed on the filter with a mixture of diethyl ether and petroleum ether (1 : 1). The product, amounting to 1.9 g was the syn-cis γ-lactone ester (III), m.p. 82-84°, which melted constantly at 87-88° after crystallization from ether.

Found %: C 65.39, 65.31; H 7.56, 7.49. $C_{13}H_{18}O_4$. Calculated %: C 65.52; H 7.53.

b) To 5 ml of a solution of hydrogen chloride in glacial acetic acid, 0.5 g of the syn-cis monoester (IV), m.p. 139° [2], was added, and the mixture was heated at 60° for one hour. The residue remaining after removal of solvent was crystallized by treatment with petroleum ether. Recrystallization from diethyl ether gave 0.35 g of the syn-cis γ-lactone ester (III), m.p. 87-88°, undepressed by admixture of the sample prepared as above. When this lactone ester was boiled with excess of sodium methoxide, the original syn-cis γ-lactone acid (II) was recovered almost completely.

cis Monoester (VI)

A mixture of 7.5 g of the syn-cis monoester (V), m.p. 126° [2], and 75 ml of a saturated solution of dry hydrogen chloride in glacial acetic acid was heated at 60° for one hour. Acetic acid was distilled off, and the residue crystallized when vacuum-distilled with benzene and petroleum ether. The product, amounting to 5.4 g was the cis monoester (VI), m.p. 113-116°, raised to 116-117° by recrystallization from a mixture of diethyl ether and petroleum ether.

Found %: C 65.69, 65.80; H 7.84, 7.73. $C_{13}H_{18}O_4$. Calculated %: C 65.51; H 7.53.

cis-Dicarboxylic Acid (VIII)

A mixture of 2.2 g of the cis monoester (VI) and 30 ml of 20% aqueous caustic soda solution was boiled for three hours, filtered, and acidified. The crystalline product was washed on the filter with a little acetone, and 1.9 g of an acid, m.p. 188-190°, was obtained. After crystallization from acetone the pure cis-dicarboxylic acid (VIII) melts at 195-196°, and admixture with the anti-cis δ-lactone acid (XIV) and with the anti-trans dicarboxylic acid (XIX) results in great depression of the melting point.

Found %: C 64.25, 64.20; H 7.27, 7.23. $C_{12}H_{16}O_4$. Calculated %: C 67.27; H 7.19.

Found: M 217.9 (by titration with NaOH)
Calculated: M 224.3.

The acid (VIII) was converted by the usual method into the diphenacyl ester, which melted at 98-99° after crystallization from 85% alcohol.

Found %: C 73.28, 73.23; H 6.24, 6.21. $C_{28}H_{24}O_6$. Calculated %: C 73.02; H 6.13.

cis Anhydride (IX)

A solution of 0.5 g of the cis acid (VIII) in 10 ml of acetyl chloride was boiled for two hours, and volatile substances were then distilled off under reduced pressure. The liquid residue gradually crystallized when allowed to stand with petroleum ether. The product, 0.35 g of cis anhydride (IX), melted constantly at 57-58° after recrystallization from petroleum ether.

Found %: C 69.87, 69.89; H 6.92, 6.88. $C_{12}H_{14}O_3$. Calculated %: C 69.88; H 6.84.

cis Diester (VII)

The cis monoester (VI) (1.5 g) was treated with ethereal diazomethane. Distillation gave 1.4 g of the cis diester (VII), b.p. 128-129° (2 mm); n_D^{20} 1.4992; d_4^{20} 1.1396; found MR 65.02; calculated MR 65.29.

Found %: C 66.65, 66.63; H 8.06, 7.89; $C_{14}H_{20}O_4$. Calculated %: C 66.65; H 7.99.

The same cis diester (VII) (n_D^{20} 1.4985) was obtained also by the action of diazomethane on the cis-dicarboxylic acid (VIII).

syn-trans γ-Lactone Acid (XI)

A mixture of 2 g of the syn-trans dicarboxylic acid (X) and 30 ml of glacial acetic acid saturated with dry hydrogen chloride was heated at 60° for one hour. Acetic acid was distilled off, and the liquid residue was dissolved in a small amount of ether and set aside at 0° overnight. The product, amounting to 0.7 g, was the syn-trans γ-lactone acid (XI), m.p. 167-169°, raised to a constant value of 170-171° by recrystallization from water containing a little acetone. The melting point was greatly depressed by admixture of the syn-cis dicarboxylic acid (II).

Found %: C 64.20, 64.14; H 7.28, 7.19. $C_{12}H_{16}O_4$. Calculated %: C 64.27; H 7.19.

Found: M 214.9 (by titration with NaOH)
Calculated: M 224.3.

The lactone acid (XI) was converted by the usual method into the phenacyl ester, which melted at 127-128° after crystallization from 70% ethanol.

Found %: C 70.30, 70.33; H 6.74, 6.59. $C_{20}H_{22}O_5$. Calculated %: C 70.16; H 6.48.

syn-trans γ-Lactone Ester (XII)

A solution of 0.8 g of the syn-trans γ-lactone acid (XV) in ether was treated with excess of diazomethane. Ether was distilled off, and the crystalline product (0.77 g) was recrystallized from petroleum ether. The product, amounting to 0.65 g, was the syn-trans γ-lactone ester (XII), m.p. 98-99°.

Found %: C 65.54, 65.47; H 7.61, 7.64. $C_{13}H_{18}O_4$. Calculated %: C 65.52; H 7.53.

Isomerization of the syn-trans γ-Lactone Ester (XII)

The syn-trans γ-lactone ester (XII) (0.6 g) was added to a solution of 1.4 g of sodium in 50 ml of absolute methanol, and the mixture was boiled for 15 hours. Methanol was distilled off under reduced pressure and the residue was dissolved in 10 ml of water. The solution was filtered, boiled for two hours, and acidified with hydrochloric acid. The oil that separated (0.5 g) gradually solidified, and was found to melt at 145-155°. Two recrystallizations from 20% aqueous acetone gave 0.3 g of the syn-cis γ-lactone acid (II), m.p. 173-174°, undepressed by admixture with the sample described above.

Lactonization of the anti-cis Dicarboxylic Acid (XIII)

A solution of 4 g of the anti-cis dicarboxylic acid (XIII) in 40 ml of acetic acid saturated with dry hydrogen chloride was heated at 60° for one hour. Acetic acid was distilled off under reduced pressure, the residue was dissolved in 35 ml of ether, and the solution was set aside overnight. The crystals that separated were filtered off and washed with ether. The product, amounting to 1.8 g, was the anti-cis δ-lactone acid (XIV), m.p. 191-193°, raised to a constant value of 195-196° by recrystallization from a mixture of acetone and ether. Admixture with the cis-dicarboxylic acid (VIII) and with the anti-trans dicarboxylic acid (XIX) resulted in great depression of the melting point.

Found %: C 64.50, 64.34; H 7.37, 7.33. $C_{12}H_{16}O_4$. Calculated %: C 64.27; H 7.19.

Found: M 222.4 (by titration with NaOH)
Calculated: M 224.3.

The phenacyl ester of the lactone acid (XIV) melted at 106-107° after crystallization from 70% ethanol.

Found %: C 70.36, 70.50; H 6.74, 6.64. $C_{20}H_{22}O_5$. Calculated %: C 70.16; H 6.48.

The ethereal solution obtained after the isolation of the lactone acid (XIV) was evaporated, and the liquid residue crystallized out completely when treated with petroleum ether. Two recrystallizations from a mixture of diethyl ether and petroleum ether gave 1.4 g of the pure chloro dicarboxylic acid (XV), melting with decomposition at 165-166°.

Found %: C 55.16, 55.21; H 6.54, 6.65; Cl 13.80, 14.04. $C_{12}H_{11}O_6Cl$. Calculated %: C 55.27; H 6.52; Cl 13.60.

Reactions of the Chloro Dicarboxylic Acid (XV)

a) A solution prepared by dissolving 0.6 g of the chloro acid (XV) in 7 ml of 5% caustic soda solution was boiled until a crystalline precipitate began to form (10 minutes). The crystalline product obtained after acidification (0.4 g) melted at 177-185°. Crystallization from 40% aqueous acetone gave 0.3 g of the cis-dicarboxylic acid (VIII), which melted with decomposition at 194-195°, no depression being shown by admixture of the above-described samples.

b) A mixture of 0.4 g of the chloro acid (XV) and 5 ml of water was boiled for 30 minutes, in the course of which the solution became acid to Congo red. On cooling, an oil separated and rapidly solidified. Washing with 30% aqueous acetone gave 0.25 g of crystals, m.p. 175-185°. One crystallization from acetone-ether mixture gave 0.2 g of the anti-cis δ-lactone acid (XIV), m.p. 193-195°, undepressed by the above-described sample but greatly depressed by admixture with the cis-dicarboxylic acid (VIII) (the mixture melted at 160-170°).

anti-cis δ-Lactone Ester (XVI)

A suspension of 0.5 g of the anti-cis δ-lactone acid (XIV) in ether was treated with excess of diazomethane, and the ether was distilled off. The crystalline product was washed on the filter with a mixture of diethyl ether and petroleum ether (1 : 1). The product, amounting to 0.5 g, was the anti-cis δ-lactone ester (XVI), which had a constant melting point of 85-86° after recrystallization from ether and showed a great depression in admixture with the syn-cis δ-lactone ester (III).

Found %: C 65.56, 65.60; H 7.50, 7.55. $C_{13}H_{16}O_4$. Calculated %: C 65.52; H 7.53.

When an attempt was made to isomerize this lactone ester by boiling it with excess of sodium methoxide, the usual treatment gave only the original anti-cis δ-lactone acid (XIV).

Lactonization of the anti-cis Monoester (XVII)

A solution of 1.5 g of the anti-cis monoester (XVII), m.p. 137° [2], in 20 ml of glacial acetic acid saturated with dry hydrogen chloride was heated at 60° for two hours, and acetic acid was distilled off under reduced pressure. The liquid residue partially crystallized out when distilled with petroleum ether. The crystalline product was filtered off and washed with ether. The product, amounting to 0.7 g, was the anti-cis δ-lactone acid (XIV), m.p. 193-194°, undepressed by admixture of the sample prepared previously.

Reaction of the anti-cis Monoester (XVIII) with Hydrogen Chloride in Acetic Acid

A solution of 2 g of the liquid anti-cis monoester (XVIII) [2] in 20 ml of glacial acetic acid saturated with hydrogen chloride was heated at 60° for one hour, and acetic acid was distilled off under reduced pressure. The liquid chlorine-containing reaction product that remained did not crystallize when treated with various solvents and subjected to freezing treatments. As the original anti-cis monoester (XVIII) was not pure and the lactonization reaction was accompanied by the formation of a hydrogen chloride addition product, we did not succeed in isolating the expected anti-cis monoester (XVI). The mixture was hydrolyzed at the boil with 15 ml of 20% aqueous caustic potash. Acidification gave an oil, which crystallized out partly on standing. From this only 0.8 g of the cis-dicarboxylic acid (VIII), m.p. 194-195° with decomposition, could be isolated; it was identical with samples prepared previously (above).

Lactonization of the anti-trans Dicarboxylic Acid (XIX)

A solution of 2 g of the anti-trans dicarboxylic acid (XIX), m.p. 195° [2], in 20 ml of acetic acid saturated with hydrogen chloride was heated at 60° for three hours. Acetic acid was distilled off under reduced pressure, and a crystalline residue remained. Washing on the filter with a little ether gave 1.85 g of

pure original anti-trans dicarboxylic acid (XIX), m.p. 195-196°, greatly depressed by admixture with the anti-cis δ-lactone acid (XIV) and with the cis-dicarboxylic acid (VIII).

SUMMARY

1. A study was made of the dependence of the lactonization reaction on steric structure for all four isomeric 1,2,3,5,6,7,8,8a-octahydro-1,2-naphthalenedicarboxylic acids (I), (X), (XIII), and (XIX).

2. It was shown that the syn-cis dicarboxylic acid (I) and the syn-trans dicarboxylic acid (X) are lactonized to the corresponding isomeric γ-lactone acids (II) and (XI), which contain γ-lactone rings. The acid (X) is lactonized considerably less readily than the isomeric acid (II).

3. Lactonization of the anti-cis dicarboxylic acid (XIII) proceeds with difficulty and gives a mixture of the chloro dicarboxylic acid (XV) and the anti-cis δ-lactone (XIV), the structure of which, as a δ-lactone acid, was confirmed by various chemical reactions and by the infrared spectrum. The anti-trans dicarboxylic acid (XIX) was found to be quite incapable of lactonization.

4. It was shown that, as a result of double-bond displacement, the isomeric syn-cis and anti-cis dicarboxylic acids (I) and (XIII) give the same cis-dicarboxylic acid (VIII), which has an intercycle double bond, this being further confirmation of our previous results on the configurations of the acids (I) and (XIII) as epimers with respect to hydrogen at C-8a.

5. The stereochemical peculiarities of the lactonization of the isomeric, 1,2,3,5,6,7,8,8a-octahydro-1,2-naphthalenedicarboxylic acids as a function of their spatial configurations were examined and explained with the aid of molecular models.

ACETYLENE DERIVATIVES

COMMUNICATION 174. CONDENSATION OF ALDEHYDES AND KETONES WITH ACETYLENE UNDER PRESSURE. II

I. N. Nazarov, I. L. Kotlyarevsky and V. F. Ryabchenko

In the preceding communication [1] we described a new method for the synthesis of acetylenic alcohols by the condensation of aldehydes and ketones with acetylene under pressure in presence of caustic potash powder. An important advantage of this method lies in the fact that increase in the pressure of acetylene greatly increases the rate at which it condenses with carbonyl compounds, and it is therefore possible to bring about this reaction rapidly with various aldehydes and ketones and obtain high yields of the corresponding acetylenic alcohols. Under a pressure of 5-10 atm acetylene readily condenses with almost all aliphatic, alicyclic, heterocyclic, aliphatic-aromatic, and aromatic ketones with formation of the corresponding tertiary acetylenic alcohols (I) in 80-95% yield:

(I)

The condensation of acetone, cyclohexanone, and some other simple aliphatic, alicyclic, and heterocyclic ketones with acetylene at a pressure of 5-10 atm in presence of one equivalent of caustic potash is practically complete within 30 minutes of the introduction of the reactants, and the corresponding tertiary acetylenic alcohols are obtained in almost theoretical yields. Higher aliphatic and branched ketones condense more slowly with acetylene and for completion of reaction the reaction mixture must be agitated for 1-3 hours after the introduction of the reactants; tertiary acetylenic alcohols are again obtained in yields of about 90%. Under pressure, acetylene condenses readily also with such alkali-sensitive ketones as cyclopentanone and tetrahydro-2,2-dimethylpyran-4-one, with formation of the corresponding acetylenic alcohols (II) and (III) in yields of about 80%, whereas in absence of pressure these alcohols are obtained in yields of only about 30% [2].

(II) (III)

Aliphatic-aromatic and aromatic ketones, such as acetophenone and benzophenone, condense still more slowly with acetylene, and to carry out this reaction successfully it is necessary to take 2-3 equivalents of caustic potash in order to raise the concentration of potassium acetylide in the reaction mixture. Under these conditions the yields of the corresponding acetylenic alcohols are again above 90%.

An interesting observation was made in the study of the condensation of acetylene with 1,2,5-trimethyl-4-piperidone. When the acetylene pressure is 1 atm, a 5 : 1 mixture of the α- and β-forms of 4-ethynyl-1,2,5-trimethyl-4-piperidinol (IV) is obtained in an overall yield of 90% [3], whereas at an acetylene pressure of 15 atm the α- and β-forms are obtained in the inverse ratio of 1 : 5.

(IV)

α-form, m.p. 110-111°
β-form, m.p. 177-178°

It is known that α,β-unsaturated aldehydes and ketones are quite unable to condense with acetylene under the usual conditions and that this reaction proceeds satisfactorily only in liquid ammonia or by the use of ethynylmagnesium halides. By the application of pressure (8 atm) we succeeded in effecting the condensation of acetylene with mesityl oxide with formation of the corresponding acetylenic alcohol (V) in 13% yield:

(V)

Condensation of acetylene with crotonaldehyde under similar conditions gave the acetylenic alcohol (4-hexen-1-yn-3-ol) in a yield of only 1.2%. However, with higher saturated aldehydes, beginning from propionaldehyde, condensation with acetylene under pressue (8-10 atm) proceeds quite satisfactorily with formation of secondary acetylenic alcohols (VI) in 70% yield:

(VI)

In the condensation of acetylene with acetaldehyde, even under a pressure of 20 atm, 3-butyn-2-ol could not be obtained in yields of greater than 40%, which is to be explained by the high sensitivity of acetaldehyde to alkali and its resinification. For the same reason it was found to be quite impossible to effect the condensation of acetylene with formaldehyde (paraform) in presence of caustic potash. It is known that, in presence of caustic potash powder under the usual conditions (without pressure), aldehydes condense very feebly with acetylene and the method is unsuitable for the preparation of secondary acetylenic alcohols.

Acetylene under pressure condenses readily also with hydroxy ketones (5-hydroxy-2-pentanone, 3-hydroxy-3-methyl-2-butanone) with formation of the corresponding acetylenic glycols (VII) and (VIII) in yields of about 80%, whereas under the usual conditions (without pressure) the glycol (VIII) is obtained in a yield of only about 20%.

In the previous communication it was pointed out that the yield of acetylenic alcohols obtained in the condensation of acetylene with aldehydes and ketones in presence of caustic potash is considerably increased (by 10-15%)

if a little alcohol (0.5-1%; ethyl, butyl, and others) is added to the solvent. This effect is probably to be explained by the action of the aliphatic alcohol as a carrier of potassium ions in the reaction mixture, so that the formation of potassium acetylide is facilitated; its mode of action can be seen from the following equations:

$$CH\equiv CH + KOH \rightleftarrows CH\equiv CK + H_2O$$

$$>CO + CH\equiv CK \rightarrow >C(OK)-C\equiv CH$$

$$>C(OK)-C\equiv CH + ROH \rightleftarrows >C(OH)-C\equiv CH + ROK$$

$$CH\equiv CH + ROK \rightleftarrows CH\equiv CK + ROH \text{ etc.}$$

This also explains the fact that, when less than one equivalent of potassium hydroxide is used in the reaction, the yield of acetylenic alcohol is always higher than would be expected from the simple stoichiometric equation. Thus, in the condensation of acetone with acetylene at 5 atm and 20° in the presence of 8% of ethanol on the weight of acetone and with the use of 1.0, 0.75, and 0.25 equivalent of caustic potash, the respective yields of 2-methyl-3-butyn-2-ol were 92, 80, 71, and 53%. Hence, addition of aliphatic alcohols to the reaction mixture permits the partial regeneration of potassium ions and so increases the yield of acetylenic alcohols.

The described condensation of aldehydes and ketones with acetylene under pressure is the simplest and most general method for the synthesis of the most varied acetylenic alcohols.

EXPERIMENTAL

All the condensations of aldehydes and ketones with acetylene under pressure were carried out in the one-liter and six-liter steel reactors described in the preceding communication [1]. After introduction of solvent and potassium hydroxide powder, air was displaced from the reactor by flushing twice with nitrogen at 5 atm. The stirrer was switched on (400-500 r.p.m.) and acetylene was introduced at the required pressure and temperature. The aldehyde or ketone was then added at a uniform rate through a steel dropping funnel with the aid of a liquid pump. Acetylene was maintained at the required pressure throughout the reaction. After the introduction of the aldehyde or ketone the reaction mixture was stirred for the required time and then treated with water in an amount equal to or double that of the alkali. The upper layer was separated, neutralized with carbon dioxide, dried, and fractionated through a 25-plate column. As solvent in this reaction not only diethyl ether can be used, but also other ethers (including ethers of ethylene glycol), acetals, and various hydrocarbons.

Condensation of Acetylene with Butyraldehyde. A mixture of 50 g of potassium hydroxide powder, 350 ml of ether, and 3 ml of ethanol was saturated with acetylene at 10° and 10 atm. In the course of 55 minutes 65 g of butyraldehyde (b.p. 75-76°) was introduced into the reactor. The reaction mixture was then stirred further for 60 minutes, after which the pressure of acetylene was released and 100 ml of water was introduced into the reactor. The product was extracted with ether, neutralized with carbon dioxide, dried with potassium carbonate, and fractionated. A yield of 64.2 g (72%) of pure 1-hexyn-3-ol (VI: R = n-C_3H_7), b.p. 142-143° and n_D^{20} 1.4350 [4], was obtained.

Condensation of Acetylene with Isobutyraldehyde. A mixture of 760 g of potassium hydroxide powder, 3500 ml of ether, and 30 ml of ethanol was saturated with acetylene at 5° and 6 atm. In the course of two hours 800 g of isobutyraldehyde was introduced into the reactor, and stirring of the reaction mixture continued for a further 50 minutes. The usual treatment gave 720 g (68%) of 4-methyl-1-pentyn-3-ol (VI: R = i-C_3H_7), b.p. 133-134° and n_D^{20} 1.4353 [5].

Condensation of Acetylene with Crotonaldehyde. A mixture of 65 g of potassium hydroxide powder and 350 ml of ether was saturated with acetylene at 0° and 8 atm. In the course of 55 minutes 70 g of crotonaldehyde was introduced into the reactor, and stirring then continued for a further 40 minutes. The usual treatment gave 1.25 g (1.2%) of pure 4-hexen-1-yn-3-ol (VI: R = $CH_3CH{=}CH$) b.p. 57-59° (13 mm) and n_D^{15} 1.4701 [6].

Condensation of Acetylene with 2-Butanone. A mixture of 50 g of potassium hydroxide powder, 300 ml of ether, and 1 ml of ethanol was saturated with acetylene at 10° and 10 atm. In the course of 80 minutes 60 g of 2-butanone was introduced into the reactor. Stirring was then continued for a further 60 minutes. The usual treatment gave 69 g (86%) of 3-methyl-1-pentyn-3-ol (I: R = CH_3, R' = C_2H_5), b.p. 121.5° and n_D^{20} 1.4310 [7]. In

addition, 1.4 g of unchanged 2-butanone was recovered and 1.2 g of the acetylenic γ-glycol was isolated.

Condensation of Acetylene with 3-Pentanone. A mixture of 50 g of potassium hydroxide powder, 300 ml of ether, and 1 ml of ethanol was saturated with acetylene at 10° and 10 atm. In the course of 80 minutes 65 g of 3-pentanone was introduced into the reactor, and stirring was then continued for a further 60 minutes. The usual treatment gave 74 g (90%) of 3-ethyl-1-pentyn-3-ol (I: R = R' = C_2H_5), b.p. 137-138° and n_D^{20} 1.4364 [8]. Also, 2.1 g of unchanged 3-pentanone was recovered and 1.2 g of the acetylenic glycol was isolated.

Condensation of Acetylene with 3-Methyl-2-butanone. A mixture of 100 g of potassium hydroxide powder, 350 ml of ether, and 2 ml of ethanol was saturated with acetylene at 10° and 10 atm. In the course of 80 minutes 120 g of 3-methyl-2-butanone was introduced into the reactor, and stirring was then continued for a further 60 minutes. The usual treatment gave 126 g (82%) of pure 3,4-dimethyl-1-pentyn-3-ol (I: R = CH_3, R' = i-C_3H_7), b.p. 133° and n_D^{15} 1.4590 [9]. Also, 2.6 g of the acetylenic γ-glycol was isolated, and 3.2 g of unchanged 3-methyl-2-butanone was recovered.

Condensation of Acetylene with 2-Pentanone. A mixture of 50 g of potassium hydroxide powder, 300 ml of ether, and 1 ml of ethanol was saturated with acetylene at 10° and 10 atm. In the course of 80 minutes 70 g of 2-pentanone was introduced into the reactor, and stirring was then continued for a further 60 minutes. The usual treatment gave 74 g (84%) of 3-methy-1-hexyn-3-ol (I: R = CH_3, R' = n-C_3H_7), b.p. 138-140° and n_D^{20} 1.4290 [10]. Also, 1.6 g of the acetylenic γ-glycol was isolated and 2 g of unchanged 2-pentanone was recovered.

Condensation of Acetylene with 4-Heptanone. A mixture of 50 g of KOH powder, 300 ml ether and 1 ml of ethanol was saturated with acetylene at 10° and 10 atm. In the course of 80 minutes 60 g of 4-heptanone was introduced into the reactor, and stirring was then continued for a further 60 minutes. The usual treatment gave 63 g (86 %) of 3-propyl-1-hexyn-3-ol (I: R = R' = n-C_3H_7), b.p. 173° and n_D^{20} 1.4375 [11]. Also, 1.5 g of the acetylenic glycol was isolated and 1.6 g of unchanged 4-heptanone was recovered.

Condensation of Acetylene with 2,4-Dimethyl-3-pentanone. A mixture of 50 g of potassium hydroxide powder, 300 ml of ether, and 1.5 ml of ethanol was saturated with acetylene at 10° and 10 atm. In the course of 80 minutes 60 g of 2,4-dimethyl-3-pentanone (b.p. 122-124°) was introduced into the reactor, and stirring was then continued for a further three hours. The usual treatment gave 63 g (86%) of pure 3-isopropyl-4-methyl -1-pentyn-3-ol (I: R = R' = i-C_3H_7), b.p. 165° and n_D^{20} 1.4500 [12]. Also, 2.5 g of the acetylenic γ-glycol was isolated and 2 g of unchanged 2,4-dimethyl-3-pentanone was recovered. It was found that if the period of stirring following the introduction of the 2,4-dimethyl-3-pentanone was 30 or 60 minutes, the yield of the acetylenic alcohol was reduced to 64% or 75%, respectively, and at the same time much of the 2,4-dimethyl-3-pentanone was recovered unchanged. When the condensation of acetylene with 2,4-dimethyl-3-pentanone was carried out at lower pressures (4-5 atm), considerable amounts of the acetylenic γ-glycol were obtained.

Condensation of Acetylene with 2-Octanone. A mixture of 60 g of potassium hydroxide powder, 300 ml of ether, and 1 ml of ethanol was saturated with acetylene at 10° and 10 atm. In the course of 80 minutes 65 g of 2-octanone (b.p. 172-173°) was introduced into the reactor, and stirring was then continued for a further 60 minutes. The usual treatment gave 72 g (92%) of 3-methyl-1-nonyn-3-ol (I: R = CH_3, R' = C_6H_{13}), b.p. 78° (5 mm) and n_D^{20} 1.4408 [13]. In addition, 0.5 g of the acetylenic γ-glycol was obtained.

Condensation of Acetylene with 2-Undecanone. A mixture of 60 g of potassium hydroxide powder, 300 ml of ether, and 1 ml of ethanol was saturated with acetylene at 10° and 10 atm. In the course of 80 minutes 65 g of 2-undecanone (b.p. 221-223°) was introduced into the reactor and stirring was continued for a further 60 minutes. The usual treatment gave 71 g (94%) of 3-methyl-1-dodecyn-3-ol (I: R = CH_3, R' = = C_9H_{19}), b.p. 127-128° (11 mm) and n_D^{20} 1.4474 [14]. Also, 0.8 g of the acetylenic γ-glycol was isolated and 1.1 g of unchanged 2-undecanone was recovered.

Condensation of Acetylene with Mesityl Oxide. A mixture of 98 g of potassium hydroxide powder, 350 ml of ether, and 4 ml of ethanol was saturated with acetylene at −5° and 15 atm. In the course of 45 minutes 95 g of mesityl oxide (b.p. 129-131°) was introduced into the reactor, and stirring of the reaction mixture was then continued for a further two hours. The usual treatment gave 10 g (11%) of 3,5-dimethyl-4-hexen-1-yn-3-ol (V), b.p. 65-66° (17 mm) and n_D^{20} 1.4629 [15], and 58 g of unchanged mesityl oxide was recovered. The residue from the distillation amounted to 29 g. The performance of this condensation at higher pressures of acetylene (up to 25 atm) did not result in appreciable increase in the yield of the acetylenic alcohol (V).

Condensation of Acetylene with 1,2,5-Trimethyl-4-piperidone. A mixture of 75 g of potassium hydroxide powder and 350 ml of dry ether was saturated with acetylene at −8° and 15 atm. In the course of 60 minutes a solution of 100 g of 1,2,5-trimethyl-4-piperidone in 100 ml of ether was introduced into the reactor, and stirring of the reaction mixture was then continued for a further 45 minutes. Treatment as described previously [3] resulted in the isolation of 19.7 g of the low-melting α-form of 4-ethynyl-1,2,5-trimethyl-4-piperidinol (IV), m.p. 110-111°, and 81.5 g of the high-melting β-form, m.p. 177-178°. When this reaction is carried out at an acetylene pressure of 1 atm, then, as shown previously [3], the α- and β-forms of the piperidinol (IV) are formed in the inverse ratio (5 : 1).

Condensation of Acetylene with 2-Methylcyclohexanone. A mixture of 80 g of potassium hydroxide powder, 350 ml of ether, and 1 ml of ethanol was saturated with acetylene at 13° and 10 atm. In the course of 65 minutes 100 g of 2-methylcyclohexanone was introduced into the reactor, and stirring was then continued for a further 60 minutes. The usual treatment gave 111 g (96%) of 1-ethynyl-2-methylcyclohexanol, b.p. 72° (8 mm) and n_D^{20} 1.4720 [16]. Also, 2.1 g of the acetylenic γ-glycol was isolated and 2.8 g of 2-methylcyclohexanone was recovered.

Condensation of Acetylene with Tetrahydro-2,2-dimethylpyran-4-one. A mixture of 120 g of potassium hydroxide powder and 350 ml of ether was saturated with acetylene at 8° and 6 atm. In the course of 60 minutes 100 g of tetrahydro-2,2-dimethylfuran-4-one was introduced into the reactor, and stirring was then continued for a further three hours. The usual treatment gave 96 g (82%) of pure 4-ethynyltetrahydro-2,2-dimethylpyran-4-ol (III), b.p. 77° (3 mm), m.p. 87° [2], and 2.6 g of unchanged tetrahydro-2,2-dimethylfuran-4-one was recovered.

Condensation of Acetylene with cis-Octahydro-2(1H)-naphthalenone. A mixture of 81 g of potassium hydroxide powder and 350 ml of ether was saturated with acetylene at 7° and 5 atm. In the course of 50 minutes 76 g of cis-octahydro-2(1H)-naphthalenone was introduced into the reactor, and stirring was then continued for a further three hours. The usual treatment gave 84 g (94%) of cis-2-ethynyldecahydro-2-naphthol, b.p. 92-93° (3 mm) and n_D^{20} 1.5112 [17], and 1.8 g of unchanged cis-octahydro-2(1H)-naphthalenone was recovered.

Condensation of Acetylene with trans-Octahydro-1(2H)-naphthalenone. A mixture of 80 g of potassium hydroxide powder and 300 ml of ether was saturated with acetylene at 15° and 10 atm. In the course of 90 minutes 90 g of trans-octahydro-1(2H)-naphthalenone was introduced as a solution in 100 ml of ether, and stirring was then continued for a further three hours. The products were 90.5 g (90%) of trans-1-ethynyldecahydro-1-naphthol, b.p. 98-99° (2 mm) and n_D^{20} 1.5060 [18], 1.5 g of the acetylenic γ-glycol, and 4.5 g of unchanged trans-octahydro-1(2H)-naphthalenone.

Condensation of Acetylene with Cyclopentanone. A mixture of 470 g of potassium hydroxide powder, 2500 ml of ether, and 10 ml of ethanol was saturated with acetylene at 10° and 7 atm. In the course of 90 minutes 465 g of cyclopentanone was introduced into the reactor, and stirring was then continued for a further 90 minutes. The usual treatment and fractionation through a column gave 458.5 g of 1-ethynylcyclopentanol (II), b.p. 157° and m.p. 27° [19].

Condensation of Acetylene with 5-Hydroxy-2-pentanone. A mixture of 130 g of potassium hydroxide powder and 350 ml of ether was saturated with acetylene at 5° and 8 atm. In the course of 35 minutes 102 g of 5-hydroxy-2-pentanone, b.p. 102-105° (20 mm) and n_D^{15} 1.4410, was introduced into the reactor, and stirring was then continued for a further two hours. The usual treatment and fractionation gave 65 g (57%) of pure 4-methyl-5-hexyn-1,4-diol (VII), b.p. 110-113° (5 mm) and n_D^{20} 1.4680.

Found %: C 65.48, 65.21; H 9.06, 8.91. $C_7H_{12}O_2$. Calculated %: C 65.52; H 9.25.

In addition, 6.2 g of unchanged 5-hydroxy-2-pentanone was recovered. In the hydrogenation of 10 g of the acetylenic glycol (VII) in 15 ml of methanol in presence of a palladium catalyst, 3620 ml of hydrogen (15°, 755 mm) was absorbed in 2.5 hours instead of 3720 ml, as required theoretically. The product, amounting to 9.2 g, was 4-methylhexane-1,4-diol, b.p. 102° (4 mm) and n_D^{20} 1.4575.

Condensation of Acetylene with 3-Hydroxy-3-methyl-2-butanone. A mixture of 65 g of potassium hydroxide powder, 300 ml of ether, and 1 ml of ethanol was saturated with acetylene at 0° and 10 atm. In the course of 70 minutes a solution of 51 g of 3-hydroxy-3-methyl-2-butanone (b.p. 140-141° [20]) in 50 ml

of ether was introduced into the reactor, and stirring was then continued for a further 60 minutes. The main product, amounting to 50.2 g (84%), was 2,3-dimethyl-4-pentyn-2,3-diol (VIII), b.p. 79-80° (10 mm) and n_D^{20} 1.4640 [21]. Also, 7 g of the acetylenic erythritol was isolated and 8 g of unchanged 3-hydroxy-3-methyl-2-butanone was recovered.

SUMMARY

A further study was made of a new method of synthesizing secondary and tertiary acetylenic alcohols by the condensation of aldehydes and ketones with acetylene under pressure in presence of potassium hydroxide powder.

SYNTHESIS AND REACTIONS OF OXYGEN-CONTAINING ORGANOSILICON COMPOUNDS

COMMUNICATION 5. SYNTHESIS AND REACTIONS OF ALIPHATIC-AROMATIC SILANEDIOLS

M. F. Shostakovsky and Kh. I. Kondratyev

For the further development of the chemistry of vinyl ethers it is important that their reactions with silanols [1-6] and silanediols should be investigated. Of the organic silanediols, those of the aliphatic-aromatic series are of great interest. In the present paper we describe the synthesis of silanediols of the following structure:

(I) (II)

The starting materials for the preparation of the compounds (I) and (II) were the following dichloro compounds:

(III) (IV)

The preparation of (III) was carried out in two ways – via organomagnesium compounds and via organolithium compounds. The dichloro compound (IV) was prepared only by the second method.

The formation of the dichloro compound (III) by the first of these methods proceeded according to the scheme:

c) $2C_{10}H_7MgBr + CH_3SiCl_3 \rightarrow \begin{matrix} C_{10}H_7 \\ C_{10}H_7 \end{matrix}\!\!>\!\!SiCl(Br) + 2MgClBr.$
$\quad\quad\quad

Ethyl-1-naphthylsilanediol was prepared by the hydrolysis of the corresponding dichloro compound with 0.1 N NaOH. The silanediols obtained, (I) and (II), were characterized by their physical constants and elementary analysis. Chlorine and bromine were determined in the mixture of products (III) and (V), and the derivatives (IX) and (X) were prepared in order to prove their structure:

(X)

EXPERIMENTAL

1. Synthesis of Dichloromethyl-1-naphthylsilane by the Organomagnesium Method

a) Preparation of 1-Naphthylmagnesium Bromide. A mixture of 52.8 g of magnesium turnings, 250 ml of absolute ether, and a crystal of iodine was prepared in a flask fitted with reflux condenser, dropping funnel, thermometer, and mechanical stirrer, and air was displaced from the apparatus by a stream of nitrogen. A feeble stream of nitrogen was maintained while 20 g of 1-bromonaphthalene and 2 ml of ethyl bromide were introduced into the flask. When reaction set in, the stirrer was switched on, water cooling was applied, and a mixture of 394 g of 1-bromonaphthalene, 750 ml of ether, and 100 ml of benzene was added at such a rate that reaction occurred with gentle boiling of the ether. The addition required about three hours, and stirring was then continued for a further 40 minutes, when 300 ml of dry benzene was added and the solution of 1-naphthylmagnesium bromide was separated from unchanged magnesium.

b) Preparation of Dichloromethyl-1-naphthylsilane. The solution of 1-naphthylmagnesium bromide was added over a period of 2.5 hours to a solution of 296 g (2 moles) of trichloromethylsilane in 100 ml of benzene under the conditions described above, the temperature being maintained at 20-35°. The mixture was then maintained at a gentle boil and was stirred until the separation of the reaction mixture into two layers ceased (2-3 hours). When the mixture was cool, the precipitate was separated, and the filtrate was vacuum-fractionated. In all, 210 g of a substance of b.p. 161-165° (9 mm) or 183-187° (19 mm) was obtained. This product was crude dichloromethyl-1-naphthylsilane. It was redistilled under reduced pressure, and chlorine and bromine was determined in the resulting fractions by titration of a sample (0.1-0.4 g) with 0.1 N NaOH to phenolphthalein, the sample being added to 20 ml of water and 20 ml of ether contained in a flask. The aqueous layer was then separated and its bromine content determined by the method proposed by Volyashko and others [15]. The results are given in the table.

TABLE

Chlorine and Bromine Contents of Crude Dichloromethyl-1-naphthylsilane

Fraction	B.p. (°C) at 19 mm	Amount (g)	Halogen content (%)		d_{20}^{20}	n_D^{20}
			Cl	Br		
I	183—184	9.0	22.76	2.47		
II	184—185	55.3	24.25	3.50	1.223	1.6018
III	185—186—2	29.8	23.2	5.50	1.252	1.6024
IV	186.2—187	15.9	21.9	7.14	1.286	1.6018
Residue		36.0	20.5	6.10		

From these results it follows that the dichloromethyl-1-naphthylsilane obtained was contaminated with bromine derivative.

2. Preparation of the Dibutyl Ether of Methyl-1-naphthylsilanediol

Over a period of 90 minutes 296 g of dichloromethyl-1-naphthylsilane* was added from a dropping funnel to a well stirred solution of sodium butoxide in xylene (139 g of butyl alcohol, 43 g of sodium, and 600 g of xylene). The mixture was diluted with an equal volume of water, and the xylene layer was separated and fractionated. The product, amounting to 257 g (81.2%), boiled at 195-204° (12.5-15 mm) and corresponded in composition to the dibutyl ether of methyl-1-naphthylsilanediol. It had d^{20} 0.9983 and n_D^{20} 1.5270.

Found %: C 72.32, 71.42; H 8.85, 8.96; Si 8.63, 8.60. $C_{19}H_{28}O_2Si$. Calculated %: C 72.10; H 8.91; Si 8.87.

Found: M 317.5, 314.7. Calculated: M 316.47.

The dibutyl ether of methyl-1-naphthylsilanediol is a colorless liquid which is of good solubility in the usual organic solvents.

3. Preparation of the Diacetic Ester of Methyl-1-naphthylsilanediol

A solution of 0.25 mole of dichloromethyl-1-naphthylsilane in 60 ml of petroleum ether (b.p. 60-75°) was added from a dropping funnel over a period of 40 minutes to a well stirred mixture of 41 g of anhydrous sodium acetate and 90.3 g of petroleum ether at about 40°. Stirring was then continued for a further 45 minutes. The reaction mixture was set aside for 12 hours, and the crystalline precipitate that had formed was then filtered off. Petroleum ether was distilled from the filtrate, and the residue was vacuum-fractionated. The main fraction boiled at 175-179° (12 mm) and had the following analysis:

Found %: CH_3COO 39.60, 39.66; Si 9.5, 9.6. $C_{15}H_{16}O_4Si$. Calculated %: CH_3COO 40.97; Si 9.70.

This corresponds to the diacetic ester of methyl-1-naphthylsilanediol. The diacetic ester of methyl-1-naphthylsilanediol is a clear viscous oil which is soluble in the usual organic solvents. Alkaline hydrolysis converts it into methyl-1-naphthylsilanediol.

4. Preparation of Dichloromethyl-1-naphthylsilane by the Organolithium Method

a) Preparation of a Solution of Butyllithium. Benzene (300 ml) was introduced into the reaction vessel, and air was displaced by dry nitrogen (all operations with lithium were carried out in a nitrogen atmosphere). Lithium (15 g, cut into small pieces) was added, and the mixture was stirred while 102 g of butyl chloride was added from a dropping funnel over a period of 90 minutes at 50-60°. When the whole of the butyl chloride had been added, the reaction mixture was heated for a further 30 minutes. Dry benzene was added to the product, the mixture was cooled to room temperature, and after two hours the butyllithium solution was separated from lithium chloride. The butyllithium content of the filtrate (640 g) was determined by titration with 0.1 N NaOH. It was found to be 50.1 g, corresponding to a yield of 73.3%.

b) Preparation of 1-Naphthyllithium. A solution of 162 g of 1-bromonaphthalene in 100 ml of benzene was added from a dropping funnel over a period of 30 minutes to the butyllithium solution, the temperature being initially 18-20° and finally 40-45°. The precipitate formed, which contained 70.7 g (67.5%) of 1-naphthyllithium, was filtered off.

c) Preparation of Dichloromethyl-1-naphthylsilane. A suspension of 70.7 g of 1-naphthyllithium in 140 ml of benzene was added from a dropping funnel to a constantly stirred solution of 78 ml of trichloromethylsilane in 120 ml of benzene, the temperature of the reaction mixture being maintained at about 40° (water cooling). The reaction mixture was stirred for a further one hour and then fractionated. The product (60.2 g) had b.p. 123-125° (1.5 mm), d_{20}^{20} 1.237; n_D^{20} 1.6028. The literature [16] gives b.p. 122° (1 mm), d_{20}^{20} 1.2333; n_D^{20} 1.6025.

Found %: C 55.62, 55.56; H 4.38, 4.36; Cl 28.35, 28.50; Si 11.60, 11.53. $C_{11}H_{10}Cl_2Si$. Calculated %: C 54.78; H 4.18; Cl 29.41; Si 11.63.

The analysis shows that the isolated product corresponds to dichloromethyl-1-naphthylsilane, which was obtained in 47.4% yield. Dichloromethyl-1-naphthylsilane is a colorless viscous liquid having a sharp suffocating odor. It gradually decomposes in the air with evolution of hydrogen chloride. In appearance and properties it is similar to the dichloromethyl-1-naphthylsilane obtained from $1\text{-}C_{10}H_7MgBr$ and CH_3SiCl_3.

* For the syntheses of the dibutyl ether and diacetic ester of methyl-1-naphthylsilanediol, dichloromethyl-1-naphthylsilane prepared by the organomagnesium method was used.

The residue from the distillation (16.7 g) was crystallized from a mixture of benzene and heptane, and 12 g of crystals melting at 132° were obtained.

Found %: C 76.51, 76.48; H 4.89, 4.79; Cl 10.39, 10.54; Si 8.19, 7.67. $C_{11}H_{17}ClSi$. Calculated %: C 75.77; H 5.15; Cl 10.65; Si 8.43.

This product is chloromethyldi-1-naphthylsilane, obtained in 18.7% yield. It forms colorless crystals, readily soluble in ether, acetone, and aromatic hydrocarbons, but of low solubility in isopentane.

5. Synthesis of Dichloroethyl-1-naphthylsilane

Dichloroethyl-1-naphthylsilane was prepared under the above-described conditions from 161.9 g of 1-naphthyllithium and 196 g of trichloroethylsilane. After removal of solvent the reaction product was vacuum-fractionated. The following fractions were obtained:

Fraction I, b.p. 79-120° (1.5-2 mm);	1.7 g
Fraction II, b.p. 122-134° (1.5-2 mm);	12.43 g (the bulk of this boiled at 132-134°)
Fraction III, b.p. 134-136° (1.5-2 mm);	153 g
Residue	68.38 g

Fraction I was recrystallized from ethanol, and 1.2 g of naphthalene was isolated. Fraction II consisted mainly of contaminated dichloroethyl-1-naphthylsilane. Fraction III was the main product; it had the following constants: d_{20}^{20} 1.222; n_D^{20} 1.5995; the yield was 49.67%.

Found %: C 56.74, 56.50; H 4.83, 4.77; Cl 28.14, 27.74; Si 11.04, 11.17. $C_{12}H_{12}Cl_2Si$. Calculated %: C 56.52; H 4.74; Cl 27.79; Si 11.0.

On the basis of our results, this substance is dichloroethyl-1-naphthylsilane. It is a viscous liquid, readily soluble in the usual organic solvents. The residue (68.38 g of a viscous semisolid mass) was repeatedly recrystallized from heptane, the crystals being washed with isopentane. The crystals, amounting to 49.9 g (23.8%), melted at 94°.

Found %: C 75.86, 75.34; H 5.69, 5.68; Cl 11.14, 11.74. $C_{22}H_{19}ClSi$. Calculated %: C 76.15; H 5.52; Cl 10.22.

The product, chloroethyldi-1-naphthylsilane, is readily soluble in ether, acetone, and aromatic hydrocarbons, but is sparingly soluble in isopentane.

6. Preparation of Methyl-1-naphthylsilanediol

a) Hydrolysis of the Diacetic Ester of Methyl-1-naphthylsilanediol with 0.1 N NaOH. Ether (30 ml), an ampoule containing 1 g of the diacetic ester of methyl-1-naphthylsilanediol, and 20 g of finely crushed ice were introduced successively into a flask, which was then shaken vigorously to break the ampoule. The mixture was titrated with 0.1 N NaOH in presence of phenolphthalein. The aqueous layer was separated from the ether layer and washed with ether. The ether extracts were washed with water, and ether was distilled off at 15-20 mm. The oily residue was dissolved in benzene. After some time, 0.36 g (50.8%) of crystals, m.p. 106-107°, separated from the benzene solution.

Found %: C 65.35, 65.30; H 6.13, 5.99; Si 12.85, 13.02; O 15.67, 15.69. $C_{11}H_{12}O_2Si$. Calculated %: C 64.69; H 5.91; Si 13.74; O 15.67.

Found M 197.3, 195.3. Calculated %: M 204.

Methyl-1-naphthylsilanediol is readily soluble in ether, alcohol, and acetone; it is sparingly soluble in benzene and petroleum ether.

b) Hydrolysis of Dichloromethyl-1-naphthylsilane with Aqueous Sodium Acetate in presence of Magnesium Oxide. A mixture of 0.5 mole of sodium acetate, 0.25 mole of magnesium oxide, 125 g of water, and 125 g of ether was prepared in a flask fitted with reflux condenser, mechanical stirrer, and dropping funnel, and 0.25 mole of dichloromethyl-1-naphthylsilane was added gradually to the mixture from a dropping funnel, the temperature being about 0°. When the hydrolysis was complete, the ether solution was separated from the aqueous layer and dried with sodium sulfate. Part of the ether was removed under reduced pressure, and petroleum ether was added to the residue, which resulted in the separation of a precipitate.

Recrystallization from benzene and petroleum ether gave methyl-1-naphthylsilanediol in the form of glistening crystals, m.p. 106-107°. In admixture with the methyl-1-naphthylsilanediol obtained by the hydrolysis of the diacetic ester of methyl-1-naphthylsilanediol, there was no melting-point depression.

7. Preparation of Ethyl-1-naphthylsilanediol

Hydrolysis of Dichloroethyl-1-naphthylsilane with 0.1 N NaOH. A mixture of 1.1087 g of dichloroethyl-1-naphthylsilane, 25 g of finely crushed ice, and 35 ml of ether was titrated with 0.1 N NaOH in presence of phenolphthalein. The ether layer was separated, ether was distilled off under reduced pressure, and 6 ml of benzene and 20 ml of petroleum ether were added to the residue. The crystals that separated were removed and dried at a residual pressure of 2 mm. The product, amounting to 0.48 g, melted at 89-90°.

Found %: C 66.20, 66.10; H 6.42, 6.63; Si 12.44, 12.43. $C_{12}H_{14}O_2Si$. Calculated %: C 66.04; H 6.46; Si 12.85.

Found: M 226.3, 216.1. Calculated: M 218.29.

The results correspond to ethyl-1-naphthylsilanediol. This substance is readily soluble in ether, alcohol, and acetone, but sparingly soluble in isopentane and benzene.

SUMMARY

1. It was shown that the dichloromethyl-1-naphthylsilane obtained by the organomagnesium method contains bromochloromethyl-1-naphthylsilane as impurity.

2. The procedure for preparing pure arylalkyldichlorosilanes was improved.

3. Conditions were found for the preparation of alkylarylsilanediols in the pure state by the hydrolysis of alkylaryldihalosilanes.

4. The following substances were prepared and characterized for the first time: methyl-1-naphthylsilanediol, ethyl-1-naphthylsilanediol, dichloroethyl-1-naphthylsilane, chloroethyldi-1-naphthylsilane, chloromethyldi-1-naphthylsilane, the dibutyl ether of methyl-1-naphthylsilanediol, and the diacetic ester of methyl-1-naphthylsilanediol.

KINETICS AND CHEMISTRY OF THE POLYCONDENSATION OF GLYCINE ETHYL ESTER

K. T. Poroshin, T. D. Kozarenko and Yu. I. Khurgin

(Abridged text of a paper read at a general meeting of the Division of Chemical Sciences of the Academy of Sciences of the USSR held in Moscow, April 25, 1956)

A considerable number of papers have appeared on the polycondensation of esters of α-amino acids [1-8]. The data now available, however, do not give us any idea of the kinetics and chemistry of the reaction and the composition of the polycondensation products. The polycondensation reaction attracts interest for two reasons: in the first place, this reaction, and its mechanism and kinetics, is closely associated with the problem of the synthesis of the peptide link, which is of great importance for biochemistry; and in the second place, as we have already shown, the polycondensation reaction carried out under our conditions [9,10] has a non-equilibrium character and therefore forms a suitable basis for a study of the polycondensation reaction.

The first attempt to determine the composition of the polycondensation product obtained from esters of α-amino acids was made by Curtius [1], who tried to determine quantitatively the piperazinedione formed in the condensation of glycine ethyl ester. The lack of success in this first attempt is to be attributed to the absence of a suitable analytical method. Frankel and Katchalski [3] investigated the polycondensation of alanine esters and used the sublimation method for the determination of piperazinediones. Using the chromatographic method, Brockmann and Musso [5] and Schramm and Restle [6] obtained more detailed information of the composition of the polycondensation product obtained from esters of low oligopeptides. It should be noted, however, that the available data on the composition of polycondensation products obtained from esters of amino acids and of oligopeptides relate to reaction conditions that are selected arbitrarily and are usually severe, the reaction generally proceeding to an advanced stage, so that there is no information about the intermediate stages of the reaction. The present work is the first attempt to make a systematic investigation of the composition of the polycondensation product at various stages of the process. In selecting a substance for investigation, we decided on glycine ethyl ester for the following reasons: 1) the reactions of glycine ethyl ester have been the subject of several investigations and have therefore been studied in the greatest detail; 2) we have previously [9,10] determined conditions for carrying out the polycondensation of glycine ethyl ester which enabled us to obtain unequivocal and reproducible results. The study of the composition of the polycondensation product of glycine ethyl ester at various stages of the process is convenient also because we have previously developed methods for the determination of piperazinedione [11] and diglycylglycine [12] in the products of this reaction. Glycine esters are readily distilled, especially at reduced pressure, and this permits the separation of unchanged monomer from the reaction mixture. This makes it possible to determine the progress of reaction with comparative ease.

The high water-solubility of the glycine peptides formed in the early stages of the polycondensation reaction considerably increases the accuracy with which their composition can be determined by titration with copper in alkaline solution and measurement of amine nitrogen by the van Slyke method. At later stages of the reaction (after 20 hours) macromolecular polyglycine makes its appearance; this is of low solubility in water and weak alkalis, and we therefore limited the duration of the experiment to 15 hours. The most interesting transformations were observed during the first 8-10 hours, after which there occurred only slight quantitative changes associated with the further gradual increase in the molecular weight of the polyglycine.

Tetrapeptides and peptides of still higher molecular weight make their appearance already after 2-3 hours, after which they increase continuously in amount. It is interesting to note that the relative amount of piperazinedione in the polycondensation product of glycine ethyl ester is not constant, but gradually falls as the reaction progresses. At the beginning of the reaction (1.5-2 hours) the amount of piperazinedione attains 40% of the total amount of polycondensation product and then gradually falls to 17-19%. In the early stages of the reaction (5-6 hours) the amount of diglycylglycine ethyl ester rises at first, attains a maximum value (about 30%), and then falls continuously as the rate of its conversion into compounds of higher molecular weight rises relative to the rate of re-formation of the ester of the tripeptide.

A study of the kinetics of the conversion of monomer into the respective condensation products showed that transformation occurs in accordance with a first-order law, the rate constant in presence of carbon dioxide being $5.85 \cdot 10^{-5}$ second^{-1}.

EXPERIMENTAL

Glycine ethyl ester, prepared by Fischer's method [13], was introduced into ampoules together with catalyst (carbon dioxide; 2 moles % on the amount of ester) in the way described previously [9]. All experiments were carried out at 40 ± 0.01°, a temperature at which no degradation of peptides was observed. At the end of the required time (more than two hours) the ampoule was opened and its contents were transferred to a vessel containing absolute ether (10-12 times the volume of the contents of the ampoule) for the extraction of monomer.

The solid mass of polymer was carefully broken down with a glass rod until a fine white suspension was formed. The polycondensation product was filtered off and washed with two or three successive portions of ether. The white powder so obtained was dried for 3-4 hours in a vacuum over concentrated sulfuric acid; it was then investigated.

In order to determine the amount of piperazinedione in these products, a weighed sample (20-30 mg) was dissolved in water (3-5 ml) and a portion of the solution was analyzed for amine nitrogen by the van Slyke method. At the same time, a sample of the solid substance was dissolved in 0.1 N NaOH and heated for two hours at 40° with subsequent determination of amine nitrogen. From the increase in amine nitrogen after hydrolysis of the piperazinedione, the amount of this in the solid phase was determined (Curve 1, Fig. 1) and was recalculated for all the products in the reaction medium (i.e. on the weight of monomer taken) to give the percentage of piperazinedione on the total weight of reaction mixture (Curve 1, Fig. 2).

It should be noted that, at the beginning of the process (after about two hours), about one-half of the solid part of the polycondensate is piperazinedione. It may be assumed that at still earlier stages of the reaction the amount of piperazinedione will be still greater, but the amount of polycondensate formed in these stages is too small for the accurate determination of piperazinedione content. Simultaneous determinations of piperazinedione were made by the "copper" method [11].

The contents of the tripeptide and "tetrapeptide" (tetra- and higher peptides) fractions were determined by differential titration in the way described previously [12]. From the amount of copper required in the titration from the "transition point" to the appearance of a suspension of $Cu(OH)_2$, the content of diglycylglycine ester was calculated as a percentage on the solid part of the reaction mixture (Curve 2, Fig. 1), and recalculation for the total amount of reaction mixture (i.e. on the weight of original ester taken) gave the amount of tripeptide ester as a percentage of the total weight of reaction mixture (Curve 2, Fig. 2). The data given show clearly that the greatest amount of diglycylglycine ester is formed after 5-6 hours from the start of the reaction. At later stages of the reaction, changes in the formation of tripeptide esters proceed much more slowly. From the fifth hour onwards the reaction mixture becomes completely solid under the conditions of the experiment, and reaction proceeds principally in a heterogeneous phase, a fact that probably determines the low rate at which the further disappearance of diglycylglycine ester from the reaction mixture occurs. Titration of the polycondensation product of glycine ethyl ester during the first hour of reaction is extremely difficult owing to the presence of considerable amounts of diglycine ester.

The data obtained on the "tetrapeptide" fraction by the same titration with 0.04 M $CuSO_4$ are shown on Curve 3, Fig. 1 (content of the solid phase). Already in the first stages of the reaction (1.5-2 hours), a certain amount of "tetrapeptide" fraction can be detected by titration with $CuSO_4$ in alkaline medium.

Fig. 1. Compositions of polycondensation products of glycine ethyl ester (%): 1) piperazinedione (●-determined by increase in amine nitrogen, ○-determined by the "copper" method); 2) diglycylglycine ethyl ester (×); 3) "tetrapeptide" fraction (▼); 4) free glycine ethyl ester (⊖).

Fig. 2. Piperazinedione and diglycylglycine contents (% on original weight of monomer): 1) piperazinedione; 2) diglycylglycine ethyl ester.

Fig. 3. Amount of glycine ethyl ester bound (M).

Unchanged monomer was washed out of the solid part with absolute ether, and was weighed after the ether had been removed under reduced pressure (10 mm, 35°). The conditions of the vacuum removal of ether were shown by experiment to be such as to ensure the complete removal not only of ether, but also of the ethanol separating during the reaction. The residual liquid was pure monomer (it gave the theoretical amount of amine nitrogen).

Quantitative data on unchanged monomer are given on Curve 4, Fig. 1, and in Fig. 3. As will be seen from Fig. 3, the experimental points fit closely to a straight line, which indicates a first-order reaction for the disappearance of monomer.

DISCUSSION OF RESULTS

As in other reactions of the same type, the primary act in the polycondensation of α-amino esters consists in reaction between two monomer molecules with formation of the dimer ester:

$$NH_2 \cdot CHR \cdot COOR' + NH_2 \cdot CHR \cdot COOR' \longrightarrow H[HN \cdot CHR \cdot CO]_2OR' + R'OH.$$

(I) (II)

It is possible also that all four functional groups of two monomer molecules might react simultaneously with formation of a cyclic dimer, but this reaction is of low probability, since special conditions of spatial disposition of one monomer molecule with respect to the other will be required. It is very much more probable that the dimer (II) will be formed and will undergo further transformations in two directions: a) reaction with monomer or with more dimer ester (II) with formation of linear peptides (III) and (IV):

b) intramolecular reaction of the functional groups of the dipeptide ester with formation of a cyclic dimer, piperazinedione

i.e. termination of the chain at the dimer stage.

The amount of piperazinedione resulting from the polycondensation depends on which of these two ways the process takes. Our results give a quantitative estimate of the relative extents of reactions (a) and (b), both in the initial stage of the polycondensation of glycine ethyl ester, and also in subsequent stages. The high content of piperazinedione in the first hours (1-2 hours) of the reaction is worthy of attention (it forms up to 40% of the whole solid phase; see Curve 1, Fig. 1). There is reason to suppose that at still earlier stages of the process the amount is still greater. Thus, at the start of the polycondensation reaction of glycine ethyl ester, cyclization and linear-polymer formation proceed at almost the same rate, but as diglycylglycine ester accumulates in the reaction mixture (Curve 2, Fig. 1), monomer begins to be used at a greater rate for the formation of polyglycine esters, so that the piperazinedione content of the polycondensate diminishes.

There is reason to suppose that, as the amount of diglycylglycine ester and of tetrapeptide fraction increases in the reaction mixture, the probability of reaction between monomer molecules and functional groups of polymer molecules increases. In this lies the cause of the preferential formation of linear polycondensation products, rather than cyclic products, in the succeeding stages of reaction (after five hours).

As will be seen from Curve 2, Fig. 1, the maximum content of tripeptide ester is observed after 5-7 hours. It is after just this period of time that the bulk of the monomer is found to have reacted, and further processes can occur only by reaction between esters of lower peptides, particularly diglycylglycine ester. We are concerned here with reactions with esters of monomer, dimer, trimer, and higher peptides. All these result in the disappearance of tripeptide esters, as these no longer have an adequate source – the monomer – for their formation.

The fact that the content of triglycine ester suffers less notable changes in the later stages (after ten hours) is probably to be explained by the solidification of the whole reaction mixture which occurs at this time; further reaction then has to occur in the solid phase.

SUMMARY

1. The composition of the polycondensation product of glycine ethyl ester in presence of 2% of carbon dioxide at 40° was investigated at various stages of the process. The contents of free monomer, piperazinedione, and diglycylglycine were determined quantitatively.

2. It was shown that the reaction of monomer is of first order. In the early stages of reaction (2-3 hours) there is preferential formation of piperazinedione. In later stages the relative amount of piperazinedione falls as a result of the rapid accumulation of linear-polycondensation products.

POLYMERIZATION AND COPOLYMERIZATION OF ALKENYLSILANES UNDER HIGH PRESSURE

COMMUNICATION 3

A. M. Polyakova, V. V. Korshak, A. A. Sakharova, A. D. Petrov, and V. F. Mironov and G. I. Nikishin

We have previously [1] carried out the radical polymerization (in presence of tert-butyl peroxide) of nineteen alkenylsilanes of various structures at 130° under a pressure of 5500 atm. It was shown that, whereas monoalkenylsilanes form liquid polymers (from dimers to hexamers), polyalkenylsilanes (di-, tri-, and tetra-allylsilanes, and tetrakis-2-methylallylsilanes) polymerize with exclusive formation of three-dimensional polymers having a decomposition temperature of above 250°. Also, it was established that there is a difference in the tendencies of 1- and 2-alkenylsilanes to undergo polymerization, the cases examined being allyltriethylsilane and triethylvinylsilane, of which the first polymerizes as far as the pentamer, whereas the second forms an octamer.

It was noted that increase in pressure results in a higher rate of polymerization and in the formation of polymers of higher molecular weight. Thus, diallyldimethyl- and diallylmethylphenyl-silanes form three-dimensional polymers under a pressure of 5500 atm, whereas they do not polymerize at all under atmospheric pressure, other conditions being the same. At high pressure (5500 atm) triallylmethylsilane polymerizes to a glassy solid – a three-dimensional polymer – in six hours, whereas in absence of high pressure a gel-like polymer is obtained. In the polymerization of triethylvinyl- and allyltributylsilanes at atmospheric pressure the products are of lower molecular weight and are obtained in lower yield than in the polymerization of these substances at high pressure.

In the present paper (Tables 1-3) we give our results on the polymerization of forty-seven alkenylsilanes, and these enable us to give a considerably more complete characterization of the tendency of sila-olefins to polymerize. The results show that alkenyltrichlorosilanes, such as trichloro(2-methylallyl)silane and trichlorovinylsilane [2], do not polymerize to an appreciable extent; the polymerization of alkenyltrialkylsilanes goes very much better, and the degree of polymerization is particularly high in the case of alkenyltrialkoxysilanes.

We, like Kanasashi [3], are inclined to explain this behavior of the alkoxy compounds as the result of the free rotation of the OR group, a view that has already been indicated by B. A. Arbuzov and Shavsha [4]. We must point out, however, that such free rotation of alkoxy groups does not occur in all cases. In a study of the polymerization of cyclopentadienyltriethoxysilane  $Si(OC_2H_5)_3$ under the same standard conditions, we found that this compound does not polymerize, whereas cyclopentadienyltrimethylsilane $Si(CH_3)_3$, forms a polymer of molecular weight 1334 (decamer).

We must point out also the low activity of alkenylsilanes in catalytic polymerization (in presence of $AlCl_3$). Kanasashi [3] found that the polymerizaton of trimethylvinylsilane by the radical scheme results in the formation of a trimer, but polymerization by the ionic scheme (in presence of $AlCl_3$) does not occur; similarly, we found

* Synthesized by V. G. Glukhovtsev.

that triethyl(2-methylpropenyl)silane forms a tetramer by radical polymerization, but a dimer by ionic polymerization. Sommer and Tyler [5] also observed the polymerization of an alkenylsilane (allyltrimethylsilane) in presence of $AlCl_3$ with formation of a product of low molecular weight.

In the synthesis of dimethyldivinylsilane, in addition to monomer we obtained also dimer. The monomer, which was found to be not altogether pure, did not polymerize (the lack of any tendency for dimethyldivinylsilane to undergo radical polymerization was indicated also by Kanasashi [3]). Under the polymerization conditions, the dimer was converted into decamer.

Tetravinylsilane, which was prepared for the first time, readily polymerized with formation of a three-dimensional polymer. One of the most interesting of our conclusions, which was based on a very large number of examples, was the high tendency of alkenyltriethylsilanes to polymerize, as compared with that of alkenyltrimethylsilanes. Thus, propenyltriethylsilane forms a dimer under conditions under which propenyltrimethylsilane does not polymerize, and similarly isopropenyltriethylsilane polymerizes to a tetramer, but isopropenyltrimethylsilane only to a dimer. This effect of ethyl groups was observed also in the case of 3-alkenylsilanes. 3-Butenyltriethylsilane polymerizes to a heptamer, whereas 3-butenyltrimethylsilane forms only a dimer under the same conditions.

We have previously observed exaltation of molecular refraction in compounds containing triethylsilyl radicals, a fact that again supports the view that a conjugated system is present.

In the present investigation, as in the previous [1], we have established, on the basis of a large number of examples, that increase in pressure results in a higher rate of polymerization and the formation of polymers of higher molecular weight. The effect of pressure is particularly notable in the case of dialkenylsilanes. Whereas diallyldiethyl- and diallyldimethyl-silanes polymerize to three-dimensional polymers under a pressure of 5500 atm, the same silanes form soluble solid polymers under a pressure of 3500 atm; Finally, it should be noted that, in the present investigation, the polymerization of sila-olefins containing two silicon atoms has been carried out for the first time – the polymerization of 1,2-bistrimethylsilylethylene (I), 1,2-bistriethylsilylethylene (II), and 1,1-bistrimethylsilylethylene (III),. It was established that (I) does not polymerize, (II) forms a dimer (a further example of the effect of ethyl radicals), and (III) – which is a structural analog of 2-methylpropene, whereas (I) is a structural analog of 2-butene – polymerizes to a pentamer.

Apart from the polymerization of alkenylsilanes we investigated the copolymerization of alkenylsilanes with methyl methacrylate. We had already [7] established the possibility in principle of obtaining copolymers

of alkenylsilanes without the use of high pressures, polyalkenylsilanes being used as organosilicon components. It was found that, of the polyalkenylsilanes investigated, only tetrakis-2-methylallylsilane formed a three-dimensional copolymer with methyl methacrylate. The others – dimethylbis-2-methylallyl- and diallylmethylsilanes – formed linear copolymers. Allyltributylsilane proved to be incapable of copolymerization with methyl methacrylate. In the present paper we give data (Table 4) on the copolymerization of mono- and di-alkenylsilanes with methyl methacrylate, which was carried out both at high pressure (5500 atm) and at atmospheric pressure. Allyldimethylphenyl-, diallyldimethyl-, diallylmethylphenyl-, and dimethylbis-2-methylallyl-silanes were investigated.

In these experiments the relative amounts of sila-olefin and methyl methacrylate and the duration of reaction were varied. We confirmed the previously established fact [7] of the formation of soluble copolymers of dimethylbis-2-methylallylsilane with methyl methacrylate under atmospheric pressure. We showed also that the copolymer obtained at high pressure (5500 atm) contains a certain amount (about 8%) of insoluble, three-dimensional polymer. The other dialkenylsilanes that we studied formed mixtures of soluble and insoluble copolymers, with a considerable predominance of the latter. Also, the amount of insoluble copolymer increased both with increase in the relative amount of sila-olefin in the original mixture, and with increase in the duration of the copolymerization reaction. The formation of a greater amount of insoluble copolymer was favored also by increase in pressure. We prepared copolymers of allyldimethylphenylsilane with methyl methacrylate having silicon contents of 0.79 and 1.63%, and the viscosities (η_{sp}/c, c = g/100 ml) of these copolymers were less than those of methyl methacrylate homopolymers prepared under the same conditions. According to our experimental results, the use of high pressures during copolymerization generally results in the formation of polymers of higher viscosity than those formed at atmospheric pressure. Investigation of thermo-mechanical compression curves, which were determined for most of the polymers and copolymers obtained, showed that homopolymers of dialkenylsilanes, such as diallyldimethyl- and diallylmethylphenylsilanes, are three-dimensional: they do not soften up to temperatures of the order of 400° (at these temperatures only charring of the outer layers of the sample was observed). Copolymers of the same dialkenylsilanes with methyl methacrylate exhibit both a temperature of transition from the vitreous to the high elastic state (T_v), and also a temperature of transition to the state of viscous flow (T_f). T_v abd T_f were determined by a continuous method at a constant applied load of 0.5 kg, the diameter of the plunger being 4 mm. T_v was taken to be the temperature at which the plunger gave an impression in the sample of 0.05 mm.

A more detailed study of the physico-mechanical properties of alkenylsilane polymers and copolymers is to be the subject of further investigation.

EXPERIMENTAL

The investigation of polymerization and copolymerization under pressure was carried out under the same conditions as those described previously [1], i.e. in presence of 3% by weight of tert-butyl peroxide at 130° and 5500 atm (in some experiments a lower pressure was used). Experiments in which a high pressure was not applied were carried out in sealed glass tubes. The duration of each polymerization experiment was six hours, and in the copolymerization experiments times of 6 and 50 hours were used.

The treatment of the polymerization products of low molecular weight was carried out as described previously [1]. Macromolecular polymers (copolymers) were purified by reprecipitation from acetone with methanol. Molecular weights of low-molecular-weight polymers were determined cryoscopically in benzene. The relative viscosities of solutions of copolymers in dichloroethane were measured with an Ostwald viscometer at 20°, concentrations of 0.4 g per 100 ml being used. The compositions of the copolymers were determined from the silicon content and were calculated, as before [7], by the formula

$$\frac{n}{m} = \frac{\frac{2806}{\%\,Si} - M_2}{M_1},$$

in which n is the number of monomer residues (M_1) of methyl methacrylate and m is the number of sila-olefin residues (M_2). The results are presented in Tables 1-4.

The authors express their thanks to B. L. Tsetlin for help in the determination of the thermo-mechanical properties of polymers and copolymers and for discussion of the results.

SUMMARY

1. An investigation was made into the tendency of mono- and poly-alkenylsilanes to polymerize at ordinary and high pressures.

2. It was shown that the tendency of alkenylsilanes to polymerize varies with their structures.

3. It was shown that increase in pressure results in increase in the rate of polymerization of alkenylsilanes and in increase in the molecular weight of the resulting polymers.

4. An investigation was made into the copolymerization of methyl methacrylate with the following mono- and di-alkenylsilanes: allyldimethylphenyl-, diallyldimethyl-, diallylmethylphenyl-, and dimethylbis-2-methylallyl-silanes. Thermo-mechanical properties of the copolymers were determined.

ALKYLATION AND DEALKYLATION OF BENZENE AND ITS HOMOLOGS IN PRESENCE OF ALUMINOSILICATES

Yu. G. Mamedaliev and G. M. Mamedaliev

The transfer of methyl groups from one aromatic hydrocarbon molecule to another and the dealkylation of alkyl-substituted aromatic compounds in the liquid phase in presence of aluminum chloride formed the subject of investigations by various workers at the end of the last century [1,2]. The practical significance of these investigations was realized during the 1914-18 war, when attention was turned to the possibility of preparing toluene from xylene and from suitable fractions of coal-tar distillate [3,4]. We studied these reactions in detail in a previous investigation [5], which was devoted to the synthesis of toluene by the alkylation and dealkylation of aromatic hydrocarbons. In this work we noted the exceptionally favorable effect of high pressure (20-25 atm) on the yield of toluene in the combined alkylation-dealkylation treatment of a mixture of xylenes, polymethylbenzenes, and benzene.

During World War II large-scale manufacture of ethylbenzene, cumene, and butylbenzenes was rapidly put into operation and later considerably extended. Industrial application was made also of the catalytic synthesis of toluene by the condensation of benzene with methanol, which was carried out over a zinc phosphate catalyst at high pressure. In the manufacture of alkylated aromatic hydrocarbons, irrespective of the kind of catalysts used and the conditions of the reaction, some di-, tri-, and poly-alkylbenzenes boiling above the upper limit for aviation gasoline were always formed [6,7]. In fact, with the coming of the above-discussed manufacture of toluene and alkylated aromatics, quantities of polyalkylbenzenes were made available, and these, together with the corresponding fraction from coal and pyrolysis tar, formed an adequate base of raw materials for industrial dealkylation.

In the last decade, in conjunction with the extensive application of aluminosilicate catalysts in the treatment of petroleum, successful application was made of these same catalysts for the dealkylation of polyalkylbenzenes. More important results were obtained when aluminosilicates were used in the combined alkylation-dealkylation of mixtures of benzene and aromatic hydrocarbons of differing degrees of substitution.

One of the authors of the present paper [8] has investigated the reactions of dealkylation and intermolecular alkyl transfer for diisopropylbenzene in presence of natural aluminosilicate catalysts. Experiments were carried out over the temperature range 350-450° and pressure range 20-60 atm for various reaction times, and the relative extents to which the main and subsidiary reactions occurred were determined.

Moldavsky and Bezdel [9] studied the mechanism of the dealkylation of various alkylbenzenes over the activated natural aluminosilicate humorin. They showed that, under their conditions (temperature 410°, rate 1.5 : 1), the readiness with which an alkyl group is eliminated increases with increase in the degree of polarization of the bond between the alkyl and phenyl groups of the original alkylbenzene. A paper by Hansford, Myers, and Sachanem [10] presents the results of experiments with xylene, 1,2,4-trimethylbenzene, methylnaphthalene, and diethylbenzene in presence of aluminosilicates at atmospheric pressure in the temperature range 450-540°.

In the catalytic treatment of tar obtained by the pyrolysis of petroleum, a substantial increase in the yield of toluene is obtained in presence of a synthetic aluminosilicate catalyst; to a considerable extent this is the result of combined alkylation-dealkylation reactions of aromatic hydrocarbons and of the hydrostabilization of olefins [11]. A study of the nature of the unsaturated hydrocarbons present in pyrolysis tar and thermal-cracking kerosene [12] showed that they are mainly cyclic compounds, which, in presence of aluminosilicate,

are converted into aromatic hydrocarbons as a result of a hydrogen-transfer reaction.

Investigations worthy of attention are those of Johanson and Watson [13] on the combined alkylation-dealkylation of a mixture of benzene and xylene in presence of aluminosilicates at high pressure. Among recent investigations the work of Roberts and Good [14] is of interest; these workers compared the readiness with which cumene and some of its derivatives are dealkylated in presence of aluminozirconosilicates at 400-500° at atmospheric pressure. The dealkylation reaction was carried out also in presence of alumina activated with hydrofluoric acid [15].

In the further development of our earlier investigations on combined alkylation-dealkylation of aromatic hydrocarbons in presence of heterogeneous catalysts, which were carried out in 1940-45, we undertook the present investigation. Part of this investigation, which is concerned with combined methylation-demethylation, is described below.

EXPERIMENTAL

The experiments were carried out in a laboratory continuous-flow apparatus, which is shown diagrammatically below.

Continuous-flow reactor for the catalytic treatment of hydrocarbons under pressure: 1) nitrogen cylinder; 2) vessel for raw material; 3) reactor; 4) tube furnace; 5) rheostat; 6) galvanometer; 7) reduction valve; 8) condenser; 9) receiver; 10) gas condenser; 11) flow-meter; 12) flow indicator; 13) gas meter.

The liquid reaction products were fractionated through a 20-25 plate laboratory column. Group chemical compositions were determined for the raw material and the catalyzates. Gases were analyzed in an Orsat apparatus. Gases obtained in experiments carried out under optimum conditions were analyzed in Podbielniak and TsIATIM (Central Research Institute for Aviation Fuels and Oils) apparatuses. For the toluene obtained, determinations were made of density, iodine and bromine values, acidity, refractive index, sulfonatability, etc. In order to obtain data for determining the material balance and the basic parameters of the process (temperature, pressure, rate of passage, duration of the reaction cycle), series of experiments were carried out with various mixtures. Synthetic aluminosilicates were used as catalysts.

Catalytic Dealkylation of o- and m-Xylenes in presence of Benzene

Experiments on the dealkylation of m- and o-xylenes with simultaneous alkylation of benzene were made over synthetic aluminosilicates under known optimumconditions: 15 atm, 525°, passage of 0.5 volume raw material per one volume of catalyst per hour, duration of cycle 50 minutes. The raw materials were cryoscopic benzene (boiling range 79.74-80.13°, bromine value 0.03, density 0.8782, sulfonatability 99.6%) and chemically pure o-xylene (boiling range 143.2-144°, density 0.8799, refractive index 1.5050, sulfonatability 100%), which analysis by the oxidation method showed content of 98.7% of o-xylene and 1.3% of m-xylene.

The experiments were carried out for a molar ratio of benzene to o-xylene of 2 : 1. According to rectification data, the benzene content of the mixture was 58% by weight, and the o-xylene content 35% by weight. It was found that at 5 atm and 525° a single passage of the mixture over the catalyst resulted in the formation of 97.1 % of catalyzate, 0.7% of gas, and 0.8% of coke. The catalyzate contained 20.1% of toluene. The benzene content fell from 58% in the raw material to 49.4% in the catalyzate. A considerable part of the o-xylene was demethylated to toluene, and as a result the xylene content fell from 35% to 11-12%. It is interesting to note that o-xylene is isomerized over synthetic aluminosilicate into the meta and para isomers with a resulting displacement in the boiling range of the fraction and a corresponding lowering of the density and refractive index. A little trimethylbenzene is formed.

Increase in pressure to 15 atm resulted in an increased yield of toluene. Its content in the catalyzate was 27-28% by weight. The process was characterized by the formation of comparatively large amounts of coke (1.9-2.2%) and gas (1.7-2.3%). The yield of catalyzate was 94.5-95.2% by weight on the raw material.

The formation of 27-28 g of toluene and about 3-3.5 g of a trimethylbenzene fraction resulted from the alkylation of 9-10 g of benzene and the dealkylation of 17.7-19.2 g of o-xylene. Hence, the formation of toluene proceeds to the extent of about 35-40% on account of the alkylation of benzene and to the extent of 60-65% on account of the dealkylation of xylene. Increase in pressure causes the process to proceed somewhat further: the various reactions are affected to about the same extent by increase in pressure, and the relative extents to which these reactions contribute to the formation of toluene remain at about the same values as at a pressure of 5 atm.

Over aluminosilicates, dealkylation of o-xylene with simultaneous alkylation of benzene proceeds extremely smoothly without any accompanying decomposition and condensation reactions. The formation of unsaturated hydrocarbons and products of higher molecular weight is not observed. The catalyzates have zero iodine value and a sulfonatability of 100%. In all of its standardized characteristics, the toluene isolated from the catalyzate is completely up to standard: its bromine value does not exceed 0.03, its density varies over the range 0.8665-0.8670, its refractive index is 1.4969-1.4972, and its sulfonatability is 100%.

Similar experiments were carried out with m-xylene. The experimental conditions and the relative amounts of the components of the mixture were the same as in the investigation of the mixture of o-xylene and benzene. The m-xylene used boiled over the range 137-139°, its density was 0.8634, its refractive index was 1.4975, and its sulfonatability was 100%. Analysis of the m-xylene by side-chain oxidation with formation of benzenedicarboxylic acids showed that the original xylene contained a little of the para isomer.

It was shown that at 5 atm the yield of catalyzate was 96.9%, and 0.09% of gas and 0.9% of coke were obtained. The toluene content of the catalyzate was 17.4%. The results obtained with m-xylene were very close to those obtained for o-xylene. Increase of the pressure to 15 atm resulted in maximum toluene formation, and the toluene content of the catalyzate then attained 28-31%.

The process was characterized by the occurrence of two main reactions: dealkylation of xylene with transfer of the methyl group to the benzene molecule, and interrelated alkylation and dealkylation of the xylene molecule. Under optimum conditions the yield of catalyzate was 94-95%, and 1.7-2.3% of gas and 1.9-2.2% of coke were obtained. The boiling limit of the catalyzate was 164°. Unsaturated hydrocarbons were absent, and the sulfonatability was 100%. The gas formed in the process consisted of methane and hydrogen.

Dealkylation of Polymethylbenzenes with Simultaneous Alkylation of Benzene

We investigated also dealkylation coupled with alkylation in a mixture of polymethylbenzenes and benzene. We studied the effect of temperature and pressure, and we established the optimum values of the parameters for toluene formation. Both a wide polymethylbenzene fraction and also its individual narrow fractions were used in the experiments. In the wide polymethylbenzene fraction there was 2.3% of toluene, 48.8% of a xylene fraction, and about 10-12% of a trimethylbenzene fraction. The amount of higher-boiling polymethylbenzenes varied over the range 20-25%. The sulfonatability of the original material was 100%, and its iodine value was zero.

The results of experiments on the catalytic treatment of a mixture of benzene and the wide polymethylbenzene fraction at a pressure of 15 atm, velocity of 0.5 : 1, duration of cycle of one hour, and weight ratio

of benzene to polymethylbenzene of 2 : 1 showed that at 450° a single passage of the mixture over the catalyst results in the formation of 96.7% of catalyzate, 1.8% of coke, and 0.2% of gas.

Toluene, which is obtained in 7.8% yield, is formed mainly on account of the conversion of polymethylbenzenes, but partly also by simultaneous alkylation of benzene. Rise in temperature to 500° results in increase in the yield of toluene, which is formed by the dealkylation and interrelated alkylation of the original aromatic hydrocarbons. At 525° the yield of toluene was 21.6%. The contents of the benzene and xylene fractions in the catalyzate were 58% and 9.6%, respectively. The yields were 94.8% of catalyzate, 2.4% of coke, and 1.8% of gas. Raising the temperature to 550°, although increasing the toluene content to 23.8%, gives comparatively high yields of coke (3.6%) and gas (3.2%) and a correspondingly lower yield of catalyzate (92.4%), so that, on the whole, the characteristics of the process are worsened. On the basis of this investigation it was established that the optimum temperature for the reaction under consideration lies in the range 500-525°.

The next series of experiments were carried out with the aim of determining the effect of pressure on the characteristics of the process. The experiments were carried out at the optimum temperature of 525°, at a velocity of 0.5 : 1, and at a cycle time of one hour. These experiments showed that some dealkylation of xylenes occurred at atmospheric pressure. The toluene content was increased from 1.8% in the raw material to 5.5% in the catalyzate. Benzene did not take part in the reaction, and the amount present remained almost unchanged. The contents of xylene and higher-boiling polymethylbenzenes fell somewhat. The residue in rectification fell from 6.1% in the raw material to 2.3% in the catalyzate. The boiling limit fell from 200° to 173°.

Increase in pressure up to 5 atm increases the rate of the reaction of demethylation of polymethylbenzenes with simultaneous methylation of benzene. The contents of benzene, xylene, and polymethylbenzene fractions are appreciably reduced. The amount of toluene in the catalyzate is 15.7%, and unsaturated hydrocarbons are absent. The maximum effect is attained at pressures of 10 and 15 atm. The toluene content of the catalyzate increases to 20.5-21.6%. Almost complete conversion of the polymethylbenzenes occurs. The benzene and xylene contents are reduced from 63.8% and 15.8%, respectively, in the raw material to 58-59% and 9-10% in the catalyzate. The boiling limit of the catalyzate is 159-162°. The toluene obtained is fully in accord with the standard specification. The use of still higher pressures (20-25 atm) has no effect on the quality of the catalyzate, but the yields of coke and gas are somewhat increased.

Investigations were carried out also on the conversion of individual fractions of the polymethylbenzenes in presence of benzene. It was shown that catalytic treatment of a mixture of a xylene fraction of b.p. 125-150° with benzene in the weight ratio of 1 : 2 at 525° and 1 atm results in insignificant formation of toluene. The toluene content was increased from 0.3% in the raw material to 3.9% in the catalyzate. There was some rise in the upper boiling limit of the catalyzate, due, no doubt, to the formation of a small amount of trimethylbenzenes by dismutation of xylene. The yields of catalyzate, coke, and gas were 97.6, 0.88, and 0.36%, respectively. Increase in pressure to 10 atm resulted in an increase of the toluene content of the catalyzate to 24.6%. The contents of benzene and xylene fractions were reduced from 57.0% and 35.8%, respectively, in the raw material to 50% and 19% in the catalyzate. The yield of catalyzate (% by weight on the raw material) was 95%, and the yields of coke and gas were 1.8% and 2.1%, respectively. The gas consisted mainly of methane (90-93% by volume) and hydrogen (7-10% by volume). The maximum effect was attained at 15 and 20 atm. The toluene content of the catalyzate was then 26.3-27%. In other respects the results were essentially the same as in the experiments carried out at 10 atm.

In all experiments, irrespective of pressure, the formation of a little methylated benzene of high boiling point was observed, and the presence of this resulted in the raising of the upper boiling limit from 142° to 164° and in an increase in the yield of the rectification residue from 1.1% to 2.2%.

The following series of experiments was carried out with a high-boiling polymethylbenzene fraction. Fractionation data indicated that this fraction contained 30.5% of trimethylbenzenes (160-172° fraction), 11.5% of tetramethylbenzenes (190-205° fraction), and 45% of penta- and hexa-methylbenzenes, boiling above 205°. From the results of experiments carried out with the high-boiling polymethylbenzene fraction it follows that a considerable part of this is converted into xylenes and toluene at atmospheric pressure. The boiling limit is lowered to 185°. The toluene and xylene contents of the catalyzate are 9% and 6%, respectively. At 5 atm the yield of toluene increases to 14.3%, and that of the xylene fraction to 8.1%. As a result of the transformations of the high-boiling fractions, the amount of residue is reduced from 13% in the

raw material to 3% in the catalyzate.

The catalyzates obtained in the experiments at 10 and 15 atm did not differ appreciably in quality. The toluene content was 17-18%. The yields of catalyzate, coke, and gas varied within the ranges 92.4 to 83%, 3.5-3.6%, and 2.0-2.1%, respectively. Increase in pressure to 20 atm resulted in a rise in the content of toluene to 21% and in the content of xylenes to 6.6%. The yields of catalyzate, coke, and gas were 91%, 4.2%, and 2.8%, respectively. Further increase in pressure to 30-40 atm had practically no effect on the quality of the catalyzate, but caused some increase in the yields of gas and coke. Hence, under the selected conditions of temperature and rate of passage of raw material, the optimum pressure is 15-20 atm.

SUMMARY

1. The catalytic treatment of a mixture of benzene, xylenes, and other polymethylbenzenes in presence of synthetic aluminosilicates is accompanied by dealkylation reactions and alkyl-transfer reactions leading to the formation of toluene in appreciable amount. The extent to which each of these reactions participitates in the process is found to be directly related to the value of the applied pressure.

2. The use of an elevated pressure is of decisive importance for maximum formation of toluene. With increase in pressure the yield of toluene increases, attaining a maximum in the range 10-20 atm. The optimum conditions for the reaction were determined.

3. The predominant reaction resulting in the formation of toluene at elevated pressure is demethylation of xylenes and polymethylbenzenes with simultaneous methylation of benzene. A small part is played in the formation of toluene by the migration of methyl groups of xylenes with formation also of trimethylbenzenes. The readiness with which methyl groups are eliminated tends to increase as their number in the benzene nucleus increases.

4. In the reaction of coupled alkylation and dealkylation in a mixture of benzene and o-xylene, isomeric transformation of o-xylene into the meta and para isomers occurs.

SYNTHESIS OF ALIPHATIC ALCOHOLS FROM THIOPHENE AND ITS HOMOLOGS*

Ya. L. Goldfarb and P. A. Konstantinov

As shown previously [1-7], the action of Raney nickel on thiophene derivatives can be used as a method for the preparation of aliphatic compounds. This method may be particularly useful when other methods for the synthesis of such compounds are not readily accessible. In the present investigation this is demonstrated for the case of the preparation of higher alcohols, including branched-chain alcohols having one or two quaternary carbon atoms.

For the preparation of the original thiophene compounds having sufficiently long carbon chains we used two methods: 1) the synthesis of alkylthiophenes having the necessary number of carbon atoms and the subsequent introduction of a functional group, and 2) the synthesis of 2,2'-methylenedithiophene derivatives and their formylation.

By formylation [8] 2-butylthiophene was converted into the previously unknown 5-butyl-2-thiophenecarboxaldehyde (I). In the same way we synthesized 2,5-di-tert-butyl-3-thiophenecarboxaldehyde (II), 5-tert-butyl-2-methyl- or 2-tert-butyl-5-methyl-3-thiophenecarboxaldehyde (III), and 5-tert-butyl-2-thiophenecarboxaldehyde (IV) from the corresponding substituted thiophenes.

It must be pointed out that the 3-carboxaldehydes are obtained in lower yields than the 2-carboxaldehydes. For example, the yield of the aldehyde (I) was 80%, whereas the yield of the aldehyde (II) was not more than 36% on the amount of 2,5-di-tert-butylthiophene that reacted. It is noteworthy that an attempt to formylate 3,5-di-tert-butyl-2-methylthiophene was not successful, probably owing to the screening of the 4-position by two very bulky tert-butyl groups.

As starting material for the preparation of decyl and undecyl alcohols we used 5-methyl-2-thienyl 2-thienyl ketone (V), which was synthesized by the acylation of thiophene with 5-methyl-2-thiophenecarbonyl chloride. When subjected to Kizhner reduction, the ketone (V) gave 5-methyl-2,2'-methylenedithiophene (VI). This fact conflicts with the conclusions of Löfgren and Tegner [9], who asserted that di-2-thienyl ketone cannot be reduced by the Kizhner method.

* Author's Certificate No. 100, 411 (April 19, 1955).

By the formylation of (VI) we obtained 5-(5-methyl-2-thenyl)-2-thiophenecarboxaldehyde (VII). It is notable that the molecular refraction found for the aldehyde (VII) is considerably greater than the calculated value. This may be due to the occurrence of the tautomeric equilibrium:

In this connection we must refer to a recently published paper [10] which rejects the widely held view that aldehydes form only traces of the enol form.

The Raney nickel required for the reaction was prepared by the method of Adkins and Billica [11]. In the treatment of the original carbonyl compound with this product, not only desulfurization occurred, but also hydrogenation of double bonds and reduction of the aldehyde or, in some cases, keto group. In this connection it must be pointed out that the available data on the behavior of ketones and keto acids in presence of Raney nickel under conditions similar to those described in the experimental part indicate that the reactions occurring are somewhat complex.

In some cases the secondary alcohol that is formed, at first may be subjected to further action by the catalyst and undergo dehydrogenation, which, as Paul showed [12], may occur at a comparatively low temperature. Hence, the fact that a compound having a C=O function may be formed during a hydrogenolysis treatment cannot always be ascribed to the preservation of the compound first formed. Available data enable us to come to the general conclusion that the nature of the product formed by the action of Raney nickel depends not only on the character of the original compound, but also on the type of solvent, the method of preparing the catalyst, the amount of catalyst, and the duration of its action.

Papa and coworkers [13] consider that, in those cases in which the C=O group is conjugated with the system of double bonds of the aromatic nucleus, reduction gives the corresponding hydrocarbons; otherwise, the process comes to an end at the secondary alcohol stage. Later, the same investigator showed [6] that, depending on the reaction conditions, 3-(2-thenoyl)propionic acid gives either 5-oxooctanoic acid or the corresponding lactone.

In work on the action of Raney nickel, Paul [12] finds that ketones do not appear to react in presence of this catalyst. This is in accord with the results of Blicke and Sheets [14], which indicate that phenyl 2-thienyl ketone gives only valerophenone; it is in accord also with the results of Hurd and Rudner [15], which show that the hydrogenolysis of methyl 2-thienyl ketone gives 2-hexanol together with small amounts of ethanol and acetaldehyde.

Under the conditions described in the experimental part, the aldehyde (I) gave nonyl alcohol (VIII) in 65% yield. Under similar conditions, the aldehyde (II) gave 5,5-dimethyl-2-neopentyl-1-hexanol (IX), but 2,5-di-tert-butyl-3-thienyl methyl ketone (X) could not be completely desulfurized even after the prolonged action of Raney nickel.•

The aldehyde (IV) gave 6,6-dimethyl-1-heptanol (XI). The analysis and molecular refraction of this alcohol corresponded to the calculated values, but we did not succeed in preparing a phenyl- or naphthyl-urethan from it in a crystalline state.••

When heated with Raney nickel, the ketone (V) gave 5-decanol (XII), which gave a naphthylurethan melting at 58°. This alcohol has been prepared by Woods and Lederle [16] from 2,4-pentadienal and pentadienylmagnesium

• Boiling under reflux for 17 hours.

•• This aldehyde was synthesized by the formylation of 2-tert-butylthiophene, which we prepared by the method of Goldfarb and Korsakova [17], and also by Caesar's method [18]. The semicarbazone of this aldehyde melted at 215-216°, which agrees with Messina's result, but not with results of Sy and Buu-Hoi [7], who give m.p. 246°.

chloride with subsequent Ponndorf reduction.

(XI) (XII)

According to these authors the naphthylurethan derived from 5-decanol melts at 56°.

As would be expected, the compound formed by the hydrogenolysis of the aldehyde (VII) was found to be undecyl alcohol, this being confirmed by comparing the melting point of its phenylurethan with that of the similar compound obtained from an authentic sample of undecyl alcohol.

Hydrogenolysis of the aldehyde (III) gave an alcohol of composition $C_{10}H_{22}O$, which was probably 2-ethyl-5,5-dimethyl-1-hexanol:

However, as the structure of the original aldehyde (III) cannot be considered to be completely established, the question of the structure of this alcohol must be regarded as an open one.

EXPERIMENTAL

5-Butyl-2-thiophenecarboxaldehyde. A mixture of 44.6 g (0.33 mole) of N-methylformanilide and 50.5 g (0.33 mole) of phosphoryl chloride was prepared in a flask fitted with stirrer, dropping funnel, calcium chloride tube, and thermometer. The mixture was stirred for 30 minutes. When the temperature had fallen to 25°, 42 g (0.3 mole) of 2-butylthiophene was added at such a rate that the temperature remained within the range 25-35°. The contents of the flask were then stirred for three hours.

On the next day the mixture was poured onto ice. The floating layer of dark-colored oil was separated, and the aqueous layer was extracted with ether. The ether extract was combined with the organic layer and washed with 10% hydrochloric acid, bicarbonate solution, and water. The solution was dried with magnesium sulfate, solvent was driven off, and distillation then gave 42.7 g of impure aldehyde, b.p. 138-146° (22 mm) and n_D^{20} 1.5493, and about 2 g of resinous residue.

Refractionation gave 40.6 g (80%) of product, b.p. 143-146° (22 mm); n_D^{20} 1.5490; d_4^{20} 1.0557; found MR 50.34; calculated MR 50.68.

Found %: C 64.47, 64.58; H 7.25, 7.35; S 18.57, 18.79. $C_9H_{12}OS$. Calculated %: C 64.24; H 7.20; S 19.05.

After being recrystallized from aqueous alcohol, the oxime of 5-butyl-2-thiophenecarboxaldehyde melted at 61-62°.

Found %: C 58.79, 58.81; H 7.06, 7.02. S 17.75, 17.42. $C_9H_{13}NOS$. Calculated %: C 59.01; H 7.10; S 17.54.

5-Methyl-2-thienyl 2-Thienyl Ketone. A mixture of 36.4 g (0.218 mole) of 5-methyl-2-thiophenecarbonyl chloride, 18.3 g of thiophene, and 20 ml of dry benzene was prepared in a flask fitted with mercury-sealed stirrer, thermometer, calcium chloride tube, and dropping funnel. The solution was cooled to 0°, and 21.4 ml (0.18 mole) of freshly distilled stannic chloride was added dropwise. The mixture was stirred for a further period of one hour at room temperature, and it was then treated with 10% hydrochloric acid. The benzene layer was separated, washed with water, and dried with anhydrous magnesium sulfate. Vacuum distillation (6 mm) of the reaction product gave

Fraction I, b.p. to 185°; a few drops
Fraction II, b.p. 185-186; 38 g
Residue 0.5 g

Refractionation of Fraction II gave 37.1 g (82%) of 5-methyl-2-thienyl 2-thienyl ketone, m.p. 46-48°, raised by recrystallization from 70% alcohol to 48.5-50°.

Found %: C 57.53, 57.53; H 3.86, 3.97; S 30.71, 30.90. $C_9H_8OS_2$. Calculated %: C 57.70; H 3.84; S 30.77.

After recrystallization from aqueous alcohol, the oxime of this ketone melted at 98-99°.

Found %: N 6.12, 6.22. $C_9H_9NOS_2$. Calculated %: N 6.27.

5-Methyl-2,2'-methylenedithiophene. A mixture of 12.2 g (0.06 mole) of 5-methyl-2-thienyl 2-thienyl ketone, 12 ml of 85% hydrazine hydrate, and 70 ml of diethylene glycol was heated to 50-60°, and 12 g (0.2 mole) of potassium hydroxide was added. The mixture was heated until gas ceased to be evolved (about four hours). The 5-methyl-2,2'-methylenedithiophene was then distilled off with superheated steam. The distillate was extracted with ether, the extract was washed – first with dilute hydrochloric acid, then with sodium bicarbonate solution, and finally with water – and was then dried over calcium chloride. Vacuum distillation (6 mm) of the reaction product gave

Fraction I, b.p. to 115°; a few drops
Fraction II, b.p. 116-117°; 7.9 g (61%)
Residue 2.1 g of resin

Refractionation of Fraction II gave 6.7 g of 5-methyl-2,2'-methylenethiophene, b.p. 116-117° (6 mm); n_D^{20} 1.5946; d_4^{20} 1.1616; found MR 56.77; calculated MR 56.11.

Found %: C 61.85; H 5.25; S 32.97. $C_9H_{10}S_2$. Calculated %: C 61.90; H 5.15; S 32.97.

5-(5-Methyl-2-thenyl)-2-thiophenecarboxaldehyde. Reaction between 6.4 g (0.033 mole) of 5-methyl-2,2'-methylenedithiophene, 8.4 g (0.062 mole) of N-methylformanilide, and 9.4 g (0.062 mole) of phosphoryl chloride gave 2.7 g of unchanged 5-methyl-2,2'-methylenedithiophene and 3.3 g (44%) of 5-(5-methyl-2-thenyl)-2-thiophenecarboxaldehyde. b.p. 156-158° (3 mm); n_D^{20} 1.6218; d_4^{20} 1.2256; found MR 63.76; calculated MR 60.74.

Found %: C 59.32, 59.58; H 4.54, 4.65; S 28.71, 28.56. $C_{11}H_{10}OS_2$. Calculated %: C 59.42; H 4.53; S 28.84.

After two recrystallizations from 80% alcohol, the oxime of the aldehyde melted 119.5-121°.

Found %: N 5.7. $C_{11}H_{11}NOS_2$. Calculated %: N 5.9.

5-tert-Butyl-2-thiophenecarboxaldehyde. Reaction between 21 g (0.15 mole) of 2-tert-butylthiophene, 20.2 g (0.15 mole) of N-methylformanilide, and 23 g (0.15 mole) of phosphoryl chloride gave 24.5 g of a product, which was fractionated at 25 mm:

Fraction I, b.p. to 135°; a few drops
Fraction II, b.p. 135-136°; 23.6 g (91%); n_D^{26} 1.5441.
Residue in flask 0.9 g

After being recrystallized twice from ethanol, the semicarbazone of the aldehyde melted at 215-216°.

2,5-Di-tert-butyl-3-thiophenecarboxaldehyde. Formylation was carried out at 55-60°, the reactants being 49 g (0.25 mole) of 2,5-di-tert-butylthiophene, 40.5 g (0.3 mole) of N-methylformanilide, and 46 g (0.3 mole) of phosphoryl chloride. Two layers formed toward the end of the reaction: the upper layer was light-colored, and the lower layer was brown. The following fractions were obtained:

Fraction I, b.p. 115-117° (30 mm); 35.6 g of original 2,5-di-tert-butylthiophene
Fraction II, b.p. 117-132° (30 mm); 1.1 g
Fraction III, b.p. 132-141° (10 mm); 12.4 g
Residue 1.6 g

Fraction III was refractionated at 10 mm:

Fraction I, b.p. 132-141°; 1.94 g
Fraction II, b.p. 144-145.5°; 8.2 g (36%, on the amount of 2,5-di-tert-butylthiophene that reacted); n_D^{20} 1.5368; d_4^{20} 1.0139; found MR 69.08; calculated MR 68.57.

Found %: C 69.43, 69.46; H 8.86, 9.02; S 14.15, 14.28. $C_{13}H_{20}OS$. Calculated %: C 69.61; H 8.99; S 14.27.

After three recrystallizations from aqueous alcohol, the oxime of the aldehyde melted at 131-132°

Found %: N 5.68, 5.75. $C_{13}H_{21}OS$. Calculated %: N 5.86.

5-tert-Butyl-2-methyl- or 2-tert-Butyl-5-methyl-3-thiophenecarboxaldehyde. Formylation was carried out at 55-60°, the reactants being 26 g (0.17 mole) of 2-tert-butyl-5-methylthiophene, 27 g (0.2 mole) of N-methylformanilide, and 30.6 g (0.2 mole) of phosphoryl chloride. From the residue from ether recovery, 29 g of bisulfite compound was prepared. This was decomposed, and fractionation then gave:

Fraction I, b.p. 96° (4 mm); 0.3 g; n_D^{20} 1.5350
Fraction II, b.p. 96-97° (4 mm); 9.2 g; n_D^{20} 1.5350
Residue 0.4 g

Found %: C 66.04, 65.92; H 7.88, 7.77; S 17.60. $C_{10}H_{14}OS$. Calculated %: C 65.89; H 7.74; S 17.59.

For Fraction II d_4^{20} 1.0553; found MR 54.48; calculated MR 54.25. After being recrystallized from alcohol, the semicarbazone of this aldehyde melted at 215.5-217°.

Found %: N 17.60, 17.61. $C_{10}H_{15}NOS$. Calculated %: N 17.60.

Preparation of Nonyl Alcohol. A solution of 11 g (0.065 mole) of 5-butyl-2-thiophenecarboxaldehyde in 700 ml of 96% ethanol was prepared in a flask fitted with mercury-sealed stirrer and reflux condenser. It was heated to 60°, and 50 g of Raney nickel was added. The mixture was boiled and stirred for one hour. When the mixture was cool, the catalyst was filtered off and washed repeatedly with hot alcohol. Alcohol was distilled off, the residue was cooled, and 150 ml of water was added. The upper layer was separated, and the lower, aqueous layer was extracted with chloroform. The organic layer was combined with the chloroform extracts and dried over magnesium sulfate. Chloroform was distilled off, and vacuum distillation (14 mm) of the residue gave:

Fraction I, b.p. 137-138°, 5.14 g (yield 65%)
Residue 0.9 g

After refractionation the product still boiled at 137-138°, and it had n_D^{20} 1.4335; d_4^{20} 0.8305; found MR 45.22; calculated MR 45.29.

Found %: C 74.98, 75.10; H 13.92, 13.92. $C_9H_{20}O$. Calculated %: C 75.24; H 13.97.

After being recrystallized from 95% alcohol, the phenylurethan prepared from Fraction I melted at 59.5-60°.

Found %: N 5.56, 5.54. $C_{16}H_{25}O_2N$. Calculated %: N 5.52.

A mixture of this with the phenylurethan prepared from an authentic sample melted at 61-62°. For this urethan the literature [20] gives m.p. 62.

Preparation of 5-Decanol. A mixture prepared by the method indicated from 35 g of Raney nickel and 7 g (0.033 mole) of 5-methyl-2-thienyl 2-thienyl ketone in 350 ml of alcohol was vacuum-fractionated and gave the fractions:

Fraction I, b.p. 90-101° (26 mm); 0.6 g
Fraction II, b.p. 101-102° (25 mm); 2.9 g

When refractionated, Fraction II came over at 111-113° and had n_D^{27} 1.4312; n_D^{20} 1.4335; d_4^{20} 0.82766; found MR 49.73; calculated MR 49.90.

Found %: C 75.65, 76.03; H 14.15, 14.26. $C_{10}H_{22}O$. Calculated %: C 75.87; H 14.01.

After being recrystallized from hexane and alcohol, the 1-naphthylurethan melted at 57-58°.

Found %: N 4.38, 4.51. $C_{21}H_{29}O_2N$. Calculated %: N 4.28.

According to the literature [16], 5-decanol has the following constants: b.p. 118-120° (30 mm); n_D^{27} 1.4321. The reported melting point of its 1-naphthylurethan is 56°.

Preparation of Undecyl Alcohol. A solution of 2.9 g (0.012 mole) of 5-(5-methyl-2-thenyl)-2-thiophenecarboxaldehyde in 200 ml of ethanol was boiled with 15 g of Raney nickel. Fractionation of the reaction product gave the following fractions:

Fraction I, b.p. to 130° (15 mm); 0.1 g
Fraction II, b.p. 130-131° (15 mm); 1.24 g
Residue 0.2 g

Fractions I and II had identical constants: n_D^{23} 1.4400; d_4^{20} 0.8368; found MR 54.27; calculated MR 54.52; yield 64%.

Found %: C 76.47, 76.33; H 13.79, 13.64. $C_{11}H_{24}O$. Calculated %: C 76.67; H 14.03.

After being recrystallized from alcohol, the phenylurethan prepared from Fraction II melted at 61-62° and showed no depression when melted in admixture with the phenylurethan prepared from an authentic sample of undecyl alcohol.

Found %: N 4.79. $C_{23}H_{29}O_2N$. Calculated %: N 4.80.

According to the literature [21], undecyl alcohol boils at 147° (25 mm) and gives a phenylurethan of m.p. 62°.

Preparation of 6,6-Dimethyl-1-heptanol. A solution of 7 g (0.041 mole) of 5-tert-butyl-2-thiophenecarboxaldehyde in 350 ml of ethanol was boiled with 35 g of Raney nickel for four hours. Distillation of the product gave 3.6 g of liquid of b.p. 86-88° (12 mm). When refractionated, the product boiled at the same temperature: n_D^{20} 1.4430; d_4^{20} 0.8439; found MR 45.32; calculated MR 45.28.

Found %: C 74.65; H 13.76. $C_9H_{20}O$. Calculated %: C 74.91; H 13.67.

Preparation of 5,5-Dimethyl-2-neopentyl-1-hexanol. A mixture of 7.8 g (0.031 mole) of 2,5-di-tert-butyl-3-thiophenecarboxaldehyde, 400 ml of ethanol, and 40 g of Raney nickel was boiled for five hours. Vacuum fractionation of the product gave a few drops of liquid boiling up to 125-126° (27 mm) and 4 g (58%) of liquid of b.p. 125-126° (27 mm). Refractionation did not affect the boiling point. The liquid had n_D^{20} 1.4488; d_4^{20} 0.84705; found MR 63.42; calculated MR 63.76.

Found %: C 77.97, 77.69; H 14.20, 14.08. $C_{13}H_{28}O$. Calculated %: C 77.92; H 14.08.

The naphthylurethan was prepared from the distilled alcohol and was recrystallized from hexane and alcohol; it then melted at 110.5-112°.

Found %: N 4.26, 4.23. $C_{34}H_{35}O_2N$. Calculated %: 3.78.

Action of Raney Nickel on 5-tert-Butyl-2-methyl- or 2-tert-Butyl-5-methyl-3-thiophenecarboxaldehyde. The product obtained from 5.5 g of the aldehyde, 400 ml of ethanol, and 55 g of Raney nickel was vacuum-distilled (13 mm) and came over at 92-93°, 3.1 g being obtained. Refractionation did not affect the boiling point: n_D^{20} 1.4350; d_4^{20} 0.8386; found MR 49.57; calculated MR 49.90.

Found %: C 75.75, 75.84; H 14.18, 14.03. $C_{10}H_{22}O$. Calculated %: C 75.86; H 14.07.

After being recrystallized from hexane and 70% alcohol, the phenylurethan prepared from this alcohol melted at 62-63°.

Found %: N 4.25, 4.33. $C_{21}H_{29}O_2$. Calculated %: N 4.28.

SUMMARY

1. The following thiophene derivatives were prepared: 5-methyl-2-thienyl 2-thienyl ketone, 5-methyl-2,2'-methylenedithiophene, 5-(5-methyl-2-thenyl)-2-thiophenecarboxaldehyde, 5-butyl-2-thiophenecarboxaldehyde, 5-tert-butyl-2-methyl- or 2-tert-butyl-5-methyl-3-thiophenecarboxaldehyde, 2,5-di-tert-butyl-3-thiophenecarboxaldehyde.

2. By the action of Raney nickel of 5-methyl-2-thienyl 2-thienyl ketone, 5-(5-methyl-2-thenyl)-2-thiophenecarboxaldehyde, 5-butyl-2-thiophenecarboxaldehyde, 5-tert-butyl-2-methyl- or 2-tert-butyl-5-methyl-3-thiophenecarboxaldehyde, 2,5-di-tert-butyl-3-thiophenecarboxaldehyde, and 5-tert-butyl-2-thiophenecarboxaldehyde we were able to prepare the following aliphatic alcohols: 5-decanol, 1-undecanol, 1-nonanol, 5,5-dimethyl-2-ethyl-1-hexanol (or 4,4-dimethyl-2-propyl-1-pentanol), 5,5-dimethyl-2-neopentyl-1-hexanol, and 6,6-dimethyl-1-heptanol.

3. An attempt to bring about the hydrogenolysis of 2,5-di-tert-butyl-3-thienyl methyl ketone over Raney nickel W-5 did not give the desired results.

PHYSICAL PROPERTIES OF SOME ISODURENE HOMOLOGS

A. L. Liberman, M. A. Pryanishnikova and B. A. Kazansky

There are no reliable data in the literature on the physical properties of homologs of isodurene [1,2,3,5-tetramethylbenzene]. Even for the closest homolog of isodurene, ethylmesitylene, the available information is very contradictory, as can be seen from Table 1. There can be no doubt that the preparations were of low purity, and only for one of them (No. 13) can the results be regarded as more or less reliable. For this preparation the freezing point was determined, and the authors [13] consider that the purity of their sample was not less than 97.5%. Unfortunately, however, the density of this comparatively pure sample was determined in a rather crude fashion – on the Westphal balance, accurate only within 0.001 g/cc. The constants of the next homolog, propylmesitylene, are given in only two papers, which appeared more than fifty years ago (b.p. 220-221°; d^{20} 0.8773 [2]; b.p. 221°; d_4^{25} 0.8757; n_D^{25} 1.5009 [14]), and these papers give no data that would permit an estimate of the purity of the preparations.

TABLE 1

Constants of Ethylmesitylene (Data from the Literature)

Preparation No.	B.p. in °C (p in mm)	M.p. (°C)	d_4^t	n_D^{20}	Literature ref.

10	207—209(750)	—	—	—	[10]
11	95—96(18)	—	—	1.5071 at 19°	[11]
12	212,4(760)	−15.5	0,883 at 20°	1.5074	[12]
13	88.5(11.8) 107.0(28) 210.2(760)	−12.2	0.888 at 18°	1.5101	[13]

In the course of work proceeding in our laboratory on the synthesis of aromatic hydrocarbons for use in a study of their Raman Spectra [15], we have synthesized the above-mentioned isodurene homologs and also allylmesitylene. As we established the degree of purity of our preparations, it was possible to determine the constants of these hydrocarbons with some precision. We therefore considered it desirable to publish our values for these constants and to give details of the synthesis and purification of our preparations.

Ethylmesitylene was prepared by Smith and Kiess's method [8], a Grignard reagent prepared from bromomesitylene being treated with diethyl sulfate:

Propylmesitylene was prepared similarly, but propyl p-toluene sulfonate was used instead of diethyl sulfate. In the preparation of allylmesitylene, allyl chloride was brought into reaction with the Grignard reagent.

In the synthesis of these hydrocarbons, measures were taken with the object of obtaining them in as pure a form as possible, not only the hydrocarbons themselves being purified carefully, but also the bromomesitylene that served as starting material for all three syntheses. The course of the purification was checked by freezing point determinations. As a result, the purified preparations contained only 0.3-1.1 mole % of impurities. The physical properties of the substances obtained are given in Table 2.

TABLE 2

Physical Properties of the Substances Prepared in this Investigation

	B.p. in °C (p in mm)	Freezing point (°C)	n_D^{20}	n_D^{25}	d_4^{20}	d_4^{25}	Cryoscopic const. (mole fraction/°C)	Purity from cooling curve (mole %)

R = C_3H_5	99.3(20)	—12.1	1.5103	1.5080	0.8859	0.8824	0.017	99.7
R = C_3H_7	100.2(11.7)	—20.5	1.5052	1.5029	0.8782	0.8744	0.021	99.7
R = C_3H_5	105.5(16)	—2.1*	1.5194	—	0.8989	—	0.023	98.9

* In one of our previous papers on the study of Raman Spectra [15], as a result of a misprint, the freezing point was given incorrectly as 2.1°.

A comparison of our data with those in the literature permits us to conclude that most of the previously described preparations of ethylmesitylene were indeed highly contaminated; even the preparation cited in the latest edition of Rossini's book [12] contained about 6 mole % of impurities. On the other hand, the preparation obtained by Buck and coworkers [13] was, according to its freezing point, even purer than the authors claimed; in any case, its degree of purity was not less than 99.2%. As would be expected, the constants they gave are very similar to ours. The data in the literature on propylmesitylene are inadequate for comparison purposes. We are the first to prepare allylmesitylene, and its constants have not been given previously in the literature.

EXPERIMENTAL

Bromomesitylene. We prepared bromomesitylene by the bromination of mesitylene (890 g) in carbon tetrachloride at low temperature [16] in 80% yield. The final purification of the bromomesitylene was effected by two recrystallizations from ether at −30°; the constants of the product are given in Table 2. Its cooling curve is shown in Fig. 1. The values given in the literature for the constants of bromomesitylene refer to products of much lower purity.

Ethylmesitylene. A solution of 155 g (0.77 mole) of bromomesitylene and 11.1 g (0.10 mole) of ethyl bromide in 780 ml of absolute ether was added with stirring to 21.2 g (0.88 g-atom) of magnesium in an atmosphere of nitrogen (the reaction was first initiated with a small amount of ethyl bromide), and the mixture was heated for two hours in a water bath. A solution of 240 g (1.55 moles) of diethyl sulfate in 155 ml of absolute ether was

then added to the stirred mixture at 10°, and stirring was continued until the precipitate formed became thick. On the next day, after decomposition with 1 : 1 hydrochloric acid, the ether layer was separated, washed with water, and dried with calcium chloride. The residue remaining after removal of ether was heated with sodium ethoxide, and the hydrocarbon was extracted with ether. Ether was distilled off, and the residue was vacuum-distilled. The hydrocarbon isolated was crystallized from ether at about −60° and was then subjected to chromatography on silica gel. The head fraction contained an appreciable amount of bromomesitylene and was rejected. The main fraction (54.2 g) was vacuum-distilled through a column having an efficiency of about 50 theoretical plates.* The results of the fractionation of ethylmesitylene are given in Table 3 and Fig. 2.

Fractions VII, VIII, and IX were combined and again crystallized from ether. The resulting ethylmesitylene had the constants given in Table 2. Its cooling curve is given in Fig. 1.

Fig. 3. Fractionation curve for propylmesitylene.

Fig. 4. Fractionation curve for allylmesitylene.

99 g (0.48 mole) of bromomesitylene, 14 g (0.58 g-atom) of magnesium, and 7 g (0.06 mole) of ethyl bromide in 350 ml of absolute ether. The reaction mixture was then heated for three hours. On the next day, after the decomposition treatment with ice and 1 : 1 hydrochloric acid, the ether layer was separated, washed with water, and

dried with calcium chloride. Ether was distilled off, and the residue was vacuum-fractionated, the fraction (49 g) boiling within the range 104-130° (39.5 mm) being collected. In all, 130 g of this fraction was obtained in the course of several parallel experiments, and this was then heated with magnesium in ether containing a little ethyl bromide, the object being the removal of residual bromomesitylene. After decomposition of the Grignard reagent and the usual treatment, the hydrocarbon still gave a positive test for bromine, and the purification treatment was repeated, after which a Beilstein test was negative. Part (38.8 g) of the propylmesitylene was then fractionated through a column. The fractionation results are given in Table 4 and Fig. 3. The constants of pure propylmesitylene are given in Table 2, and its cooling curve is given in Fig. 1.

Allylmesitylene. A solution of 76.5 g (1 mole) of allyl chloride in 50 ml of absolute ether was added at 15° to a solution of mesitylmagnesium bromide prepared from 199 g (1 mole) of bromomesitylene (with an addition of 14 g (0.13 mole) of ethyl bromide) and 30 g (1.2 g-atoms) of magnesium in 500 ml of absolute ether. The mixture was stirred at room temperature for a further two hours. On the next day, after decomposition with ice water acidified with acetic acid, the ether layer was separated, washed with water, and dried with calcium chloride. The residue remaining after removal of ether was vacuum-distilled, the fraction (74.4 g) of b.p. 113-136° (68 mm) being collected. Purification from unchanged bromomesitylene was carried out as in the case of propylmesitylene, but the allylmesitylene gave a negative Beilstein test already after the first treatment. A part (44.4 g) of the allylmesitylene was vacuum-fractionated through a column. The results of the fractionation are given in Table 5 and Fig. 4.

Fraction VI was recrystallized from ether at low temperature. The constants of the preparation obtained are given in Table 2, and the cooling curve is shown in Fig. 1. Analysis gave the following results:

Found %: C 89.86, 89.76; H 10.11, 10.03. $C_{12}H_{16}$. Calculated %: C 89.93; H 10.07.

SUMMARY

1. Highly pure (above 99.5%) samples of ethyl- and propyl-mesitylenes were synthesized, and their constants were determined.

2. A sample of about 99% purity of previously undescribed allylmesitylene was synthesized.

EFFICIENCIES OF VARIOUS CATALYSTS IN THE ALKYLATION OF BENZENE WITH PROPENE

Ya.M. Paushkin and M.V. Kurashev

The alkylation reaction has attracted the attention of chemists for a very long time [1]. As benzene homologs have found wide application in industry, interest in this reaction increases with every year. Among the alkylbenzenes that have already found application, particular mention may be made of isopropylbenzene, which is prepared in the petroleum industry as a component of aviation gasoline. In recent years alkylbenzenes have begun to be applied mainly as raw material for the chemical industry in the manufacture of styrene, methylstyrene, phenol, acetone, dicarboxylic acids, synthetic detergents, etc. The field of application of the alkylation of benzene is shown diagrammatically in Fig. 1.

Fig. 1. Field of application of the alkylation of benzene.

The catalysts mainly used at present for the alkylation of benzene with olefins are sulfuric acid, phosphoric acid, aluminum chloride, aluminosilicates, hydrogen fluoride, and the compounds formed by boron trifluoride with water and phosphoric acid [2-7]. More rarely, zinc chloride and other such halides find application [8-10].

The catalysts vary in catalytic activity, and their specificity in the alkylation of benzene with olefins manifests itself in the yield of monoalkylbenzenes, the yield of di- and poly-alkylbenzenes, the formation of polymers, the optimum molar ratio of benzene to olefin, and the volume of the reaction space and ancillary apparatus.

All this, taken as a whole, determines the efficiency of the alkylation process, so that the correct choice of catalyst is of great importance, particularly when we consider the scale on which various alkylbenzenes are manufactured – it attains tens and hundreds of thousands of tons per year. Of the catalysts mentioned above, only phos-

phoric acid (on kieselguhr), sulfuric acid, aluminum chloride, and hydrogen fluoride have as yet found industrial application. Characteristics of processes of alkylation of benzene with propene over various catalysts are given in Table 1.

TABLE 1

Characteristics of Various Processes of Alkylation of Benzene with a Propane-Propene Fraction

Conditions of process	Catalyst	Composition of mixture (%)			Yield (%) of isopropylbenzene
		benzene	alkylbenzene	polyalkylbenzene	
Temperature 15-20° Excess pressure 10 atm $C_6H_6 : C_3H_6$ ratio = 2:1	Sulfuric acid	40	40	20	50
Temperature 180-20° Excess pressure 15-20 atm $C_6H_6 : C_3H_6$ ratio = 10	Phosphoric acid on kieselguhr	46.3	43.4	10.3	58
Temperature 350° Excess pressure 20 atm $C_6H_6 : C_3H_6$ ratio = 5:1	Aluminosilicate				
Temperature 20° Excess pressure 10 atm $C_6H_6 : C_3H_6$ ratio = 2:1	Hydrofluoric acid	46.3	43.4	10.3	58
Temperature 50° Atmospheric pressure $C_6H_6 : C_3H_6$ ratio = 2:1	Aluminum chloride	45	43	12	46
Temperature 50° Atmospheric pressure $C_6H_6 : C_3H_6$ ratio = 2:1	Phosphoric acid with BF_3	44	47	9	76

The comparison of results obtained with various catalysts is difficult in some cases because the experimental conditions are different. However, on the basis of the data in Table 1, we may conclude tentatively that catalysts based on boron trifluoride and orthophosphoric acid are to be preferred. The present paper is devoted to the question of the choice of alkylation catalysts having high alkylating power and to the investigation of catalysts based on boron trifluoride, as being the most promising with respect to activity.

EXPERIMENTAL

1. Alkylation of Benzene with Propene in Presence of the Catalysts $H_2O \cdot BF_3$, $H_3PO_4 \cdot BF_3$, H_2SO_4 and $AlCl_3$. The alkylation of benzene with propene was investigated in a three-necked flask containing benzene and catalyst, which were stirred vigorously while propene was passed into the reaction mixture through a capillary tube. The benzene used in the reaction had d_4^{20} 0.8784; n_D^{20} 1.5010; and m.p. 5.1°, and the propene was prepared by dehydration of isopropyl alcohol over alumina. After separation from the catalyst (and in the case of $AlCl_3 \cdot HSO_4$ and $AlCl_3$, after the decomposition of the catalyst with water), the reaction products were washed, dried, and fractionated from a flask with a column into a benzene fraction, b.p. 80-120°, and a monoalkyl fraction, b.p. 120-170°. The residue, the fraction boiling above 170°, was a mixture of mono-, di-, tri-, and tetraisopropylbenzenes. Also, the monoalkyl fraction (fraction boiling above 120°) was fractionated through a 15-plate column. It was found that the diisopropylbenzene, which was made use of in the reaction in some cases, consisted of the ortho and para isomers.

The catalysts $H_2O \cdot BF_3$ and $H_3PO_4 \cdot BF_3$ were prepared by saturating water and phosphoric acid, respectively, with boron trifluoride in accordance with the usual method [11]. Physical properties of catalysts based on boron trifluoride are given in Table 2.

In Table 3, we give the results of the alkylation of benzene with propene in presence of various catalysts at 50°; 156 g of benzene and 42 g of propene were taken in all cases.

TABLE 2

Characteristics of Catalysts Based on Boron Trifluoride at 20°

Catalyst	Boron trifluoride content		Density	Viscosity (centistokes)	Conductivity ($ohm^{-1}cm^{-1}$)
	found	calculated			
$H_3PO_4 \cdot BF_3$	40.5	40.9	1.9030	43.08	0.00583
88.7% $H_3PO_4 \cdot BF_3$	52.0	51.0	1.8784	16.96	0.01025
$H_2O \cdot BF_3$	78.1	79.0	1.7793	–	0.03507

TABLE 3

Yield of Alkylbenzene Upon Alkylyzation of Benzene with Propene in Presence of Various Catalysts (Molar Ratio of $C_6H_6 : C_3H_6 = 2:1$)

Catalyst	Composition of hydrocarbon layer (%)			Yield of fraction (%)			Consumption of catalyst (%)
	up to 120°	120-170°	above 170°	120-170°	152-153°	above 170°	
$H_3PO_4 \cdot BF_3$	42.0	53.0	5.0	88.0	82.0	8.3	2.9•
88.7% $H_3PO_4 \cdot BF_3$	41.8	53.6	4.6	88.4	82.8	7.6	3.3
$AlCl_3$	46.2	39.2	14.6	64.2	57.7	26.2	10.0
$AlCl_3 \cdot HSO_4$	45.8	32.2	22.0	53.2	49.0	36.3	15.0
$H_2O \cdot BF_3$	40.2	56.8	2.5	93.3	87.8	4.2	15.4
H_2SO_4	43.6	47.6	8.8	78.6	71.1	14.5	22.0

•Under conditions excluding loss of boron trifluoride, the consumption of catalyst was less than 1%.

TABLE 4

Characteristics of the Alkylation of Benzene with Propene in Presence of $H_3PO_4 \cdot BF_3$ and $AlCl_3$ at 50° with Various Benzene : Propene Molar Ratios

Catalyst	Molar ratio benzene : : propene	Composition of hydrocarbon layer			Yield of reaction products (%)		
		up to 120°	120-170°	above 170°	120-170°	152-153°	above 170°
$AlCl_3$	2:1	46.2	39.2	14.6	64.2	57.7	26.2
$AlCl_3$	4:1	68.7	25.7	5.6	75.3	63.3	16.5
$H_3PO_4 \cdot BF_3$	1.5:1	32.0	55.0	13.3	73.0	63.3	17.2
$H_3PO_4 \cdot BF_3$	2:1	42.0	53.0	5.0	88.0	79.0	8.3
$H_3PO_4 \cdot BF_3$	4:1	67.6	29.2	3.2	90.0	79.1	4.0

Values of the consumptions of six catalysts in the alkylation of benzene with propene, as given in Table 3, show that the most efficient catalysts for this reaction are compounds of boron trifluoride with orthophosphoric acid, which are superior to aluminum chloride. A comparison of the action of aluminum chloride with that of the complex formed between orthophosphoric acid and boron trifluoride in the alkylation of benzene with propene for various molar ratios of the reactants (Table 4) confirms our conclusion concerning the high alkylating power of the complex $H_3PO_4 \cdot BF_3$. Thus, similar yields of isopropylbenzene are obtained with $H_3PO_4 \cdot BF_3$ (69.3%) and $AlCl_3$ (63.3%) for benzene : propene molar ratios of 1.5 : 1 and 4 : 1, respectively.

Fractionation curves for the monoalkyl fraction (b.p. above 120°) are given in Fig. 2.

Under comparable experimental conditions, the highest concentration of isopropylbenzene is obtained by the use of catalysts based on boron trifluoride. The results of the investigation show that this catalyst has considerable advantages over aluminum chloride and sulfuric acid, for it increases the yield of isopropylbenzene, while at the same time depressing the formation of polyisopropylbenzenes. The specific action of the catalyst affects the composition of the reaction product, for thermodynamic equilibrium is not attained during the time taken by the reaction. If it were attained, then all catalysts would give the same result as far as the composition of the product is concerned.

Fig. 2. Fractionation of fractions of b.p. above 120° obtained with different catalysts.

Fig. 3. Dependence of the yield of isopropylbenzene (fraction of b.p. 152-153°) on the molar ratio benzene: propene in the alkylation of benzene with propene in presence of various catalysts: 1) $H_3PO_4 \cdot BF_3$; 2) H_2SO_4; 3) $AlCl_3$; 4) $AlCl_3 \cdot H_2SO_4$.

Investigation of the alkylation of benzene with propene in presence of various catalysts with various molar ratios of benzene to propene shows that over the whole range investigated the yield of isopropylbenzene is greatest with a catalyst based on boron trifluoride. The results of the experiments are shown graphically in Fig. 3.

2. The Effects of Various Factors on the Alkylation of Benzene with Propene in Presence of 88.7% of $H_3PO_4 \cdot BF_3$. We studied the effects of various factors on the alkylation of benzene with propene in presence of the catalyst obtained by saturation of the usual 88.7% orthophosphoric acid with boron trifluoride. The composition of the catalyst can be represented as follows: 11.3% $H_2O \cdot BF_3$ + 88.7% $H_3PO_4 \cdot BF_3$. It is actually a solution of $H_2O \cdot BF_3$ in $H_3PO_4 \cdot BF_3$.

As will be seen from these results, as the amount of catalyst taking part in the reaction increases, the yield of isopropylbenzene increases. Thus, when 5% of catalyst is taken, the yield is 71.8%, whereas for 35% of catalyst the yield is already 84.5%. In this case the increase in yield is more than 12%.

The effect of reaction temperature is very marked when it is raised from 20° to 50° (see Table 5). The optimum temperature for the alkylation of benzene with propene in presence of the complex formed between orthophosphoric acid and boron trifluoride is 50°, for further rise in temperature has practically no effect on the yield of isopropylbenzene, but increases the rate at which the catalyst is exhausted. The yield and composition

Fig. 4. Fractionation of alkylated benzene: 1) Fraction of b.p. above 170° ($C_6H_6 : C_3H_6 = 1:1$); 2) Fraction of b.p. above 170° ($C_6H_6 : C_3H_6 = 2:1$); 3) Fraction of b.p. 120-170°.

of the alkylation products is affected appreciably by change in the molar ratio of benzene to propene. Results of an investigation into the effect of variation of the molar ratio of the reactants from 1:1 to 8:1 are given in Table 6.

A favorable condition for this reaction is the use of a large excess of benzene, which helps to suppress reactions of secondary alkylation and polymerization. Whereas a molar ratio of benzene to propene of 1:1 gave a 68.0% yield of the 120-170° fraction and a 32% yield of the fraction boiling above 170°, at a ratio of 8:1 the yields were 92.4% and 7.4%, respectively.

With the object of determining the amounts of the various alkylbenzenes in the reaction product, the latter was fractionated through a 20-plate column. First a fraction boiling up to 120° was collected, then a fraction of b.p. 120-170°, and finally a fraction boiling above 170°. The corresponding fractions from identical experiments were combined and refractionated together with definite amounts of alkylbenzenes of various degress of substitution. Typical fractionation results are shown in Fig. 4. The alkylation product obtained at a 2:1 molar ratio of benzene to propene contained 83.2% of isopropylbenzene, 4.0% of intermediate fractions, consisting of mixtures of benzene, isopropylbenzene, and diisopropylbenzene, and also 12.4% of a fraction that was almost pure diisopropylbenzene. The results were rendered more precise by taking the molecular weights of the intermediate fractions into account, and it was found that the hydrocarbon layer obtained after reaction consisted of 42.84% of benzene and 57.16% of alkylation products. Under the experimental conditions no polymerization of propene was observed.

TABLE 5

Effects of the Amount of Catalyst and of the Reaction Temperature on the Yield and Composition of the Reaction Products in the Alkylation of Benzene with Propene (molar ratio $C_6H_6 : C_3H_6 = 2:1$).

Temperature, °C	Amount of catalyst (% on benzene)	Yield of isopropylbenzene (152-153° fraction (%)	Composition of reaction product (% by weight)		
			up to 120°	120-170°	above 170°
20	15	74.0	43.0	47.3	8.9
50	15	78.0	42.3	49.6	7.3
80	15	78.2	42.0	50.0	7.0

50	25	81.0	41.3	51.5	6.1
50	35	84.5	41.8	52.6	5.0

TABLE 6

Alkylation of Benzene with Propene at Various Molar Ratios of Benzene to Propene

Molar ratio benzene : propene	Yield of fraction (%)			Composition of reaction product (% by weight)		
	120-170°	152-153°	above 170°	up to 120°	120-170°	above 170°
1:1	68.0	67.0	32.0	9.9	68.1	21.5
2:1	82.0	78.0	18.0	42.3	49.6	7.3
4:1	88.0	84.0	12.0	66.7	29.8	2.7
6:1	91.4	85.5	8.6	76.2	21.6	1.3
8:1	92.4	86.0	7.4	81.4	16.6	0.9

TABLE 7

Contents of Various Alkylbenzenes in Alkylation Products Obtained at Various Molar Ratios of Benzene to Propene

Molar ratio benzene : propene	Product	Isopropylbenzenes (%)				Residue	Total
		Mono	Di	Tri	Tetra		
1:1	Monoalkyl fraction	77.1	13.1	7.5	1.8	0.5	100.0
	Polyalkyl fraction	–	57.2	32.8	7.9	2.1	100.0
2:1	Monoalkyl fraction	90.0	9.3	0.7	–	–	100.0
	Polyalkyl fraction	–	93.0	7.0	–	–	100.0

The diisopropylbenzene fraction, b.p. above 170°, was investigated carefully. As can be seen from the fractionation curve (Fig. 4), 72% comes over in the temperature ranges 194-200° and 200-207°, and the curve then has an inflection and gradually rises. This form of curve indicates that the mixture being distilled probably consisted of various isomers of diisopropylbenzene. In order to determine the amounts of the isomers formed more exactly, the 194-200° and 200-207° fractions were collected together and refractionated. The following fractions were obtained:

Fraction I	b.p. 192-202°	1.2%
Fraction II	b.p. 202-204°	90.0%
Fraction III	b.p. 204-207°	2.3%
Fraction IV	b.p. above 207°	6.5%

When adequate amounts of the fractions had been collected, the one-degree fractions of b.p. 203-204° and 210-211° were isolated from them. Fraction of b.p. 203-204° had d_4^{20} 0.8695; n_D^{20} 1.4905; found MR 54.08; calculated MR 54.02; Fraction of b.p. 210-211° had d_4^{20} 0.8565; n_D^{20} 1.4898; found MR 54.51; calculated MR 54.02.

In order to determine the positions of the alkyl groups the fractions were oxidized with potassium permanganate in an alkaline medium. As a result of the oxidation of the fraction of b.p. 203-204° and repeated boiling of the product with water, insoluble crystals, m.p. 300°, were isolated in a yield of 75% on the total amount of acids produced. Oxidation of the fraction of b.p. 210-211° also gave water-insoluble crystals, m.p. 300°, the yield being 99%. The acids so obtained were converted into the dimethyl ester, which melted at 140°. It may be considered to be proved that the dicarboxylic acid was terephthalic acid.

TABLE 8

Effect of Different Catalysts on Yield and Composition of Diisopropylbenzene Fraction (50° $C_6H_6 : C_3H_6 = 2:1$)

Catalyst	Yield of polyisopropylbenzenes (%)	Diisopropylbenzene content of the polyisopropylbenzene fraction (%)	p-Diisopropylbenzene content of the diisopropylbenzene fraction (%)
$AlCl_3$	35	60	30
$AlCl_2 \cdot HSO_4$	54	58	70
H_2SO_4	20	70	75
$H_3PO_4 \cdot BF_3$	10	93	78
$H_2O \cdot BF_3$	6	93	80

The aqueous extracts of the products of the oxidation of the fraction of b.p. 203-204° yielded 25% of white crystals, m.p. 190°, undepressed by admixture of phthalic acid. These crystals therefore consisted of phthalic acid. The amounts of the acids isolated and the relative amounts of the respective fractions indicate that the diisopropylbenzene fraction consisted of 78% of p-diisopropylbenzene and 22% of o-diisopropylbenzene.

From the alkylation product obtained at a molar ratio of benzene to propene of 1:1, a fraction of b.p. 235-237° was isolated; after purification with sulfuric acid, this fraction had the following constants: b.p. 236-237.5°; d_4^{20} 0.8588; n_D^{20} 1.4912; bromine value 0; molecular weight 202.

In order to determine the structures of the triisopropylbenzenes formed in the alkylation of benzene with

propene, the fraction of b.p. 236-237.5° was oxidized with potassium permanganate in an alkaline medium. Oxidation of 18 g of the triisopropylbenzene fraction resulted in the isolation of 10 g of acids, from which, by repeated recrystallization from various solvents (water, ethanol, acetone), 15% of trimesic acid (1,3,5) and 85% of trimellitic acid (1,2,4) were obtained. Also, a tetraisopropylbenzene fraction of b.p. 234-280° and a fraction boiling above 280° were isolated from the alkylation product. The first fraction contained 80% of tetraisopropylbenzene, which melted at 117° after recrystallization from ethanol; this corresponds to 1,2,4,5-tetraisopropylbenzene. The residue - the fraction of b.p. above 280° - was an oily liquid, d_4^{20} 0.8690; n_D^{20} 1.5020; molecular weight 341; bromine value 3.5.

The physicochemical properties of the residue indicate that it consisted of a mixture of hydrodehydropolymerization products of propene and alkylbenzenes.

Table 7 shows the total contents of the various isopropylbenzenes in the alkylation products obtained at various molar ratios of benzene to propene.

In investigating the alkylation of benzene with propene in presence of various catalysts, we paid particular attention to the diisopropylbenzene fraction. We determined the p-diisopropylbenzene content of this fraction. The results are given in Table 8.

It follows from this that catalysts based on boron trifluoride and sulfuric acid direct the isopropyl group largely into the para position.

3. Retardation of the Formation of Polyalkylbenzenes in the Alkylation of Benzene with Propene in Presence of Aluminum Chloride. The alkylation of benzene with propene in presence of aluminum chloride can be regarded as a coupled equilibrium process of alkylation and dealkylation:

$$C_6H_6 + C_3H_6 = xC_6H_5C_3H_7 + yC_6H_4(C_3H_7)_2.$$

TABLE 9

Alkylation of Benzene with Propene in Presence of Added Polyisopropylbenzenes at 50°

Experiment	Reactants and their amounts*	Yield of reaction products (% on propene)			Productivity of reaction space
		Isopropylbenzene 145-160°	Alkylation product 190-270°	Polyisopropylbenzene fraction, b.p. above 280°	alkylation product, kg / reactor volume, liter
1	C_6H_6 — 2.0 C_3H_6 — 1.0 $AlCl_3$ — 15	145	181.2	75.6	0.378
2	C_6H_6 — 4.0 C_3H_6 — 1.0 $AlCl_3$ — 15	177	208	50.0	0.218
3	C_6H_6 — 1.75 C_3H_6 — 1.0 $AlCl_3$ — 15	165	209.8	40.2	0.440
4	C_6H_6 — 1.5 C_3H_6 — 1.0 $AlCl_3$ — 15 $C_{12}H_{18}$ — 0.5	161	221	18.9	0.464
5	C_6H_6 — 1.35 C_3H_6 — 1.0 $C_{12}H_{18}$ — 0.85 $AlCl_3$ — 15	214.4	227.5	61.6	0.476
6	C_6H_6 — 1.1 C_3H_6 — 1.0 $C_{12}H_{18}$ — 0.9 $AlCl_3$ — 15	—	228.7	—13.2	0.480
7	C_6H_6 — 3.0 C_3H_6 — 1.0 $C_{12}H_{18}$ — 1.0 $AlCl_3$ — 15	214	285.9	—46.6	0.316

*Hydrocarbons - in moles; $AlCl_3$ - in percentage; $C_{12}H_{18}$, i.e., diisopropylbenzene - amount expressed as number of moles of benzene replaced by an equivalent amount by weight of $C_{12}H_{18}$.

It would appear that the relative amounts of isopropyl- and diisopropyl-benzenes are determined by the

equilibrium conditions, which depend mainly on the excess of benzene taken for reaction. It was thought that a preliminary addition of diisopropylbenzene to the reaction mixture would displace the equilibrium and hinder the formation of polyisopropylbenzenes from benzene and propene, so that the whole of the propene taken would be used for the formation of the monoalkylbenzene.

For the reaction we took 31-42 g of propene, 117-176 g of benzene, 20-60 g of polyisopropylbenzene, and 15% on the weight of the reaction mixture of commerical aluminum chloride. Propene was passed in from a gas holder at the rate of 1.5-2 liters per hour. The treatment of the reaction mixture was as before. Table 9 gives the results of experiments on the alkylation of benzene with propene at molar ratios $C_6H_6 : C_3H_6$ of 2:1 and 4:1, part of the benzene being replaced by polyisopropylbenzenes in some of the experiments. Experiments 1 and 2 in Table 9 show the effect of molar excess of benzene over propene on the yield of alkylation product (fraction of b.p. 120-170°) and of isopropylbenzene (fraction of b.p. 145-160°): they increase with increase in the amount of benzene.

Increase in the benzene : propene ratio, though resulting in an increased yield of monoalkylbenzene, makes it necessary to distill off a large amount of benzene in order to isolate the alkylation product. As can be seen from the last column of Table 9, the productivity of the reaction space with respect to alkylation product is lowered from 0.379 to 0.218. It follows from Experiments 3-6 that the replacement of 0.25, 0.5, 0.65, and 0.9 mole of benzene by polyisopropylbenzenes results in an increase in the yield of alkylation product from 181% to 228% and in an increase in the yield of isopropylbenzene from 145% to 214%, without change in the volume of the reaction mixture. At the same time, the productivity of the reaction space is increased from 0.379 to 0.46 kg of alkylation product per liter of useful reaction space.

These experiments show that alkylation of benzene with propene with addition of polyisopropylbenzenes to the reaction mixture may be carried out without appreciable formation of polyisopropylbenzenes, if the relative amounts of benzene, polyisopropylbenzenes, and aluminum chloride are suitably chosen. New polyisopropylbenzene is not formed, or is formed in only very small amount, and the added polyisopropylbenzene is recirculated in the process. The addition of polyisopropylbenzenes in the alkylation of benzene with propene in presence of acid catalysts such as H_2SO_4 and $H_3PO_4 \cdot BF_3$ does not result in increase in the yield of monoisopropylbenzene.

SUMMARY

1. The alkylation of benzene with propene in presence of $H_2O \cdot BF_3$, $H_3PO_4 \cdot BF_3$, $H_3PO_4 \cdot BF_3 - H_2O \cdot BF_3$, $AlCl_3$, H_2SO_4, and $AlCl_3 \cdot HSO_4$ was investigated at atmospheric pressure under given experimental conditions, account being taken of the molar ratio of the reacting hydrocarbons, the temperature, and the amount of catalyst. The superiority of the catalyst $H_3PO_4 \cdot BF_3$ was demonstrated.

2. In the alkylation of benzene with propene in presence of aluminum chloride, the formation of polyisopropylbenzenes may be effectively prevented by addition of polyisopropylbenzenes to the reaction mixture. In alkylation in presence of acid catalysts such as H_2SO_4 and $H_3PO_4 \cdot BF_3$, addition of polyisopropylbenzenes is not effective, for the reaction does not attain an equilibrium state.

QUANTITATIVE INVESTIGATION OF STERIC HINDRANCE

C.K. Ingold

The concept of steric hindrance, as an inhibitory effect arising in a reaction from the shielding of the reaction center by ramified structures in other parts of the molecule, was developed in its general form during the nineties of the last century [1], but there followed a period of more than forty years in which no further progress was made toward a more precise formulation of the concept. A glance into the past will enable us to understand the cause of this long delay. Steric hindrance is associated with reaction rates: it is a kinetic, not thermodynamic phenomenon, and it therefore depends on reaction mechanism. For this reason, the operation of steric hindrance could not be described precisely until the various possible reaction mechanisms had been determined and adequately characterized.

Much of the necessary information on reaction mechanisms was collected during the thirties of this century, and it became clear that any given reaction of a general type may proceed by different mechanisms and that the mechanism by which it will actually proceed will depend both on the structures of the reactants and on the reaction conditions - including, in particular, the electrochemical properties of the solvent. It was established that steric factors may have greatly differing effects on different reaction mechanisms, and it became clear also that steric factors affecting reaction rate are very directly associated with the geometry of transition states (which had not been elucidated at that time), and not only with the well established geometry of normal molecules, on which all previous attempts to explain steric hindrance had been based.

By 1940 our picture of the operation of steric hindrance had become clear [2]: the effect is determined partly by reaction mechanism and partly by molecular structure. Its most important feature, which we shall now discuss, is associated with mechanism.

It has been shown that, in the main, the mechanisms of the principal types of investigated organic reactions fall into two classes, termed "unimolecular" and "bimolecular" respectively. The first of these is characterized by a reaction rate determined by a dissociation process, whereas for the second the determining process is associative in type. These two types of mechanisms tend to be grouped symmetrically. Thus, for nucleophilic substitution two mechanisms are possible, one of each type; the hydrolysis of carboxylic esters can proceed by six mechanisms, three of each type; and so on. Whatever the reaction may be, however, steric effects influence the two different types of mechanisms in substantially different ways. Unimolecular reactions are determined kinetically by dissociation, so that in the formation of the transition state the mean density of matter in the neighborhood of the reaction center must diminish and there must be local reduction in the value of some previously existing internal pressure. Even when we take into account the possible effect of geometric changes due to the formation of the transition state, it is nevertheless found that, owing to the general diminution in the density of matter, there can be no appreciable overall increase in pressure - or, more exactly, in potential energy due to pressure. Correspondingly, in the case of unimolecular mechanisms, steric factors can bring about some acceleration of reaction, but not any great retardation. In the case of bimolecular mechanisms, reaction rate is determined by an association process in which there is an increase in the density of matter near the reaction center in the transition state. It follows that bimolecular reactions may be greatly retarded under the influence of steric factors.

On the basis of this view concerning the main feature in our picture of the operation of kinetic steric efforts, we undertook exploratory work, mainly of a somewhat simplified and qualitative character, with the object of determining more completely the distinctive characteristics of this picture. This work still continues.

In the course of these investigations it was found that, apart from the general distinction associated with the character of the mechanism, there are finer, though appreciable, differences associated with the type of

molecular structure. The structure of a molecule directly determines its geometry in the proximity of the reaction center in its original state, whereas the corresponding geometry of the transition state is determined both by the structure of the molecule and by the mechanism of the reaction. For a given mechanism, therefore, the structural type of the substrate determines the change in geometry associated with the change from the initial to the transition state, and so determines also the increase or reduction in internal pressure due to the kinetic steric effect. For example, the reaction of nucleophilic substitution corresponds essentially to one unimolecular and one bimolecular mechanism. In the unimolecular mechanism, the changes in geometry are different in the alkyl, aryl, and aralkyl series. These differences enable us to understand why, in the first two cases, groups in the immediate vicinity can cause a small acceleration [3,4], which may be explained by the occurrence of an overall reduction of pressure in the formation of a transition state of the dissociative type. In the third case a slight retardation is observed [5] when the change in geometry results in an additional pressure which more than compensates for the lowering of pressure peculiar to dissociative process. In just the same way, in the bimolecular mechanism the kinetically important changes in geometry are not the same in the alkyl, aryl, and aralkyl series [5-7]; and when we take these differences into account, we can understand why the retardation of reaction attributable to steric hindrance - which is observed in all three series - is so much greater in the first series than in the other two.

This exploratory work is still continuing, for even when we confine ourselves to the fundamentally most important reactions, possible mechanisms, and structural types, the number of combinations deserving attention still remains very great. Investigations in such a wide field must necessarily have a somewhat superficial and qualitative character, but this stage of the work is essential for the selection of individual topics for more profound study, such as the topic discussed in this paper. Generally speaking, there is no reason why any of the fair variety of fields covered by this exploratory work should be left without a more intensive, quantitative investigation. As yet, however, very few topics have been so treated. A more profound investigation of this sort has been carried out during the last decade (1945-55) in parallel with the further development of the above-mentioned extensive, but superficial, investigations.

The topic selected for investigation was nucleophilic substitution in alkyl compounds by the bimolecular mechanism - the reaction of S_N2 aliphatic substitution, as we shall refer to it for the sake of brevity. Long before the start of this work, a crude analysis of the appropriate geometric relationships led to some unexpected conclusions [7]. These conclusions were very surprising in that, although they were arrived at by a rigorous treatment, from the point of view of the old intuitive approach they were absurd. One of these conclusions was that in S_N2 aliphatic substitutions steric hindrance may increase as the point of substitution recedes from the ramified part of the molecule, as, for example, when we pass from a tert-butyl halide to a neopentyl halide - a view that is in conflict with Victor Meyer's results on the esterification of ortho-substituted benzoic and phenylacetic acids. Another conclusion was that, although, steric hindrance should depend greatly on the shape of the alkyl group, it should be almost independent of the size of the incoming group; a large group should enter a confined space just as readily as a smaller group. Although these conclusions were published, it can scarcely be said that their validity was at all widely accepted. Later, however, they were confirmed experimentally, and their quantitative aspects were elucidated theoretically. These investigations revealed still other such phenomena, which were also found to be capable of rational explanation. Properly speaking, these phenomena should have been foreseen, though, as a matter of fact, they were not. We shall refer to them in the appropriate places.

The example selected for our study of substitution [8] was the Finkelstein reaction

$$Y^- + RX \rightarrow RY - X^-,$$

in which X and Y are isotopically or chemically different halogens, and R is an alkyl group. The solvent used was acetone, for it has suitable solvent properties for various combinations of halogens; moreover, for alkyl groups varying greatly in structure, reaction in this solvent proceeds exclusively, or almost exclusively, by the bimolecular mechanism.

In investigations of this kind we have to work simultaneously along two directions - theoretical and experimental - basing our strategy on the concurrence found between the results of these two lines of work, and advancing, as it were, by a pincer movement.

We shall first discuss the results of our experimental observations, the extent of which can be judged from the data on reaction rates given in Table 1. Seven of the possible nine Finkelstein exchange reactions

with chlorine, bromine, and iodine were investigated for the seven alkyl groups comprising the simplest members of the α- and the β-methylated series of branching homologs.

According to the Arrhenius equation, the rate constant of a reaction can be expressed, in principle, as the product of two factors: $k = Be^{-E/RT}$, or $\log k = \log B - E/4.575\,T$. The frequency factor B, otherwise called the entropy factor, is multiplied by the energy factor $\exp(-E/RT)$, which depends on the activation energy E. The most immediate experimental problem is therefore the resolution of each rate constant into its component factors. This resolution is based on the well known fact that only the energy factor is explicitly dependent on temperature.

Any examination that we may make of the effect of structure on any property capable of undergoing change can be only a relative one: we can consider only the effect of changes in structure. Hence, in order to examine the effect of structural peculiarities on the rate constant and on its component factors, we must select a suitable structure as standard. Suitable standards for these reactions are the methyl derivatives, and we shall examine the changes in the experimental values of the two factors in the expression for the rate constant by comparison with this standard.

TABLE 1

Finkelstein S_N2 Exchange Reactions in Acetone for the α-Methylated Branching Homologous Alkyls CH_3, C_2H_5, i-C_3H_7, t-C_4H_9 and the β-Methylated Branching Homologous Alkyls C_2H_5, n-C_3H_7, i-C_4H_9, neo-C_5H_{11} (Values of $10^5 \cdot k_2$ at 25° in liter · sec^{-1} $mole^{-1}$).

Reactants	CH_3	C_2H_5	i-C_3H_7	t-C_4H_9	n-C_3H_7	i-C_4H_9	neo-C_5H_{11}
$Cl^- + RCl$ . . .	3.9	0.050	—	—	—	—	—
$Cl^- + RBr$ . . .	600	9.9	0.13	0.029	6.4	1.5	0.00026
$Cl^- + RI$ . . .	470	42	1.3	—	25	1.6	0.00058
$Br^- + RBr$ . . .	13 000	170	1.8	0.51	110	5.7	0.0026
$Br^- + RI$ . . .	27 000	1490	37	—	1050	32	—
$I^- + RBr$ . . .	25 000	170	1.3	0.10	140	6.0	0.0020
$I^- + RI$ . . .	—	6000	53	18	—	—	0.11

As regards the energy factor, the procedure adopted is to subtract the activation energy for the methyl derivative from that for the derivative under consideration. In this way we obtain the values given in Table 2 for the excess of activation energy ΔE. These values give a measure of the effect of structure on activation energy, i.e., they represent an effect that is amenable to theoretical discussion.

TABLE 2

Observed Increments in Activation Energy ΔE for Finkelstein S_N2 Exchange Reactions (in acetone as solvent)*

Reactants	CH_3	C_2H_5	i-C_3H_7	t-C_4H_9	n-C_3H_7	i-C_4H_9	neo-C_5H_{11}
$Cl^- + RCl$ . . .	0.0	1.3	—	—	—	—	—
$Cl^- + RBr$ . . .	0.0	1.9	2.9	5.3	2.1	2.6	6.0
$Cl^- + RI$ . . .	0.0	1.2	1.6	—	1.4	1.8	6.0
$Br^- + RBr$ . . .	0.0	1.7	3.9	6.0	1.7	3.1	6.2
$Br^- + RI$ . . .	0.0	1.4	2.2	—	1.6	2.5	6.9
$I^- + RBr$ . . .	0.0	2.6	4.2	6.9	2.7	3.6	7.9
$I^- + RI$ . . .	0.0	1.7	3.7	5.7	—	—	6.5

*All values are in kcal/mole.

It will be seen from Table 2 that no general tendency can be observed in the changes of ΔE as we pass from the smaller halogen atoms to the larger: there is only an irregular scatter. On the other hand, as we pass from one alkyl group to another, notable changes in activation energy are observed: there is a general increase in the α-methylated series (CH_3, C_2H_5, i-C_3H_7, t-C_4H_9), and there is an increase, at first scarcely appreciable and then more rapid, in the β-methylated series (C_2H_5, n-C_3H_7, i-C_4H_9, neo-C_5H_{11}). The activation energy is somewhat higher for neo-C_5H_{11} than for t-C_4H_9.

For an analogous examination of the frequency factor, values of log B for the methyl derivatives are subtracted from values for each of the given reactions so that we obtain a series of experimental differences that we call increments, although they are all negative except a few which have a value of zero. They are given in Table 3 and they reflect the effect of structure on the logarithm of the frequency factor, or what amounts to the same, if we neglect the change in scale, on the activation entropy. These quantities are also amenable to theoretical discussion.

TABLE 3

Observed Increments in the Logarithm of the Frequency Factor Δ log B for Finkelstein S_N2 Exchange Reactions (in acetone as solvent).

Reactants	CH_3	C_2H_5	i-C_3H_7	t-C_4H_9	n-C_5H_{11}	i-C_5H_{11}	neo-C_5H_{11}
Cl^-+RCl . . .	0.0	—0.8	—	—	—	—	—
Cl^-+RBr . . .	0.0	—0.4	—1.4	—0.4	—0.7	—0.9	—1.9
Cl^-+RI . . .	0.0	—0.3	—1.1	—	—0.6	—1.1	—1.5
Br^-+RBr . . .	0.0	—0.6	—1.0	±0.0	—0.9	—1.1	—2.1
Br^-+RI . . .	0.0	—0.3	—1.2	—	—0.6	—1.1	—1.3
I^- + RBr . . .	0.0	—0.4	—1.2	—0.3	—0.6	—1.1	—1.2
I^- + RI . . .	0.0	—0.5	—1.0	±0.0	—	—	—1.8

Here also we can observe some general regularities: 1) as we pass from the smaller halogen atoms to the larger, no general tendency is to be observed, only a certain scatter; 2) in the replacement of alkyl groups the changes occurring are striking and uniform. For the first three members of the α-methylated series (CH_3, C_2H_5, i-C_3H_7) the values of Δ log B gradually fall, but then return, or almost return, to their original values at the fourth member (t-C_4H_9). In the β-methylated series (C_2H_5, n-C_3H_7, i-C_4H_9, neo-C_5H_{11}) Δ log B falls in a regular fashion. For neo-C_5H_{11} the frequency factors are thus less than for t-C_4H_9.

Such are the results which the purely experimental development of the problem has contributed to the investigation.

The theoretical treatment of the problem is based on the model of the transition state that has been established for S_N2 alkyl-substitution reactions. In this model, semi-ionic semi-bonds, holding the groups that are substituting and being substituted in the transition state, are disposed on the two sides of a plane containing three bonds originally having a pyramidal configuration, which must undergo inversion in the course of the reaction. This, of course, is a general, qualitative model: at this stage it does not convey the exact configuration of any concrete transition state.

Hence, the main problem in the preliminary stage of the theoretical investigation of the effect of structural factors on the kinetics of any of the reactions under consideration consists in calculations for several configurations of atoms which may be regarded as close to the arrangement in the transition state, the object being to determine the energies required to build up all these configurations from the original reactants. For each assumed configuration it is necessary to calculate the energy required for the stretching of the carbon-halogen bond to a certain distance between the atoms, the energy required to cause a halide ion to approach an α-carbon atom to a given distance, the energy required for the bending of certain bonds, and so on. All these energies must then be added together in order to give the total energy necessary for the formation of a given configuration, expressed as a function of this configuration. If an intelligent choice of configurations is made, the energy will have a minimum value for a certain configuration, which will correspond to the transi-

tion state. If we use the graphical method, we may say that we are constructing an "energy surface", and the spatial and energy coordinates of the lowest point of this surface corresponds to the configuration and energy of the transition state. Such calculations must be carried out for each individual reaction, i.e. for each combination of halogens and alkyl group.

The only mathematical equipment required consists of three approximate, but well verified, formulas of the simplest possible type: a formula for bond-stretching, a formula for bond bending, and a formula for non-bonding compression potentials. All the constants in these formulas are either universal constants, or are determined by known values of certain mechanical, thermal, and optical properties of standard substances. No auxiliary parameters are introduced at any stage in the construction of these energy surfaces.

TABLE 4

Calculated Positions of Iodine in Transition States of the Reaction $I^- + RI \rightarrow IR + I^-$

R	Extra length of each semi bond $C_{...}I$ (A)	Angle at which $I_{...}C_{...}I$ bond is bent
CH_3	0.36	0.0°
C_2H_5	0.37	3.8°
$i\text{-}C_3H_7$	0.38	5.0°
$t\text{-}C_4H_9$	0.40	0.0°
$n\text{-}C_4H_7$	0.37	3.8°
$i\text{-}C_4H_9$	0.39	5.0°
$neo\text{-}C_5H_{11}$	0.43	17.6°

The simplest application of these surfaces consists in the determination of the configurations and energies of transition states. As an illustration of calculated configurations of transition states, in Table 4 we give the positions of iodine in the transition states of reactions of isotopic exchange of iodine, these being expressed by the lengths and angles of the carbon-iodine bonds. In the transition states, all the carbon-halogen bonds are stretched, some to a greater and others to a lesser extent owing to the differences in the pressures of the different alkyl groups. With the exception of transition states containing methyl and tert-butyl groups, which have trigonal symmetry with respect to strictly linear halogen-carbon-halogen bonds, in all cases the carbon-halogen bonds are bent; in the transition states containing neopentyl groups, these bonds are very severely bent.

In Table 5 we give the calculated differences between the energy of the transition state containing the methyl group and the energies of the transition states containing the other groups, i.e., the calculated increments of activation energy due to steric effects ΔW_{ster} for three reactions of exchange between identical halogens. As will be seen from the table, as we pass from the smaller halogen atoms to the larger, the calculated steric increments of energy change only slightly and not always in the way that would be expected on the basis of the usual intuitive approach: for example, some of the values fall. However, as the alkyl groups are changed, there is a marked regular change in the energy increments, which rise in the α-methylated series, but remain constant at first in the β-methylated series and then rise at an increasing rate. The relationship between these calculated values are in accord not only with earlier qualitative predictions, but also with basic laws governing these activation energies which were discovered subsequently by experiment.

TABLE 5

Calculated Steric Increments of Energy ΔW_{ster} (kcal/mole) for S_N2 Finkelstein Substitutions

	CH_3	C_2H_5	$i\text{-}C_3H_7$	$t\text{-}C_4H_9$	$n\text{-}C_4H_7$	$i\text{-}C_4H_9$	$neo\text{-}C_5H_{11}$
$Cl^- + RCl$ . .	0.0	0.8	1.6	2.8	0.8	2.1	6.5
$Br^- + RBr$ . . .	0.0	0.8	1.6	2.5	0.8	2.3	7.3
$I^- + RI$ . . .	0.0	0.7	1.3	2.0	0.7	2.5	7.8

The calculated quantities are steric increments of activation energy ΔW_{ster}. We do not yet possess a suitable method for the calculation of the fraction of the activation energy due to polarity ΔW_{pol} on the basis of simple assumptions. We can make a further step forward, therefore, only by comparing experimental values of ΔE with calculated values of ΔW_{ster} and determining whether the differences between these quantities, which may be considered to be the ΔW_{pol} component, correspond to the actual picture of the polar effect. It was found that there is indeed a correspondence in two important respects: 1) the differences found can be as-

sociated exclusively with α-alkyl substitution, but in the case of β-alkyl substitution there is no appreciable variation in the differences, which is the behavior to be expected when there is a weak polar effect in a non-conducting system (for a steric effect such a distribution would be incorrect); 2) the differences are governed, approximately, by an additive free energy equation, as is generally observed for polar effects isolated from steric effects. These two simplifying relationships, and also the close electrochemical similarities between the halogens, enable us to assume a single round value of 1.0 kcal per mole for the polar effect of an α-alkyl substituent in any alkyl group in any Finkelstein exchange reaction, thus enabling us to calculate all 49 values of ΔW_{pol}.

In general, the sum of ΔW_{ster} and ΔW_{pol} is very close to the experimental value of ΔE, although the agreement is only approximate in the case of the neopentyl group. The less satisfactory agreement in this case may be explained by the fact that the calculation of ΔW_{ster} for neopentyl is associated with large errors, and high calculated values may be expected. As an illustration of the numerical values found, data for the bromine-exchange reaction are given in Table 6. A more general but equally good illustration is provided by the closeness and absence of trend in both calculated and experimental values for the replacement of one halogen by another; this will be seen from the comparison made in the table between the average calculated values for all of the reactions investigated and the mean experimental values.

Another way of using the calculated energy surfaces consists in finding the frequency factor in the expression for the reaction-rate constant. The logarithm of the frequency factor is the activation entropy, if we leave out of account possible (or arbitrary) changes in the origin and the units of entropy; the entropy of the transition state is greatly dependent on these energy surfaces - and on their geometric form rather than on their energy level.

In the general case, every surface has the form of a basket. To use a figurative comparison, we may say that the reagent and the group being removed can be regarded as participants in a game of basketball, in which an "energy basket" is used. The lower and the wider the basket, the more frequently will molecules fall into it with formation of the transition state. The height of the basket, which represents energy, has been already considered. We shall now consider its width, which represents entropy.

TABLE 6

Calculated and Experimental Effects of Alkyl Structure in Finkelstein S_N2 Exchange Reactions on Activation Energies (kcal mole)

	CH_3	H_5C_5	i-C_3H_7	t-C_4H_9	n-C_5H_7	i-C_4H_9	neo-C_5H_{11}

Difference	0	+0.4	+0.4	−0.6	−0.1	+0.6	+1.6

Basketlike surfaces of this sort are shown in Fig. 1 for four alkyl groups in the bromine-exchange reaction. The groups are selected so as to illustrate the peculiar character of the effect of steric conditions on the frequency factor in the expression for the reaction-rate constant: the sign of the effect is essentially determined by symmetry.

These contour diagrams clearly reflect the fact that for the tert-butyl group the transition state preserves the axial symmetry of the transition state of the methyl group, whereas for the ethyl and neopentyl groups the transition states are characterized by increasing departure from this symmetry. It must here be pointed out

that for the tert-butyl group the basket is wider than for the methyl group, particularly in the axial direction (along the axis of abscissae), whereas the baskets for the ethyl and neopentyl groups become increasingly narrow, particularly in the transverse direction. The reason for the greater width of the tert-butyl basket lies in the fact that steric pressure is here directed outwards and the forces in the bonds, which are in a stretched condition, are weakened; as a result, the energy gradients will be less steep and the basket will become shallower and more open. In this particular instance, there is no side pressure or force tending to bend the bonds which could compensate for this effect by means of pressure on the sides of the basket. In the case of the ethyl group, however, and still more in the case of the neopentyl group, steric pressure directed from the sides is the dominant effect. Hence, this pressure acts on the basket from one side, and a bending potential acts from the other, so that the walls of the basket become steeper and the basket itself becomes narrower. It can be seen, therefore, that, depending on its direction, steric pressure may have either an accelerating or retarding effect on the frequency factor. From the point of view of the usual intuitive approach, the part played by the direction distribution of this effect is an absurd one, since steric interaction that directly repels the reagent acts as an accelerator of reaction, and interaction tending to direct the reagent sideways acts as a retardant.

Fig. 1. Calculated energy surfaces for the reaction $Br^- + RBr \rightarrow BrR + Br^-$. Four basket-shaped surfaces for R = CH_3, C_2H_5, t-C_4H_9 and neo-C_5H_{11}. The figures against the contours are energies (kcal/mole) reckoned from the lowest point of the methyl surface as zero. The horizontal axis is a line passing through C-α perpendicular to the plane of the three intact C-α bonds in the transition state. The intersection of the axes of coordinates corresponds to the positions which, according to calculation, the halogen atoms would have in absence of steric hindrance, and the points are the calculated positions of the halogen atoms in presence of steric hindrance. The relative heights of the bottoms of the baskets correspond to the contribution made by steric factors to the activation energy, and the relative widths of the baskets to the contribution of steric factors to the activation entropy (in all the diagrams the contours are at 1 kcal/mole intervals).

In the interest of correct "score-keeping", we must point out that this game of basketball does not proceed according to Newton's laws of mechanics, but follows quantum laws, so that we must estimate the widths of our baskets not with the aid of classical measurement, but by quantum counting. It is necessary to calculate the number of energy levels in the basket - statistically weighted according to Boltzmann - since it is this number which, according to quantum rules, determines the capacity of the basket, which we express in the form of the logarithm of the entropy.

However, as soon as we begin to calculate the capacity of the basket in this way, it is found that this capacity depends not only on the geometry of the energy surface, but also on the masses and their distribution in the particles taking part in the reaction. As is well known, a given energy well contains a greater number of energy levels in the case of a heavy particle than in the case of a light one, and moreover this increase in the number of levels represents a step toward the limit constituting an energy continuum at infinitely large mass, as required by Bohr's correspondence principle. These simple considerations result in the disclosure of a new

type of structural effect on reaction rate which has not yet been examined in sufficient detail and which is neither a steric nor a polar effect; it was called "ponderal", since it depends on mass and does not depend on how a given heavy group fills space and how any charge it may have is distributed. A purely ponderal effect should be brought about by neutrons added, as is completely feasible, to the molecule by isotopic exchange, since neutrons, while possessing mass, have neither volume nor charge.

The structural effects that affect kinetics can therefore be divided into three categories. The ponderal effect depends on the presence and distribution of masses, the steric effect on the presence and distribution of volumes, and the polar effect on the presence and distribution of charges. There can be no doubt that appreciable ponderal effects have often remained undetected when associated with steric and polar effects.

In principle, ponderal, steric, and polar effects affect both the energy, and also the entropy factor in the reaction-rate constant. In the present work, however, since we are concerned with relatively heavy particles, we may neglect – and in fact have neglected – the influence of the ponderal effect on the energy. Similarly, we may neglect the polar effect when considering the entropy term, for alkyl substituents are only weakly polar; only contributions made by ponderal and steric effects need be considered. The contribution of the ponderal effect is to be related to the number of possible energy levels when steric pressure does not deform the energy surface. The total value of the entropy depends on the number of permitted energy levels arising when the surface is deformed. By first calculating the ponderal effect we isolate the steric effect, which was the original object of our investigation. The formulas permitting the calculation of energy levels with due regard to statistical weights are simple and are well known in statistical mechanics.

The contributions made to the activation entropy ΔS by ponderal and steric effects in the bromine-exchange reaction are given in Table 7. The numerical values are here given in thermal units, not frequency units.

TABLE 7

Calculated Contributions Made to the Activation Entropy ΔS (cal · degree^{-1} mole^{-1}) by Structural Effects in the Reactions $Br^- + RBr \rightarrow BrR + Br^-$.

	CH_3	C_2H_5	$i\text{-}C_3H_7$	$t\text{-}C_4H_9$	$n\text{-}C_5H_{11}$	$i\text{-}C_5H_9$	$neo\text{-}C_5H_{11}$
Ponderal	0.00	—1.45	—2.30	—1.95	—2.64	—3.66	—4.39
Steric	0.00	—0.66	—1.52	+0.83	—0.67	—1.06	—1.86
Total	0.00	—2.11	—3.82	—1.12	—3.31	—4.72	—6.25

With increase in mass the ponderal effect generally results in a retarding action, as indicated by the negative signs of values given in Table 7. The ponderal effect may be somewhat confused with the steric effect in these considerations in which mass has the predominating effect, but they cannot be confused in our considerations relating to another law on the distribution of masses, which is considered below. As can be seen by a comparison of isomers, extra mass generally has the greater retarding effect, the greater its distance from the reaction center. Elementary intuition might lead us to the first of the above rules, but not in any circumstances to the second. The point is that addition or removal of mass causes a greater increase in the number of energy levels in the original molecule than in the transition state. However, the actual effect of the distribution of masses is so complex that there may be exceptions to these rules.

As regards the steric entropy effect, the values obtained confirm qualitative conclusions based on the form of the energy surface. As can be seen from the fact that the positive sign occurs only once, the steric effect causes acceleration only in the case of the tert-butyl group, for which steric pressure is directed outwards; in all the other cases, in which the pressure is directed sideways, the steric effect results in retardation.

When the contributions of the individual effects are added together, it is found that the total entropy effect always leads to retardation, which is least for the tert-butyl group and greatest for neopentyl.

The relationship between entropy in thermal units and the frequency factor in the expression for the re-

action-rate constant has the form $\Delta \log B = \Delta S/4.575$; a simple change of scale therefore makes it possible to make a comparison with experiment. This comparison is given in Table 8, first for the bromine-exchange reaction, and second for mean values from all the reactions investigated.

TABLE 8

Calculated and Observed Structure Effects on log B for Bimolecular Finkelstein Exchange Reactions.

Calculated*	0.0	−0.46	−0.84	−0.24	−0.72	−1.03	−1.37
Observed (mean)	0.0	−0.5	−1.1	−0.2	−0.7	−1.1	−1.6

* (Br exchange)

It will be seen that, in general, agreement is good. In all cases, except that of the neopentyl group, agreement is within the limits of experimental error, which may attain ±0.2. Even the poorer agreement for the neopentyl group can be explained by the fact that in this case the calculation is less accurate than in the remaining cases and can result in a departure in just that direction in which it is observed. It should be noted that at no stage in these calculations of entropy were any supplementary parameters introduced: the formulas used contain only constants that have been found by independent methods.

The last step of the theoretical investigation consists in the combining of the calculated activation energies and entropy factors with the object of determining to what extent the combination corresponds to the observed reaction-rate constants. This is done in detail in the diagrams in Fig. 2, in which the vertical scales for ΔE, $\Delta \log B$, and $\Delta \log k$ (for 25°) have been selected so that corresponding points give direct indications of the relative parts played by energy and entropy in the determination of reaction rate: by subtracting the ordinate ΔE from the ordinate $\Delta \log B$, we may immediately find the ordinate $\Delta \log k$. The lines for the α-methylated series (continuous) and for the β-methylated series (broken) are theoretical and have a dual purpose: in the first place they unite calculated points for the reaction of bromine exchange, and in the second place they unite points for the mean values for all reactions; these mean points are so near to those calculated for the bromine-exchange reaction that the lines cannot be drawn separately. The crosses correspond to the observed points for bromine exchange, and the circles to the means of the observed values for all reactions. With the exception of the points for neopentyl groups, the observed values are well reproduced by the calculated ones. These calculations also enable us to understand some important features, such as the fact that in the case of the tert-butyl group the reactions are only slightly slower than in the case of the isopropyl group and the fact that for the neopentyl group reaction is much slower than for all the other groups, even the tert-butyl group.

Fig. 2. Calculated and observed effects of alkyl structure on the energy and entropy rate factors and on the resulting rates of Finkelstein reactions (for explanation see text).

Table 9 gives a comparison of numerical values of observed and calculated rate constants for the bromine-exchange reaction. Most of the calculated values depart from the experimental values by a factor of less than two, although the departure is by a factor of five in the case of the neopentyl group, this being the max-

imum departure over the whole range of reaction rates, which vary by a factor of 5,000,000.

TABLE 9

Observed and Calculated Effects of Structure on the Rate Constant for 25° for the Reaction $Br^- + RBr \rightarrow BrR + Br^-$ in Acetone.

	CH_3	C_2H_5	$i\text{-}C_3H_7$	$t\text{-}C_4H_9$	$n\text{-}C_3H_7$	$i\text{-}C_4H_9$	$neo\text{-}C_5H_{11}$
Observed	1	0.013	0.00014	0.000039	0.0085	0.00044	0.00000020
Calculated	1	0.017	0.00035	0.000053	0.0090	0.00035	0.000000037

This comparison shows to what extent the "pincer movement" carried out by the theoretical and experimental investigations has closed in this campaign for the solution of the problem we have been set. Further improvements in accuracy are possible in the application of each of these methods, but this is a very laborious task. However, since a rather approximate analysis of the effect of structure on reaction rate in a certain particular system has enabled us to reveal so many effects of general character which are not only not revealed, but are even masked in an intuitive examination, we consider that a similar approximate examination of other types of structure, of other reaction mechanisms, and of other reactions could also lead to conclusions of wide significance at which it would be impossible to arrive by any other means. Work on a similar approximate treatment of new material may therefore be of greater value than attempts to attain significantly higher accuracy.

PRINCIPLES UNDERLYING NEW METHODS FOR THE CHEMICAL TREATMENT OF COMPLEX IRON AND NICKEL ORES

G. G. Urazov and D. P. Bogatsky

For an economically satisfactory solution of the problem of the chemical treatment of iron-nickel oxide and oxide silicate ores, it is of primary importance that the iron, which is present in these ores in considerable amounts, should be utilized rationally. The previous extensive investigations on the hydrometallurgy of iron-nickel oxide ores [1] did not provide a satisfactory solution of this problem; the passage of iron into solution in an amount substantially greater than that of nickel led to considerable consumption of solvents, which made the proposed processes uneconomic and resulted in the loss of the whole of the extracted iron in solutions and filter cakes. Investigations carried out in various institutes over many years with the object of reducing the passage of iron into solution as much as possible did not yield the desired results: the consumption of acid reagents still remained above the acceptable limit, so that the proposed acid-leaching procedures were unsatisfactory from the economic and technological points of view.

In these earlier investigations [1] special procedures were adopted with the object of lowering the rate of extraction of iron from the ore and diminishing the consumption of reagents, but we proposed [2] to utilize the iron that must inevitably react by repeated use of iron-containing lyes and other intermediate products as cheap active reagent-solvents. This procedure greatly reduces the consumption of reagents in hydrometallurgical treatments of complex iron-nickel ores.

In the processes of greatest practical importance, namely, leaching with sulfuric acid with utilization of sulfurous gases [2,3] and chlorination [4,5], both proposed by us [2-4] for the treatment of complex iron-nickel oxide and oxide-silicate ores, the iron is extracted in the form of its sulfates and chlorides. For this reason, the greatest practical interest is presented by an investigation into the possibility of using various solutions of these iron compounds as reagent-solvents in hydrometallurgy and into the conditions required in their application. The tasks undertaken in the work carried out with this aim were 1) a study of the chemical interaction of solutions of ferric sulfate, of ferric chloride, and of mineral acids of various concentrations with typical nickel silicate minerals, with nickelous oxide, and with metallic nickel; 2) an investigation of the relation between the rates of these processes and the physicochemical conditions under which they are carried out; 3) the determination of the optimum conditions for carrying out these processes in practice in order to effect maximum transfer of valuable metals into solution; and 4) an investigation of the possibility in principle and the optimum conditions for the efficient chemical treatment of complex iron-nickel oxide and oxide-silicate ores from the principal commercially worked Soviet deposits with the recommended solvents under the conditions proposed.

EXPERIMENTAL

Materials Investigated, Experimental Procedure, and Experimental Results

The materials investigated were a) magnesium-nickel hydrosilicate minerals — Ufalei garnierite, Akkerman garnierite, Ufalei nepouite-garnierite, Akkerman nickel cerolite, and Akkerman nickel deweylite; b) nickel hydroaluminosilicate minerals — Aidyrlin nickel aluminosilicate and Aidyrlin aidyrlite; c) nickelous oxide; d) "active" metallic nickel prepared by the reduction of nickelous oxide and nickel oxide solid solutions [6] with hydrogen under the conditions previously [7, 8] found to be optimum for these processes; and e) complex iron-nickel oxide-silicate ores — Ufalei oxide-silicate ore, low-grade oxide-silicate ore from Batamshin, and waste oxide-silicate ore from Aiderbak (Khalil region).

The nickelous oxide taken for the leaching process was prepared by roasting (above 1100° to constant weight) the nickel oxide solid solution prepared by the decomposition of chemically pure nickel nitrate in the low-temperature region [8]. The oxide-silicate minerals and ores were obtained from the Museum of Geology and Mineralogy of the Academy of Sciences of the USSR and from the mining and geological sections of the Ufalei nickel works and the South Urals Nickel Combine.

In order to make a detailed physicochemical study of these minerals and ores, they were subjected to chemical, mechanical, screening, magnetic, mineralogical, differential, thermal, and densimetric investigations; also, their reducibility with various reducing agents was studied [9].

Garnierite – $(Ni, Mg)O \cdot SiO_2 \cdot H_2O$ – is the most widely distributed nickel oxide-silicate mineral. It is green and has a dull appearance; its hardness is 2-2.5; it has an even fracture – plane-conchoidal and conchoidal. Its aggregates are gellike, or sometimes ocherous. In the cold, dilute acids have almost no action, but at the boil the mineral decomposes slightly. It is decomposed by concentrated hydrochloric and sulfuric acids. The action of salt solutions on garnierite has not been studied.

Nepouite – $3(Ni, Mg)O \cdot 2SiO_2 \cdot 2H_2O$ – is a widely distributed oxide-silicate mineral of nickel, being the product of the partial replacement of magnesium oxide by nickelous oxide in serpentine. It is a distinctly crystalline mineral, probably hexagonal in form, and it generally gives small long bluish-green crystals or plates. Its hardness is 2-3 and its density 2.7-2.8. It reacts like garnierite with mineral acids. The action of salt solutions on nepouite has not been studied.

Nickel cerolite – $(Mg, Ni)O \cdot SiO_2 \cdot H_2O$ – is a gellike magnesium-nickel hydrosilicate. It is bright bluish green. It is very brittle and has a conchoidal fracture. Its hardness is 2-2.5. It will not mark paper, and it cannot be polished with the fingernail. Its aggregates are compact and gellike. In the cold, weak acids have almost no action on cerolite, and at the boil they decompose it only partially. In boiling concentrated hydrochloric and sulfuric acids cerolite is completely decomposed. The action of salt solutions on nickel cerolite has not been studied.

Nickel deweylite – $4(Mg, Ni)O \cdot 3SiO_2 \cdot 3H_2O$ – is a magnesium-nickel hydrosilicate. It is bright grass-green and varies from mat to glasslike in appearance. It is brittle and has a hardness of 2.5-3.5. Its aggregates are gellike. Weak acids have almost no action on deweylite, but boiling concentrated hydrochloric acid decomposes it. The action of salt solutions on nickel deweylite has not been studied.

Nickel aluminosilicate and aidyrlite are hydroaluminosilicates of variable composition: their chemical formulas have not been firmly established. Macroscopically, nickel aluminosilicate has the appearance of large bright-blue completely homogeneous pieces having a greasy feel, and aidyrlite is a bright greenish-blue mineral that is rather dry to the touch. Microscopically, the bulk of a sample of aidyrlite is seen to be an intimate mixture of this mineral, in the form of radiating columnar nepouite-like aggregates, with quartz. In samples of nickel aluminosilicate, none of the known nickel oxide-silicate minerals could be detected microscopically. Both aidyrlite and nickel aluminosilicate are new oxide-silicate nickel minerals, and their physicochemical properties have not yet been studied in detail.

Ufalei oxide-silicate ore is a yellowish-brown, ocherous-argillaceous mass having an indefinite schistose texture and containing fine lenslike inclusions of nontronite and well-leached chrysotile. The nonmagnetic part of the various fractions from screen analysis consists mainly of talc, quartz, nontronite, ocherous hydrogoethite, hydrohematite, and ferrihalloysite. The magnetic part of the various fractions consists of highly corroded free grains of magnetite. Most of the fine granular part of the ore consists of minerals that do not contain nickel (talc, magnetite, quartz). The nickel-bearing constituents of this ore are 1) argillaceous fractions containing adsorbed nickel compounds; 2) nontronite; 3) ferrihalloysite; and 4) ocherous hydrogoethite. Apart from extremely rare single scales of nepouite, there are no clearly individualized nickel minerals in the ore investigated. Apart from some extremely rare single inclusions of asbolan, no cobalt-bearing minerals were detected in the ore. The results of a chemical and mineralogical investigation of Ufalei ore show that this ore belongs to a type of low-grade talc-like iron-nickel oxide-silicate ores which do not contain cobalt and that it is characteristic for the ores of this type found in the Ufalei district.

Batamshin oxide-silicate ore is a dark-brown ocherous spongy mass which contains much fragmental material consisting of well-leached serpentinite that is somewhat cerolitized, nontronitzed, and opalized, and also of opal, nontronite, dolomite, and serpophite. The nonmagnetic part of the various fractions from screen analysis

Fig. 1. Extraction of nickel from garnierite by leaching with ferric sulfate solutions, expressed as a function of the composition of the solvent and the duration of the leaching process: 1) 2 hours; 2) 4 hours; 3) 6 hours.

Fig. 2. Extraction of nickel from nepouite-garnierite and nickel aluminosilicate by leaching treatments: 1) leaching of nepouite-garnierite with ferric sulfate solution (65 g/liter); 2) leaching of nickel aluminosilicate with ferric sulfate solution (30 g/liter); 3) leaching of nickel aluminosilicate with sulfuric acid solution (3%).

consists mainly of hyalite, chalcedony, quartz, serpentinite, nontronite, and ocherous hydrogoethite. The magnetic part of the various fractions consists mainly of magnetite and well-leached serpentinite in admixture with other minerals. In its chemical and mineralogical composition the ore, being formed mainly from ocher and nontronitized, leached serpentinite, belongs to the type of mixed ores. The nickel, which passes mainly into the nonmagnetic fractions, is present in the ore in the form of the following minerals: 1) garnierite, containing up to 45% of nickelous oxide; 2) asbolan, containing up to 10-12% of nickelous oxide; 3) psilomelanvade, containing up to 20% of nickelous oxide; 4) nontronite, containing up to 3-5% of nickelous oxide; 5) serpentine, containing up to 1% of adsorbed nickelous oxide; 6) cerolite, containing up to 1% of adsorbed nickelous oxide; and 7) iron hydroxides, containing various amounts of adsorbed nickelous oxides. Of the nickel-containing minerals in the ore, nontronite and iron hydroxides greatly predominate in amount. The amounts of individualized nickel silicates are very slight. Owing to the insignificance of the amount of asbolan and psilomelanvades in this ore, it is a very low-grade ore from the point of view of cobalt content. The low-grade Batamshin iron-nickel oxide-silicate ore is characteristic for most deposits of this ore in the Orsko-Aktyubin district.

Aiderbak oxide-silicate ore, which belongs to the class of final decomposition products of serpentinites, is an ocherous nontronitized serpentinite having an olive-green to brown color. Most of the ore consists of nontronite, and hydrohematite is present in appreciable amount. A little fragmentary material present in the main friable mass of the ore consists principally of opal and films and dendrites of manganese oxides, highly leached nontronized serpentinite, and black manganese chalcedony. The nonmagnetic part of various fractions from screen analysis consists mainly of opal, chalcedony, nontronite, and hydrohematite. The magnetic fractions are mainly magnetite, but hydrogoethite and chrome spinelides are also present. Individualized nickel minerals are present in the ore only in extremely small amount. The nickel is finely dispersed in the ore in the form of garnierite, prasopal, and nontronite. Cobalt-containing asbolans and psilomelanvades are altogether absent. The investigated Aiderbak ore is a typical waste iron-nickel oxide-silicate ore, characteristic of the deposits of this type of ore in the Khalil district.

As planned, the nickel silicate minerals, nickelous oxide, metallic nickel, and nickel oxide-silicate ores were leached with solutions of ferric sulfate, ferric chloride, sulfuric acid, and nitric acid of various concentration. The leaching conditions were suitably varied with the object of studying the following basic questions: 1) dependance of the intensity of the leaching processes on the composition of the original solutions, on the temperature, and on the duration of the process; 2) the part played by the concentration and variation in concentration of ferric sulfate, ferric chloride, or mineral acid in leaching processes; 3) the effect of variation in the acidity of the medium in such processes; and 4) the effect of these factors on the passage of nickel into solutions in the investigated leaching processes.

Fig. 3. Extraction of nickel from nickel cerolite and nickel deweylite: 1) leaching of nickel cerolite with ferric sulfate solution (30 g/liter); 2) leaching of nickel deweylite with ferric sulfate solution (45 g/liter); 3) leaching of nickel deweylite with ferric sulfate solution (30 g/liter).

The oxides, minerals, and nickel ores that were to be leached were ground so as to pass 200 mesh. The leaching experiments were carried out in glass beakers, the pulp being stirred with a propellor stirrer driven by an electric motor. The reduction of oxides, minerals, and ores before the leaching process was carried out under the optimum conditions found for these processes in previous investigations [9, 10].

The chemical analysis of the solutions and filter cakes obtained by the leaching process was carried out by the usual methods of analytical chemistry.

Some results of our investigations are shown in Figures 1-8. Unlike existing data in the literature [11], these experimental data show that nickelous oxide does not react sufficiently readily with ferric sulfate solutions of various concentrations, so that bunsenite cannot be adequately leached from nickel oxide ores by this method. As we have shown for the first time, in spite of contrary indications in the literature [11], much more intense reaction occurs between ferric sulfate solutions and natural magnesium-nickel hydrosilicates and nickel hydroaluminosilicate minerals, a fact that is of great scientific and practical interest.

Fig. 4. Extraction of nickel from aidyrlite by leaching with ferric sulfate solutions: 1) 30 g/liter; 2) 45 g/liter.

Nickel can be almost completely leached by the investigated method of treatment with ferric sulfate solutions from the magnesium hydrosilicate minerals garnierite (Fig. 1), nepouite-garnierite (Fig. 2), and nickel cerolite and deweylite (Fig. 3). From its hydroaluminosilicate minerals aidyrlite (Fig. 4) and nickel aluminosilicate (Fig. 2), nickel can again be removed almost completely by leaching with ferric sulfate solutions.

These new experimental results on the interaction of various nickel-magnesium and nickel-aluminum hydrosilicate minerals with ferric sulfate solutions open up new prospects in the hydrometallurgy of nickel oxide-silicate ores. As previous investigations have shown [12], in these ores nickel is present mainly as nickel-magnesium and nickel-aluminum hydrosilicates of variable composition. In fact bunsenite is found very rarely and in very small amounts in nickel oxide-silicate ores. Since nickel-magnesium and nickel-aluminum hydrosilicates are leached out fairly readily with ferric sulfate solutions, it may be expected that nickel will be leached fairly readily from its oxide-silicate ores by the proposed leaching procedure with the aid of the solutions indicated.

Special investigations confirmed this practical conclusion. We showed experimentally that the proposed procedure of leaching with ferric sulfate solutions extracts up to 95.16% of the nickel in Ufalei oxide-silicate nickel ore, up to 96.71% of the nickel in Batashin oxide-silicate nickel ore, and, moreover, up to 95.71% of the nickel in the waste Aiderbak oxide-silicate ore.

Owing to the adequate efficiency of the method previously proposed by us for the leaching of oxide-silicate nickel ores with ferric sulfate solutions [2], there are great possibilities of lowering the consumption of sulfuric acid in the hydrometallurgical treatment of these ores. The sulfuric acid that is consumed in enormous amounts in reactions with iron and its compounds is not removed from the cycle of production, but is utilized in repeated leachings with sulfate solutions with the result that the expense of each treatment is reduced.

Apart from the advantage of utilizing sulfuric acid that has reacted with iron in the course of the leaching of iron-nickel oxide ores, there are great practical advantages in the method that we have developed [3] with respect to the possibility of preparing the sulfuric acid solutions required for hydrometallurgical treatments from waste sulfurous gases. Treatment of waste iron sulfate lyes with air and sulfurous gases [2, 3] provides the ferric sulfate solutions required, the sulfurous gases being utilized for the regeneration of sulfuric acid in solution.

Fig. 5. Passage of nickel into solution in the course of leaching with ferric chloride solutions: 1) garnierite for 1, 2, and 3 hours at 15°; 2) garnierite for 0.5 hour at 100°; 3) metallic nickel for 1 hour at 15°; 4) garnierite for 2 hours at 100°; 5) metallic nickel for 1 hour at 15°; 6) metallic nickel for 2 hours at 15°; 7) metallic nickel for 0.5 hour at 100°; 8) metallic nickel for 1 hour at 100°.

Fig. 6. Reaction of nickel oxides and their solid solutions with sulfuric acid solutions: 1) reaction of nickelous oxide with 10% H_2SO_4 solution at 10° for 1-5 hours; 2) reaction of nickelic oxide with 10% H_2SO_4 solution at 10° for 1-5 hours; 3) reaction of solid solutions of nickel oxides with 10% H_2SO_4 solution at 10° for 1 hour; 4) reaction of solid solutions of nickel oxides with 10% H_2SO_4 solution at 10° for 2 hours; 5) reaction of solid solutions of nickel oxides with 10% H_2SO_4 solution at 10° for 3 hours; 6) the same, for 4 hours; 7) the same, for 5 hours; 8) reaction of nickelous oxide with 0.1 N H_2SO_4 at 80° (the temperature (°C) at which the solid solutions of nickel oxides are prepared and the duration of the process (hours) are plotted along the axis of abscissae).

Fig. 7. Passage of nickel into solution during the leaching of nepouite-garnierite: 1) 1% H_2SO_4 solution; 2) 2% H_2SO_4 solution; 3) 3% H_2SO_4 solution.

It has thus been shown experimentally that the utilization of waste iron liquors in the manner proposed by us earlier [2,3] considerably reduces the total consumption of sulfuric acid, which can be obtained directly in the course of the leaching by the utilization of waste sulfurous gases, these being applied in the aeration of the pulp. Such a procedure is very economical.

The results of our experimental investigation of the interaction of ferric chloride solutions and mineral acids with nickel oxides and oxide-silicate nickel minerals and ores present not only technological, but also analytical interest. Under the conditions investigated (without warming the pulp or the use of high pressures) ferric chloride solutions do not react appreciably with nickelous oxide and garnierite, and they react only slightly with these during the boiling of the pulp. On the other hand, active metallic nickel obtained by reduction of nickelous oxide with hydrogen dissolves almost completely during leaching under the investigated conditions with ferric chloride solutions containing 30 g/liter and more of iron (Fig. 5). This gives us reason to suppose

Fig. 8. Dependence of the extraction of nickel from rich Akkerman ore on the concentration of the leaching acid solution: 1) H_2SO_4; 2) HCl; 3) HNO_3.

that the leaching of reduced nickel oxides and oxide-silicate minerals and ores with ferric chloride solutions can be applied as a method for the determination of the degree of reduction under industrial conditions. Moreover, our experimental investigations indicate effective ways of utilizing ferric chloride in the hydrometallurgy of nickel: ferric chloride is obtained in the processes that we developed earlier [4, 13] for the chlorination of iron-nickel-cobalt oxide-silicate ores. This is of great practical importance from the point of view of the economics of the chlorination process, the consumption of chlorine being considerably reduced by the use of the resulting ferric chloride as a reagent-solvent.

The investigation of the interaction of solutions of mineral acids with nickel oxides, silicate minerals, and oxide-silicate ores showed that the investigated sulfuric acid solutions react only very slightly with nickelous and nickelic oxides under the conditions studied (Fig. 6). A somewhat higher extraction of nickel is attained in the leaching of oxide-silicate minerals and ores of nickel with these sulfuric acid solutions (Fig. 7). The extent to which these processes proceed is however much smaller than the extent of the leaching of oxide-silicate minerals and ores of nickel by means of ferric sulfate solutions. Our experiments show that the leaching of unreduced oxide-silicate nickel ores by means of sulfuric acid solutions is not sufficiently effective, a fact that can be explained completely by the physicochemical characteristics of these ores, which have been studied previously [12].

Experiments on the leaching of nickel oxides and silicate nickel minerals with nitric acid solutions showed that this process proceeds even more slowly than in the case of leaching with sulfuric acid solutions. For example, when nickelous oxide is leached with 20% nitric acid solution for two hours, only traces of nickel pass into solution, and in the leaching of nepouite-garnierite under the same conditions only about 1% of the nickel present is removed, i.e. only oxidized nonsiliceous nickel compounds – which are present in various amounts in oxide-silicate nickel minerals – pass into solution.

Our experimental results on the interaction of solutions of sulfuric and nitric acids with nickel oxides and oxide-silicate minerals and ores (Fig. 8) show that it is possible to use treatments with these acids to determine approximately the extent to which nickel oxides, minerals, and ores have been reduced by hydrogen. Since the nickelous sompounds in oxide-silicate nickel ores are reduced almost completely [10, 14] in the very earliest stages of the reduction process and roasted unreduced nickel silicates react with these solutions only to a very slight extent, it is mainly the chemically reactive freshly reduced metallic nickel that passes into solution in the leaching process. When we consider the low nickel contents of the low-grade and waste iron-nickel ores under investigation, the tenths of one percent of silicate nickel in the unreduced residues which may pass into solution together with the very reactive freshly reduced nickel will represent a negligible error in the determination of the degree of reduction of the ore by this method.

The method of leaching with sulfuric or nitric acid is much less applicable to the determination of the extent of reduction of oxide-silicate nickel ores with carbon monoxide (or gases containing carbon monoxide) or with solid carbon. As our previous investigations have shown [15, 18], nickel reduced under these conditions is of low reactivity in hydrometallurgical processes and so passes into solution much more slowly and less completely during leaching. The fact, which we established for the first time [2, 15], that there is a substantial fall in the solubility of nickel as the temperature at which it is reduced is raised makes this method completely inapplicable in this case.

Before the present investigations there was no exact method for the determination of the extent of reduction of nickel and cobalt oxides, minerals, and ores, and it may be considered that the approximate method that we have proposed for this purpose will have some importance for control and analysis.

There are no references in the literature to the possibility of effective selective leaching of nickel from its silicates with ferric sulfate solutions. The statement of Herrenschmidt [11] that ferric sulfate solutions react actively with nickelous oxide was not confirmed in our investigations.

Special experiments showed that nickelous oxide reacts to a negligible extent with ferric sulfate solutions, even under optimum conditions which result in almost complete extraction of nickel from its oxide-silicate minerals and ores.

In conclusion, the authors thank G. S. Gritsaenko, L. G. Berg, S. P. Gandelman, and the director of the Nickel-Cobalt Board of the Ministry of Nonferrous Metallurgy of the USSR, A. A. Mironov, for active participation and cooperation in the work.

SUMMARY

1. Metallic nickel freshly formed by reduction with hydrogen is almost completely dissolved during interaction with solutions of ferric chloride and mineral acids under the conditions investigated. Hence, before being leached with these solvents, iron-nickel oxide and oxide-silicate ores must be subjected to reduction with hydrogen or with technical or natural gases enriched as far as possible in hydrogen.

2. Ferric sulfate solutions of the compositions investigated interact considerably more intensively with nickel-magnesium and nickel-aluminum hydrosilicate minerals than solutions of ferric chloride and mineral acids; under suitable conditions they leach nickel from these minerals with an adequate degree of efficiency.

3. Nickel can be extracted almost completely from its various oxide-silicate minerals and ores by the proposed method of leaching with ferric sulfate solutions.

4. It was shown experimentally that it is possible to attain a high extraction of nickel from waste and low-grade iron-nickel oxide-silicate ores from various commercially worked deposits by the method of leaching with ferric sulfate solutions, which are readily obtained from recirculated iron-containing sulfate lyes by very simple methods.

5. It was shown that our previously proposed method [2] of making simultaneous use of recirculated iron-containing sulfate lyes and waste sulfurous gases for the preparation of the necessary sulfuric acid solutions substantially reduces the total consumption of acid in the sulfuric acid method of leaching oxide and oxide-silicate iron-nickel-cobalt ores.

6. It was shown that the methods investigated are of importance for control and analysis.

SURFACE AND SORPTION PROPERTIES OF ACTIVE CARBONS

COMMUNICATION 2. INVESTIGATION OF THE EFFECT OF CHEMICALLY ADSORBED AND CHEMISORBED OXYGEN ON THE ADSORPTION PROPERTIES OF ACTIVE CARBONS WITH RESPECT TO WATER VAPOR

M. M. Dubinin and E. D. Zaverina

A review of the literature and a generalization of the results of previous investigations were given in a paper by one of the authors [1]. According to the experimental conditions, for active carbons previously evacuated at 1000° interaction with oxygen through chemical forces constitutes either chemical adsorption (up to about 100°) or chemisorption, which is marked at temperatures of about 200° and higher. These processes result in the formation of surface carbon oxides, the functional properties of which depend on the temperature at which the sorption of oxygen occurs.

The effect of surface oxides formed by reaction between active carbons and oxygen at 350-500° on the adsorption of various vapors has been studied by Bruns and Maksimova [2] and by us [3-6]. The elementary compositions of carbons containing surface oxides were studied in one of our investigations [7]. Hence, the effect on the adsorption of various vapors of the presence of acidic surface oxides formed at relatively high temperatures (350-500°) has been subjected to fairly detailed investigation. We are not aware of any investigation on the effect of chemically adsorbed and chemisorbed oxygen in the initial chemisorption range, i.e. 200°, on the adsorption of vapors. Investigation in this direction formed the main purpose of the present work.

EXPERIMENTAL

1. In order to exclude as far as possilbe the part played by chemically adsorbed oxygen, it was necessary to carry out the thermal treatment of the weighed sample of carbon in a vacuum at 1000° and then, after cooling with continued evacuation to the experimental temperature of 20°, measure the adsorption isotherm of vapor without bringing the carbon into contact with atmospheric oxygen. In accordance with the aims of the investigation, the previously evacuated carbon must then be brought into contact with oxygen under the conditions for chemical adsorption or chemisorption. The apparatus must therefore provide for the direct determination of the amount of chemically bound oxygen from the increase in weight of the carbon and for the subsequent measurement of the adsorption isotherm for vapor.

For the performance of these tasks we used the sorption-balance method. The previously described apparatus for the measurement of sorption isotherms [8] was modified, the design of the tube and sorption balance being altered. The new sorption tube was constructed of thick-wall quartz in its lower part (560 mm) and it had a diameter of 40 mm and total length of 920 mm. The upper part of the tube (360 mm) was made of glass and was attached to the lower part by means of a ground joint. The lower end of the tube was closed, and the upper end carried a ground-in stopper provided with a hook for the attachment of the sorption balance.

The stopper was mercury-sealed, and a side tube on the glass part of the tube connected it through a mercury seal to the unchanged part of the apparatus, which included a U-shaped mercury manometer, a McLeod gage, and a funnel with a porous base for the introduction of gas (oxygen, hydrogen, vapor of liquid to be adsorbed) into the system through a layer of mercury.

A quartz spiral was hung on the hook in the stopper; it had a sensitivity of 0.0145 mg for each division of the ocular screw micrometer of the cathetometer, which corresponded to 0.0025 mm. There was a hook at the

lower end of the quartz spiral, and this carried a quartz thread, weight 100 mg and length 895 mm, and a thin-walled quartz sphere, diameter 10 mm, which was provided with a hook and two side openings. The carbon (about 100 mg) was placed in the sphere, which weighed 46.3 mg. The sphere was at about 75 mm from the sealed end of the quartz tube. The use of spherical vessel having two side openings in its upper part (diameter about 2mm) instead of an open dish, largely prevented the scattering of carbon in the initial stage of evacuation.

With the aid of a wide clamp placed near the joint, the sorption tube was fixed in a strictly vertical position to a massive metal stand in such a way that there was free access to the lower end of the tube. A simple lifting device made it possible to place the lower part of the sorption tube into an electric tube furnace with a platinum winding or into an ultrathermostat. The furnace tube was 65 mm in diameter and 300 mm in length. The body of the furnace was furnished with a water-cooled copper jacket to prevent any heating of the apparatus by rising currents of hot air. The lower opening of the furnace tube was closed by sheets of asbestos paper. When the furnace was in position, complete closure at the upper opening was effected with the aid of asbestos gaskets which fitted around the sorption tube. In this working position, the sphere containing the carbon was in a constant-temperature zone. The temperature was measured with a thermocouple of platinum and platinum-rhodium, which was placed in the space between the furnace tube and the quartz tube at the level of the sphere containing the sample of carbon.

2. The materials investigated were two ashless active carbons prepared by the activation of the carbonization product from sucrose by means of carbon dioxide at 850°. For Carbon 1 the combustion loss due to activation was 6%, and for Carbon 2 it was about 20%. Both carbons belonged to the first structural type [9]. The constants for the adsorption-isotherm equation for the standard vapor (benzene) were:

Carbon 1: $W_0 = 0.093$ cc/g; $B = 0.552 \cdot 10^{-6}$
Carbon 2: $W_0 = 0.305$ cc/g; $B = 0.547 \cdot 10^{-6}$

The equation of the adsorption isotherm for active carbons of the first structural type was found to be closely obeyed over a wide range of relative pressure (from $1 \cdot 10^{-5}$ to 0.4). It will be seen that the selected carbons differed greatly in limiting sorptive capacity, whereas the constant B, which characterizes the curvature of the isotherm in the initial region, is almost the same for both carbons. In the course of the investigation it was found to be desirable to use Carbon 1 in the form of a rather coarse fraction that did not contain carbon dust. The screened fraction having grains that pass 0.5 mm mesh but not 0.25 mm mesh will be referred to as Carbon 1k. With respect to adsorption properties, Carbons 1 and 1k were almost identical.

Owing to the relatively low volume of micropores in Carbon 1, this carbon had distinct advantages in investigations on the cause of the relatively low values of sorption in the region of the filling of the micropores. With respect to the volume of micropores, Carbon 2 differed little from technical carbons.

Water vapor was used as adsorbate, for it is most sensitive to changes in the chemical state of the carbon surface due to changes in the number of primary adsorption centers [5]. A great reduction in the number of primary adsorption centers was brought about by thermal treatment of the active carbon in a vacuum at 1000°. The experiments of this series, which is denoted by the letter A, were carried out under the following conditions: 4 hours at 1000° under evacuation by a three-stage mercury pump. Pumping was continued while the carbon was cooled to 20°. The system was then disconnected from the evacuation apparatus by a turn of a tap, the loss in weight of the carbon sample was determined, and the sorption isotherm for water vapor was measured without allowing the carbon to come into contact with atmospheric oxygen (such contact occurred in experiments of previous investigators).

In experiments of Series B, the carbon evacuated and cooled to 20° under the above-described conditions was brought into contact with oxygen at a pressure of 50 mm. The oxygen was prepared by the thermal decomposition of chemically pure potassium permanganate. When the carbon had been kept in the oxygen atmosphere for 12-14 hours, the vessel was evacuated until the carbon sample attained a constant weight. The increase in weight of the carbon due to irreversible chemical adsorption of oxygen was measured. Sorption isotherms for water vapor were then measured.

In order to study the effect of the presence of chemisorbed oxygen on adsorption, the carbon, after evacuation at 1000° (or at 450° in certain experiments), was cooled to 200° and oxygen was admitted up to a pressure of 50 mm. The carbon was kept in contact with oxygen at 200° for ten hours. After the carbon had been cooled

Fig. 1. Sorption and desorption isotherms for water vapor at 20°: 1) Carbon 1A; 2) Carbon 1; 3) Carbon 1C (the black points correspond to the desorption branches).

to 20°, the apparatus was evacuated at this temperature until the carbon attained constant weight. The sorption isotherm for water vapor was then measured. These experiments comprised Series C.

In order to estimate the effect of a reducing atmosphere on the destruction of surface carbon oxides, in some experiments the thermal treatment of the carbon was carried out in an atmosphere of hydrogen at 1000° (Series D). For this purpose the carbon was first evacuated for six hours at 450°, cooled to 20°, and weighed (initial weight). The temperature was raised, and when it attained 450° hydrogen was admitted into the system up to a pressure of about 100 mm. Heating was continued to 1000°, and the carbon was kept at this temperature for four hours. On the next day the carbon was again heated to 1000° for one hour, after which the mercury pump was turned on and the carbon was evacuated for one hour. After cooling to 20° under evacuation, the carbon was weighed and the adsorption isotherm was determined for water.

As these preliminary treatments of the carbons affected the chemical properties of their surfaces, the samples obtained were described by the Carbon number and the Series letter, for example Carbon 2A. For each variant of preliminary treatment, several experiments were generally carried out. Where essential, therefore, apart from these characterizations of the carbon, the number of the experiment will be given. In most cases conclusions were drawn on the basis of the mean results of experiments.

Apart from the above measurements, we made the usual measurements of sorption isotherms for water vapor on carbon samples that had been kept in sealed tubes in contact with air. In these cases, the preliminary evacuation of the carbons was carried out at 450° for six hours, after which the isotherms were determined. The carbons from these experiments will be denoted by a number only, e.g. Carbon 2.

3. For a general appraisal of the effect of the chemical state of the carbon surface on the form of the sorption and desorption isotherms for water vapor, preliminary experiments were carried out with Carbon 1 thermally treated in a vacuum at 1000° (Carbon 1A), the same sample of carbon with the usual state of the surface (Carbon 1), and a sample of carbon containing chemisorbed oxygen in the form of surface oxides (Carbon 1C). The results of the measurements on the sorption and desorption isotherms for water vapor at 20° are shown graphically in Fig. 1.

The isotherms indicate a very considerable effect of the chemical state of the carbon surface in the adsorption region. Carbon 1A, which has a preliminary evacuation at 1000°, adsorbs only small amounts of water vapor up to a relative pressure of h = 0.4 (Curve 1). At higher relative pressures there is a sharp rise in the adsorption branch of the isotherm. Carbon 1, which has the usual surface state and is kept in contact with atmospheric oxygen, contains chemically adsorbed oxygen on its surface in the form of surface oxides having a basic character. The presence of a larger number of adsorption centers results in increased adsorption in the initial region of the isotherm; the isotherm passes on to the sharp rise more smoothly and at lower relative pressures (Curve 2). Finally, in the case of Carbon 1C, the formation of considerable amounts of surface oxides as a result of chemisorption of oxygen at 200° leads to a considerable rise in the extent of adsorption in the initial part of the isotherm. The region in which the sharp rise occurs is still further displaced in the direction of lower relative pressures (Curve 3).

At high relative pressures the sorption and desorption branches of the isotherm do not coincide and form hysteresis loops which are characteristic of the sorption isotherms for water vapor on active carbons. Owing to

the low combustion loss in the activation of Carbon 1 and its extremely fine state of porosity (for this carbon a reverse series is found for the adsorption of acetic, propionic, valeric, and heptanoic acids from aqueous solutions), the points for the start of hysteresis correspond to sorption values of 4-5 mmoles/g. At lower sorption values the sorption and desorption points fit satisfactorily on a single curve for each carbon sample, a fact that indicates the reversible character of the primary adsorption process.

In the hysteresis region, the effect of the chemical state of the carbon surface is not so marked and is due mainly to the displacement of the regions of sharp rise of the isotherms in the primary adsorption process. The limiting sorption values for Carbons 1A, 1, and 1C are almost the same and are found in the range 9.78-9.83 mmoles/g. The mean limiting sorption value for water vapor corresponds to a limiting sorption capacity of $v_s = 0.176$ cc/g. According to experiments with benzene, $v_s = 0.101$ cc/g, which is substantially less and is close to the value of the limiting adsorption capacity of this carbon $W_0 = 0.093$ cc/g. It follows from the results that Carbon 1 has an extremely fine microporosity, part of it being inaccessible to the larger molecules of benzene. For Carbon 1 we observe the typical effect of ultraporosity in the adsorption of vapors of substances having molecules of different sizes.

The main effect of the chemical nature of the surface of active carbon is therefore manifested in the adsorption region of the isotherm, which for Carbon 1 includes adsorption values up to 40-50% of the limiting values. This peculiar feature of Carbon 1 formed the basis of its choice as the main object for investigation.

It follows from these preliminary experimental results that it is desirable to concentrate attention on the study of the adsorption regions of isotherms for carbon samples having surfaces differing in chemical nature. The systematic investigation consisted in prior treatments of carbon samples by the above described procedures A, B, C, and D and the measurement of isotherms in the adsorption region.

In Fig. 2 a comparison is made between the initial sections of the adsorption isotherms for water vapor on Carbons 1kA and 2A, which have partially destroyed surface oxides as a result of the preliminary evacuation at 1000°. In accord with the higher specific surface of Carbon 2, at relative pressures of less than 0.5, its isotherm is in the higher position. However, as in Fig. 1, the region of sharp rise in the isotherm for this carbon is displaced in the direction of higher relative pressures. The reduction in the amount of surface oxides has led to a considerable reduction in the adsorptive power of the carbons with respect to water vapor at relative pressures up to 0.5.

Chemical adsorption of oxygen at 20° on active carbons that have received prior thermal treatment in a vacuum at 1000° results in a substantial increase in the adsorption values and causes a more rapid rise of the curves in the initial region of relative pressures. The experimental adsorption isotherms for Carbons 1kB and 2B are shown graphically in Fig. 3, in which the scale along the axis of ordinates is doubled. The relative disposition of the curves for Carbons 1 and 2 remains unchanged.

Chemisorption of oxygen by active carbons at 200° results in a still greater increase in adsorption and in a steeper rise in the isotherms in the initial region. Fig. 4 shows the adsorption isotherms for Carbons 1 and 2 containing chemisorbed oxygen. Experimental points for various samples of Carbons 1C and 2C fit the same curves satisfactorily. The less active Carbon 1 has a higher power of chemisorbing oxygen than Carbon 2. This peculiarity of carbons of low combustion loss has been noted already in the work of Bruns and Maksimova [2] and in one of our investigations [7]. As a result, the adsorption isotherms for the oxidized Carbons 1 and 2, unlike those represented in Figures 2 and 3, do not intersect.

In examining the experimental results represented graphically in Figures 2-4, we turned our attention mainly on the differences in properties between Carbons 1 and 2 subjected to preliminary treatments of the same type. Fig. 5 shows the initial sections of the adsorption isotherms for samples of Carbon 1k differing in the chemical state of the surface; the scale along the axis of ordinates is doubled. The discrepancies between the continous and broken lines give an idea of the reproducibility of the experiments; it may be noted that Carbon 1kB of Experiment 19 contained about 20% more chemically adsorbed oxygen on its surface than Carbon 1kB of Experiment 19.

The curves in Fig. 5 indicate the considerable variation of the adsorption values with the variation of the chemical state of the surface of Carbon 1k. Increase in the content of oxygen chemically bound at the carbon surface results in an increase in adsorption values in the initial sections of the isotherms and in a displacement of the regions of sharp rise toward lower relative pressures.

Thermal treatment of Carbon 1k in hydrogen at 1000° (the preliminary evacuation of the carbon for the determination of its original weight was also carried out at 1000°) resulted in an appreciable ignition loss: 1.37% in Experiment 21 and 1.89% in Experiment 22. These Series D active carbons were evacuated to remove hydrogen at 1000° and cooled under constant pumping to 20°; adsorption isotherms for water vapor were then determined without bringing the carbons into contact with atmospheric oxygen. In Fig. 6 a comparison is made between the isotherms so obtained and the adsorption isotherm for Carbon 1kA, which received only thermal treatment in a vacuum at 1000°. The effect of the treatment of the carbons in hydrogen is shown by appreciably increased adsorption in the initial region of the isotherm and a somewhat less abrupt rise to the steep almost linear section of the curve (h = 0.5-0.7), as compared with Carbon 1kA. These effects are enhanced in the sample carbon having the higher ignition loss in the hydrogen atmosphere. Hence, thermal treatment of a carbon at high temperature in a hydrogen atmosphere also results in chemical modification of the surface of the active carbon.

4. Theoretical concepts relating to the mechanism of the adsorption of water vapor [10-13] made it possible to derive an equation for the adsorption isotherm for the region of unimolecular coverage of the carbon surface [5]. To the first approximation, this equation expresses the most characteristic features of the adsorption of water vapor by carbon adsorbents; it has the form:

$$a = \frac{a_0 ch}{1 - ch}, \qquad (1)$$

in which a_0 is the number of primary adsorption centers on the carbon surface, c – is the ratio of kinetic constants, and $h = p/p_s$ is the relative pressure. Equation 1 is applicable for relative pressures of less than 1/c. As c and h are dimensionless quantities, the number of primary adsorption centers a_0 is expressed in the same units as the adsorption a.

The values of the constants a_0 and c can be readily determined from the parameters of the straight line corresponding to the isotherm equation (1) in the linear form:

$$\frac{h}{a} = \frac{1}{a_0 c} - \frac{1}{a_0} h: \qquad (2)$$

The table gives the constants a_0 and c of Equation 1 for various samples of active carbon, including some studied in the preceding investigation [6].

TABLE

Constants in the Equation for the Adsorption Isotherm

Carbon	Experiment	a_0 (mmole/g)	c
1kA	17	0.033	1.85
1kA	18	0.037	1.85
1kB	19	0.090	1.78
1kB	19a	0.091	1.93

E-2	[6]	1.43	1.85
E-3	"	0.110	1.69
E-4	"	0.205	1.50
B	Bruns [2]		1.71
C	"	0.075	1.58

According to the table, the number of primary adsorption centers in Carbon 1kB, which contains chemically adsorbed oxygen, is 2.5 times as great as in Carbon 1kA, which was ignited in a vacuum at 1000°. Oxidation of the carbon with oxygen at 200° (Sample 1kC) results in an increase in the number of primary adsorption centers, which is 12.5 times as great as in Carbon 1kA. Carbon 2B has 1.8 times as many primary adsorption centers as Carbon 2A. Oxidation of Carbon 2 at 200° (Carbon 2C) is accompanied by an increase in the number of primary adsorption centers by a factor of only 2.9, as compared with Carbon 2A. As compared with Carbon 1, Carbon 2 has a greater number of primary adsorption centers after evacuation at 1000° and after chemical adsorption of oxygen at 20°, but, as already noted, in oxidation with oxygen at 100° Carbon 2 acquires fewer primary adsorption centers than Carbon 1.

Chemisorption of oxygen at 450° results in a still greater increase in the number of primary adsorption centers, which attains 1.5-3 mmoles/g (Carbons E-1, E-2, and B; see Table); this number falls sharply after themal treatment of the oxidized carbons in a vacuum at 900-1000° (Carbons E-3, E-4, and C; see Table).

The extent to which the experimental results correspond to the adsorption isotherm (1) can be judged from Fig. 7, in which the adsorption isotherms calculated from the values of a_0 and $\underline{c}$ given in the table are represented by continuous lines and the experimental points are represented in various ways.

5. Carbon 1k evacuated at 1000° and brought into contact with oxygen at 20° and about 50 mm for 12-14 hou hours adsorbed oxygen to the extent of $a^0 = 0.110$ mmole/g (Experiment 19) or $a^0 = 0.115$ mmole/g (Experiment 19a). The value of the adsorption a^0 expresses the sum of the amounts of physically and chemically adsorbed oxygen. Exposure to a high vacuum at 20° to constant weight of carbon (two hours) results in the removal of physically adsorbed oxygen. The residual adsorption represents irreversible chemical adsorption of oxygen, $a = 0.064$ mmole/g (Experiment 19) and $a = 0.074$ mmole/g (Experiment 19a). For an unscreened sample of the carbon we obtained $a = 0.099$ mmole/g (Experiment 4). In the case of Carbon 2 under similar conditions we obtained $a = 0.121$ mmole/g (Experiment 10) and $a = 0.095$ mmole/g (Experiment 13). Hence, on the average the values of the chemical adsorption of oxygen at 20° were $a = 0.069$ mmole/g for Carbon 1k and $a = 0.108$ mmole/g for Carbon 2.

Chemisorption of oxygen by carbon at 200° is accompanied by appreciable formation of carbon dioxide, which can be detected in the equilibrium gas phase [1]. Hence, the change in weight of the carbon is the net result of an increase due to chemisorption and a decrease due to ignition loss of the carbon. Thus, in Experiment 7 on Carbon 1 there was no appreciable change in the weight of the carbon, in Experiment 20 Carbon 1k there was a diminution of 0.30% in the weight of the carbon, and in Experiment 14 on Carbon 2 there was an increase in weight of 0.41%. Hence, the amount of chemisorbed oxygen cannot be judged by the change in weight of the carbon resulting from oxidation.

DISCUSSION OF RESULTS

The question of the nature of the primary adsorption centers on the surface of carbon adsorbents — in particular, active carbons — is of fundamental importance for the discussion of our results. The results of the present investigation show that the adsorptive power of active carbons for water vapor in the region of unimolecular coverage is greatly dependent on the amount of oxygen chemically bound to the carbon surface. This is shown in the close relationship between the constant a_0 of Equation 1 for the adsorption isotherm, i.e. the number of primary adsorption centers in millimoles per gram, and the amount of chemically adsorbed or chemisorbed oxygen.

For several technical reasons we were unable to treat the investigated samples of active carbon at temperatures above 1000°. For such carbon samples of Series A (Carbons 1kA and 2A), although the number of primary

adsorption centers was greatly reduced (e.g. to 0.33 mmole/g for Carbon 1kA), it did not become zero. Thermal treatments at higher temperatures have been used for nonporous carbon adsorbents, namely carbon black. Raising of the temperature of the treatment of carbon black over the range 1000-2800° yields samples for which the regions of the isotherm associated with the sharp rise are displaced toward higher relative pressures. The curves representing the isotherms become less and less steep, and the adsorption values for unit surface of the carbon black diminish [12, 14]. For carbon black ignited in a vacuum at about 2800°, the adsorption of water vapor remains negligibly small up to h = 0.95 [14].

There can be no doubt that thermal treatment of carbon adsorbents in the temperature range 1000-2800° results in further reduction in the number of primary adsorption centers. However, the causes of this reduction may vary in character. In the first place, it may be a question of further destruction of particularly stable surface oxides. In the investigations cited, however, the experimental procedure differed from ours: after thermal treatment at high temperature the carbon black was cooled to room temperature and brought into contact with atmospheric oxygen for weighting and transference to the sorption apparatus. As our experiments show, under such conditions chemical adsorption of oxygen occurs on particularly active sites containing carbon atoms with unsaturated valencies, so that there is re-formation of surface oxides that act as primary adsorption centers.

Thermally treated carbon black in contact with atmospheric O_2 shows no appreciable tendency to acquire primary adsorption centers comparable to the original numbers. Such carbon black loses power to form an appreciable number of primary adsorption centers on its surface. This may result from recrystallization of carbon with formation of considerably larger crystals. Hence, the number of active sites (having unsaturated valencies, e.g. fragments of carbon side chains consisting of 1-2 atoms [1]) per unit surface area of the carbon is greatly reduced and the extent of chemical adsorption is similarly reduced. Consequently, the growth in carbon crystallites accompanying the reduction in the energetic heterogeneity of the surface is probably the main cause of the reduction in the number of primary adsorption centers resulting from thermal treatment of carbon black above 1000° (which, according to x-ray data, is the temperature at which appreciable growth of crystallities begins). It is thus found that, by the oxidation of Graphon carbon (prepared from carbon black by thermal treatment at 2800°), it is impossible to prepare adsorbents in which the number of primary adsorption centers is at all comparable to the number in the original carbon black, ignited at more moderate temperatures (up to 1000°).

Hence, the question of the nature of the majority of the primary adsorption centers in carbon adsorbents ignited in a vacuum at 1000° remains an open one. It is doubtful whether all of them can be associated with chemically adsorbed oxygen atoms. On the other hand, it is very unlikely that they can be associated with the ash elements present in the carbons, for a reduction of almost a hundred-fold in the ash of the carbons (treatment with hydrofluoric and hydrochloric acids and subsequent washing) does not effect the form of the adsorption isotherms for water vapor to an appreciable extent [6, 15]. The carbons were prepared from twice-recrystallized sucrose contained less than 0.005% of ash. If we assume that all the ash in such carbon consists of SiO_2, then 1 g of carbon will contain $8 \cdot 10^{-4}$ mmole/g SiO_2. Not all of the SiO_2 molecules can be hydrated with formation of OH groups that can act as primary adsorption centers. Such a process can result in the formation of only a few OH groups on the surface of the ignited silicon dioxide. In all, the number of possible primary centers due to ash elements will be less than that observed for carbons of Series A by a factor of 10-100. It may be added that the ash of technical carbons activated with gaseous substances (the product of the complete ashing of the carbons) adsorbs only an extremely small amount of water vapor [15].

Laying aside the question of the nature of the primary adsorption centers in carbons ignited in a vacuum at 1000°, we may consider the question of the additional, very substantial number of adsorption centers formed as a result of the chemical adsorption of oxygen at 20°. According to the table, as we pass from Carbon 1kA to Carbon 1kB, the number of primary adsorption centers increases by:

$$0.090 - 0.035 = 0.055 \text{ mmole/g}$$

This increase is due to the chemical adsorption of oxygen, which amounts to 0.069 mmole/g on the average. Hence, as a result of the chemical adsorption of one molecule of oxygen, approximately one primary adsorption of one molecule of oxygen, approximately one primary adsorption center is formed. An analogous estimate for the passage from Carbon 2A to Carbon 2B gives a change in the number of primary adsorption centers of

$$0.169 - 0.097 = 0.072 \text{ mmole/g}$$

as a result of chemical adsorption of oxygen to the extent of 0.108 mmole/g. We again obtain the same relationship, although the approximation is not so close.

It is important to note that the values we have found for the chemical adsorption of oxygen— from 0.069 mmole/g for Carbon 1 to 0.108 mmole/g for Carbon 2— lie in the range 0.080-0.150 mmole/g, as found by various methods for various active carbons [1].

As already pointed out, the interaction of oxygen with active carbons at 200° is accompanied by appreciable ignition loss. Loebenstein and Deitz have recently made a detailed study of the chemisorption of oxygen by various carbons at 200° by careful analysis of the gas phase and desorption products [16]. These authors found that, in the interaction of active carbon prepared from coconut shell with oxygen at 200°, chemisorption of oxygen amounted to 0.47 mmole/g and, on the average, about 1.3 mmoles/g of oxygen was consumed in the oxidation of the carbon with formation of gaseous products, mainly carbon dioxide. It is therefore not surprising that in many experiments we observed a small loss in the weight of carbon after chemisorption of oxygen at 200°. It may be noted that the amount of chemisorbed oxygen in the experiments of Loebenstein and Deitz on coconut-shell carbon ($a = 0.47$ mmole/g) is close to the number of primary adsorption centers for Carbon 1kC after chemisorption of oxygen at 200° ($a_0 = 0.437$ mmole/g). It would appear that, under these conditions also, one primary adsorption center is formed as a result of the chemisorption of about one molecule of oxygen. This number may be high, but it is unlikely that it will be more than double the true value.

If we assume, as a first approximation, that in the case of Carbon 1kC with a number of primary adsorption centers of $a_0 = 0.437$ mmole/g every center is formed as a result of the chemisorption of one molecule of oxygen, then, in conformity with chemisorption of oxygen to the extent of $a = 0.437$ mmole/g, the oxygen content of the carbon should be about 1.4%. This amount lies within the limits of possible oxygen content for an active carbon that has interacted with air at 200° for a longer time [7]. It will be important in the future to have direct data, based on chemical analysis, on the oxygen contents of such carbons.

It must be pointed out that the oxidation of an active carbon by oxygen at a still higher temperature, e.g. 450°, results in a further increase in the number of primary adsorption centers formed by the chemisorption of oxygen (see Table, Carbons E-1, E-2, and B).

The chemical changes in the surface of active carbons due to thermal treatment in a hydrogen atmosphere at 1000° have received little study. The appreciable ignition loss of the carbon is not surprising, for the interaction of active carbons with hydrogen at high temperatures with formation of methane has been referred to several times in the literature [17]. However, on the basis of the isotherms in Fig. 6 it may be concluded that the ignition of carbon in a hydrogen atmosphere results in an increase in the number of primary adsorption centers. It is possible that these arise as a result of the formation of surface compounds of hydrogen with carbon. Further investigations in this direction will be of undoubted interest.

SUMMARY

1. An experimental procedure was developed and was applied to the study of the effect of the chemical state of the surface of an active carbon— as determined by chemical adsorption or chemisorption of oxygen— on adsorption isotherms for water vapor.

2. It was shown that the formation of surface oxides has a very substantial effect, particularly on the adsorption region of the isotherm.

3. The question of the nature of the primary adsorption centers on the surface of active carbons was discussed on the basis of the experimental results. It was shown that the chemical adsorption of one molecule of oxygen results in the formation of approximately one primary adsorption center.

EFFICIENCY OF PROTECTOR BLOCKS OF ALUMINUM – ZINC ALLOYS

V. V. Gerasimov and I. L. Rozenfeld

Akimov [1] and Tomashov [2] have shown that protector blocks of Al–Zn alloys have considerable advantages over those made of pure zinc or aluminum. In their investigations, however, the aluminum content of the zinc alloys was not more than 10%, and the zinc content of the aluminum alloys was also not more than 10%.

EXPERIMENTAL

In the present work, Al–Zn alloys in the central part of the system were investigated (Fig. 1). The compositions of the alloys are given in the table. The alloys were prepared from Grade 00 aluminum and Grade 0 zinc. The iron, silicon, and copper contents of all the alloys did not exceed the permissible limits for the original metals. The tests were carried out in 1.5% sodium chloride solution. The ratio of the area of the steel sample to the area of the protector block was 13 : 1. The relation between the protective current per unit area of protector block (measured ten days after the start of the tests) and the composition of the block is shown in Fig. 2, from which it follows that the highest protective current is given by Alloys 2, 3, and 4, which contain 30–70% of zinc.

TABLE

Chemical Compositions of the Alloys Investigated.

Alloy No.	Content (%) of	
	Al	Zn
1	91.30	8.51
2	70.52	29.31
3	47.13	52.76
4	29.26	70.42
5	14.58	85.20
6	4.37	95.52

An investigation of the stationary electrode potentials of the alloys showed (Fig. 3) that with increase in the zinc content from 0 to 30% the potential of the alloy is markedly displaced in the negative direction. Further increase in the zinc content up to 70% has almost no effect on the stationary potential of the alloy. Further change toward pure zinc results in a further small movement in the negative direction. When a couple is formed with the steel to be protected, the potential of the protector block is displaced in the positive direction (the block is anodically polarized). It follows from Fig. 4 that the least polarized blocks contain 50–70% zinc. These alloys, which have a fairly high negative potential (Fig. 3) and a low polarizability, give the highest protective current. It is important that the protective current should fall as little as possible with time. It will be seen from Fig. 5 that in the course of ten days the protective current of protector blocks containing 30–70% zinc falls to 60% of its initial value, whereas for pure zinc it falls to 40% of its initial value and there is a particularly great fall in the case of an aluminum protector block (to 20% of its initial value). Hence, from this point of view also, the central part of the Al–Zn system is more satisfactory than pure aluminum or zinc. Another important characteristic of a protector material is the number of amp-hours obtained in the dissolution of 1 g of the protector block. It follows from Fig. 6 that this number increases as the aluminum content of the alloy increases.

These results indicate that alloys of the central part of the Al–Zn system can be used for the preparation of protector blocks. These alloys have potentials close to that of zinc, but they polarize anodically to a lower extent, give a high protective current, are more stable over a period of time, and show a smaller loss of protector material in providing the same quantity of electricity.

Fig. 1. Phase diagram of Al– Zn system.

Fig. 2. Protective current per sq. cm of protector surface (ratio of area of protected surface to area of protector block = 13 : 1).

Fig. 3. Stationary electrode potentials of alloys of the Al– Zn system (with respect to the normal hydrogen electrode).

Fig. 4. Anodic polarizability of Al– Zn alloys for a current density of 1.5 ma/cm².

Fig. 5. Ratio of current given by protector after ten days to initial current (%).

Fig. 6. Number of amp-hours obtained in the dissolution of 1 g of protector block.

Laboratory worker N. N. Ponsova took part in the experimental part of the work.

SUMMARY

1. An investigation was made of the stationary electrode potentials, the protective currents, the anodic polarizabilities, and the stability in use of six aluminum-zinc alloys together with pure aluminum and zinc.

2. It was shown that protector blocks of alloys containing 30-70% of zinc are more efficient than protector blocks made of pure aluminum or zinc or alloys of zinc content 0-30% and 70-100%.

SYNTHESIS OF ALKENYL 2-CHLOROVINYL KETONES

N. K. Kochetkov, A. Ya. Khorlin, B. P. Gottikh, and A. N. Nesmeyanov

The great potentialities of the use of 2-chlorovinyl ketones in organic synthesis [1] prompt investigation into the possibility of preparing new types of compounds of this class. Methods of synthesizing alkyl 2-chlorovinyl ketones [2] and aryl 2-chlorovinyl ketones [3] are now well established. The present paper is devoted to the synthesis of alkenyl 2-chlorovinyl ketones of the type $R_2C{=}CHCOCH{=}CHCl$. The combination of very active 2-chlorovinyl and alkenyl groups conjugated with a carbonyl group in one molecule provides a basis for attempts to use these compounds in various syntheses.

We examined two possible ways of synthesizing alkenyl 2-chlorovinyl ketones. The first way, which is analogous to the method used for alkyl and aryl 2-chlorovinyl ketones, consisted in the direct condensation of acid chlorides of α,β-unsaturated acids with acetylene in presence of aluminum chloride:

$$R_2C{=}CHCOCl + CH{\equiv}CH \xrightarrow{AlCl_3} RC{=}CHCOCH{=}CHCl.$$

The second way – a two-stage process – consisted in the condensation of acetylene with acid chlorides of α- or β-halo acids [cf. 4] and subsequent dehydrohalogenation of the 1- or 2-haloalkyl 2-chlorovinyl ketone formed; for example:

$$RCH_2CHXCOCl + CH{\equiv}CH \xrightarrow{AlCl_3} RCH_2CHXCOCH{=}CHCl \xrightarrow{-HX} RCH{=}CHCOCH{=}CHCl.$$

We used the first variant for the preparation of propenyl and 2-methylpropenyl 2-chlorovinyl ketones, in which crotonoyl and senecioyl chlorides, respectively, were condensed with acetylene. The reaction was carried out in carbon tetrachloride or dichloroethane solution under conditions similar to those used for the synthesis of alkyl 2-chlorovinyl ketones; it was accompanied by considerable resinification of the reaction mixture owing to the relative instability of the substance formed. However, after the usual treatment of the reaction mixture with ice, distillation gave propenyl and 2-methylpropenyl 2-chlorovinyl ketones in 35-50% yield.

In order to check the second possibility we investigated the condensation of acetylene with acid chlorides of α-bromo and α-chloro aliphatic acids. It was considered to be more expedient to use the bromo acids, owing to their greater accessibility, but several attempts to use them in the synthesis were made without success: condensation with acetylene in presence of aluminum chloride and subsequent dehydrobromination of the product gave a complex mixture of several substances, and this method was abandoned. The lack of success is probably to be explained by halogen exchange in the chlorovinyl group with the result that a difficultly separable mixture of the 2-chlorovinyl and 2-bromovinyl ketones is formed. This supposition appears to be well grounded, for exchange of the chlorine atom in alkyl 2-chlorovinyl ketones is well known [5].

The use of acid chlorides of α-chloro acids gave positive results. After trials with several methods of synthesizing these acids chlorides, Kharash's method [6] was found to be most convenient; this consists in the chlorination of acid chlorides with sulfuryl chloride in presence of catalytic amounts of iodine. After modifying the procedure somewhat, we were able to obtain acid chlorides of α-chloro acids in 40-60% yield.

Investigation of the condensation of acid chlorides of 2-chlorobutyric, 2-chloro-3-methylbutyric, and 3-chloropropionic acids with acetylene in carbon tetrachloride or dichloroethane at 10-15° showed that the usual treatment of the reaction mixture gave a mixture of two products – the corresponding 1- or 2-chloroalkyl 2-chlorovinyl ketone and the alkenyl 2-chlorovinyl ketone – the latter being obtained without a separate dehydro-

chlorination process. The elimination of hydrogen chloride from the chloroalkyl 2-chlorovinyl ketone that is formed in the first place evidently occurs in the reaction mixture itself, and it is known that, under certain conditions, aluminum chloride is a catalyst for the dehydrochlorination process [7]. Also, we regularly observed elimination of hydrogen halide during distillation. In this connection it must be pointed out that the readiness with which hydrogen chloride is eliminated is in some degree dependent on the structure of the corresponding chloroalkyl 2-chlorovinyl ketone. It is interesting that in one case – the condensation of 3-chloropropionyl chloride with acetylene – we succeeded in isolating both reaction products – 2-chloroethyl 2-chlorovinyl ketone and 2-chlorovinyl vinyl ketone – in the pure state by distillation. This result is not in accord with the earlier results of Yakubovich and Merkulova [8], who obtained only 2-chloroethyl 2-chlorovinyl ketone under these conditions. However, the separation is accompanied by considerable losses, and the method is not of preparative value for 2-chlorovinyl vinyl ketone. Under other conditions it is generally not possible to isolate both or one of the components of the mixture obtained by reaction of acid chlorides of α-chloro acids since distillation is always accompanied by elimination of hydrogen chloride and the distillate is always a mixture of the two substances. For our purpose there was no need to carry out the separation, and we subjected the mixture obtained by distillation to dehydrochlorination.

In spite of the difficulty to be expected in such operations, the selective elimination of hydrogen chloride without action on the chlorovinyl group was effected with the aid of diethylaniline, for even when distilled with such reagents alkyl 2-chlorovinyl ketones are not dehydrochlorinated [5]. The mixture of two products obtained by reaction of the acid chloride of a chloro acid with acetylene was heated with diethylaniline for one hour in a water bath. Diethylaniline hydrochloride was separated, and the alkenyl 2-chlorovinyl ketone was isolated by distillation. It must be stated here that a single treatment with diethylaniline is not always sufficient, a second treatment being necessary to remove a small residue of chloroalkyl 2-chlorovinyl ketone. It must be stated also that the use of dimethylaniline in this reaction does not give satisfactory results. By means of this two-stage method of synthesis we prepared 2-chlorovinyl vinyl ketone, 2-chlorovinyl propenyl ketone, and 2-chlorovinyl 2-methylpropenyl ketone in 30-50% yields.

As regards the comparative merits of the two methods described for the synthesis of alkenyl 2-chlorovinyl ketones, it should be noted that the direct method of synthesis from acid chlorides of α,β-unsaturated acids has the disadvantage that the latter are relatively inaccessible; in this case, however, pure alkenyl 2-chlorovinyl ketones are obtained directly. The second, two-stage method makes use of more accessible starting materials, but the procedure is more protracted and it is necessary to purify the reaction products carefully.

The alkenyl 2-chlorovinyl ketones are oily liquids, apart from 2-chlorovinyl propenyl ketone, which is a low-melting solid. All these compounds are unstable and rapidly darken in color, but they may be preserved several days in cold ethereal solution in presence of hydroquinone and in absence of light. 2-Chlorovinyl vinyl ketone has a marked tendency to polymerize; the reaction begins within several hours or, in ether solution, after one or two days. All alkenyl 2-chlorovinyl ketones have pungent odors and have a powerful effect on the mucous membrane and skin.

A notable feature in the chemical behavior of 2-chlorovinyl ketones is the high mobility of the chlorine atom [1]. It is interesting that, as far as can be judged from the characteristic reaction with 2-naphthol in hydrochloric acid in presence of ferric chloride [9], the mobility of chlorine in the new system, with its supplementary conjugation between the carbonyl group and the double bond of the alkenyl group, is not reduced. It was found that alkenyl 2-chlorovinyl ketones react like their saturated isologs, forming 3-(1-alkenyl)naphtho[2,1-b]pyrilium chloroferrates in high yields, a result which proves the structure of the compounds we obtained:

In this way we prepared pyrilium salts containing propenyl and 2-methylpropenyl radicals; these substances form dark-green crystals. 2-Chlorovinyl vinyl ketone also reacts with 2-naphthol, but the pyrilium salt formed rapidly undergoes further change, and we did not succeed in isolating it. The rate of this reaction when carried out under the usual standard conditions and the high yields of the pyrilium salts obtained give no reason to suppose that the mobility of the chlorine atom in alkenyl 2-chlorovinyl ketones is greatly different from the mobility of chlorine in alkyl-2-chlorovinylketones.

EXPERIMENTAL

2-Chlorobutyryl chloride. A mixture of 88 g of butyryl chloride, 119 g of sulfuryl chloride, and 1 g of iodine was boiled (90-110°) for 45-50 hours and then distilled, the fraction of b.p. 115-150° being collected. The product was shaken with mercury to free it from iodine and then distilled through a fractionating column of 10-15 theoretical plates. The fraction of b.p. 129-132° (756 mm), n_D^{20} 1.4475; and d_{17}^{4} 1.2360; was obtained in a yield of 70.0 g (80.3%).

2-Chloro-3-methylbutyryl chloride. This was prepared similarly from 147 g of 3-methylbutyryl chloride, 167 g of sulfuryl chloride, and 1 g of iodine. Similar treatment gave 110 g (58%) of a substance of b.p. 145.5-146.5° (749 mm).

2-Chlorovinyl vinyl ketone [1-chloro-1,4-pentadien-3-one]. A solution of 81 g of 3-chloropropionyl chloride [8] in 150 ml of carbon tetrachloride was introduced into a 500 ml three-necked flask fitted with stirrer, reflux condenser, and a tube through which a fairly gentle current of acetylene was passed. In the course of two hours 85 g of aluminum chloride was added, the temperature of the reaction mixture being kept below 10-15°. After acetylene had been passed for six hours, the mixture was decomposed by pouring it onto ice. The organic layer was separated, and the aqueous layer was extracted with chloroform. Solvent was vacuum-distilled from the combined extracts (bath temperature not above 50°), and vacuum-distillation of the residue gave 63 g of a substance of b.p. 50-92° (15 mm) which consisted of a mixture of 2-chlorovinyl ketone and 2-chloroethyl 2-chlorovinyl ketone. This mixture was treated with 65 g of freshly distilled diethylaniline, first at room temperature and then for one hour in a water bath. The mixture was cooled and diluted with 150 ml of ether. Diethylaniline was filtered off, and the ethereal solution was washed several times with 5% sulfuric acid and with water; it was then dried over sodium sulfate. Ether was distilled off, and distillation of the residue gave 21 g (31.5%) of 2-chlorovinyl vinyl ketone.* After being redistilled, the substance had the following constants: b.p. 48-49.5° (14 mm); n_D^{20} 1.4938; d_4^{20} 1.1274; found MR 30.07; calculated MR 29.23

Found %: C 51.29; 51.24; H 4.52; 4.41. C_5H_5OCl. Calculated %: C 51.54; H 4.32.

2-Chlorovinyl vinyl ketone is a slightly yellowish liquid of pungent odor which has a powerful action on the mucous membrane and skin. It rapidly turns into a dark-colored viscous mass, but it can be kept for some time in solution in ether containing hydroquinone.

2-Chlorovinyl propenyl ketone [1-chloro-1,4-hexadien-3-one]. 1. This was prepared similarly from 81 g of 2-chlorobutyryl chloride and 85 g of aluminum chloride in 200 ml of carbon tetrachloride, acetylene being passed for 7-8 hours at not above 15-20°. The fraction (57 g), b.p. 81-86° (15 mm), obtained after the usual treatment was a mixture of 2-chlorovinyl propenyl ketone and 1-chloropropyl 2-chlorovinyl ketone. It was treated with diethylaniline (51 g) as described above. Vacuum distillation gave 35 g (47.3%) of 2-chlorovinyl propenyl ketone, b.p. 70-72° (10 mm), which crystallized out completely in the receiver as a colorless crystalline mass, m.p. 38-39°.

2. The apparatus used was similar to that described above. Aluminum chloride (13.3 g) was added in small portions over a period of 15 minutes to a stirred, cooled (ice water) solution of 10.5 g of crotonoyl chloride in 50 ml of dichloroethane, and a stream of dry acetylene was passed in. Passage of acetylene was continued for 3.5 hours, and the temperature of the reaction mixture was not allowed to rise above 20-25°. The reaction mixture was poured onto ice, the aqueous layer was extracted twice with chloroform, and the organic layer combined with extracts was dried over calcium chloride. Solvent was vacuum-distilled off, and the residue was distilled, the fraction of b.p. 64-65° (7 mm) being collected. This solidified in the receiver to a crystalline mass, m. p. 37-39°. The yield was 6.5 g (50.5%).

2-Chlorovinyl propenyl ketone forms colorless crystals having a characteristic pungent odor.. It has a powerful action on the mucous membrane and skin.

Found %: C 54.94; H 5.57 . C_6H_7OCl. Calculated %: C 55.11; H 5.46.

2-Chlorovinyl propenyl ketone is soluble in organic solvents, but insoluble in water. It rapidly becomes dark-colored, but it can be kept for a long time in the dark as a solution in ether containing hydroquinone.

2-Chlorovinyl 2-methylpropenyl ketone [1-chloro-5-methyl-1, 4-hexadien-3-one]. 1. The procedure of Method 1 for the preceding compound was used. Acetylene was passed for seven hours at 15-20° through a solu-

* When a high-boiling fraction is present, it is necessary to give further treatment with diethylaniline in order to convert it into 2-chlorovinyl vinyl ketone.

tion of 60 g of 2-chloro-3-methylbutyryl chloride and 60 g of aluminum chloride in 150 ml of dichloroethane. The fraction (30 g), b.p. 78-92° (10 mm), obtained after the usual treatment was a mixture of 2-chlorovinyl 2-methylpropenyl ketone and 1-chloro-2-methylpropenyl 2-chlorovinyl ketone. It was treated with 32.5 g of freshly distilled diethylaniline by the above described method. Vacuum distillation gave 18.2 g (32.7%) of 2-chlorovinyl 2-methylpropenyl ketone, b.p. 76-79° (11 mm).

2. The procedure of Method 2 for the preceding compound was used. Acetylene was passed for 9 hrs. at not above 8-12° through a mixture 25 g senecioyl chloride [10], 75 ml of dichloroethane, and 32 g of aluminum chloride. The usual treatment and distillation gave 10.3 g (34%) of 2-chlorovinyl 2-methylpropenyl ketone, b.p. 71-73° (10 mm).

After being redistilled the 2-chlorovinyl 2-methylpropenyl ketone had the following constants: b.p. 71-73° (10 mm); n_D^{20} 1.5038; d_4^{20} 1.0644; Found MR 40.21; Calculated MR 38.47.

Found %: C 58.18; H 6.44. C_7H_9OCl. Calculated %: 58.16; H 6.28

2-Chlorovinyl 2-methylpropenyl ketone is a slightly yellowish liquid which has a powerful action on the mucous membrane and skin. It gradually darkens in color, but it can be kept a long time in the dark as a solution in ether containing hydroquinone.

Simultaneous preparation of 2-chloroethyl 2-chlorovinyl ketone [1,4-dichloro-1-penten-3-one] and 2-chlorovinyl vinyl ketone [1-chloro-1,4-pentadien-3-one]. Aluminum chloride (60 g) was added over a period of two hours with passage of acetylene into a mixture of 57.3 g of 3-chloropropionyl chloride and 120 ml of carbon tetrachloride contained in an apparatus similar to that described above. Passage of acetylene continued for seven hours in all, the mixture being stirred continuously and the temperature maintained below 20°. After the usual treatment and drying of the extracts, solvent was distilled off under reduced pressure (bath temperature not above 60°). Vacuum distillation of the residue gave a fraction (40.2 g) of b.p. 48-103° (15 mm). Two redistillations gave 10.1 g (17.7%) of 2-chlorovinyl vinyl ketone, b.p. 48-49° (15 mm) and n_D^{20} 1.5027 and 20.8 g (38.5%) of 2-chloroethyl 2-chlorovinyl ketone having the following constants: b.p. 100-102° (15 mm); d_4^{20} 1.2754 n_D^{20} 1.5045; Found MR 35.47, calculated MR 34.57. For 2-chloroethyl 2-chlorovinyl ketone the literature [8] gives b.p. 100-101° (15-16 mm).

2-Chloroethyl 2-chlorovinyl ketone is a colorless oil having a rather pungent odor. It can be kept in ethereal solution for a long time.

3-Propenylnaphtho[2,1-b]pyrilium chloroferrate. 2-Naphthol (2 g) and 12 ml of a solution of anhydrous ferric chloride in concentrated hydrochloric acid (prepared by dissolving 10 g of ferric chloride in 15 ml of concentrated hydrochloric acid) were added to a solution of 1.3 g of 2-chlorovinyl propenyl ketone in 20 ml of glacial acetic acid. The precipitate that formed after several hours was washed with a little glacial acetic acid and then with absolute ether. The yield was 2.8 g (67%). Recrystallization from glacial acetic acid gave fine dark-green crystals, m.p. 135-137° (with decomposition). This substance rapidly decomposes when kept, and for this reason we were unable to isolate it in an analytically pure state.

3-(2-Methylpropenyl)naphtho[2,1-b]pyrilium chloroferrate. This was prepared similarly from 0.7 g of 2-chlorovinyl 2-methylpropenyl ketone in 10 ml of glacial acetic acid, 1 g of 2-naphthol, and 6 ml of a solution of ferric chloride in concentrated hydrochloric acid. The yield was 1.5 g (71.5%). Recrystallization from glacial acetic acid gave fine dark-green crystals, m.p. 186-188°.

Found %: C 47.16; 47.35; H 3.30; 3.36 Fe 12.80; 12.69. $C_{14}H_{11}OCl_4Fe$. Calculated %: C 47.16; H 3.48; Fe 12.89.

SUMMARY

1. Two methods were developed for the synthesis of the previously unknown alkenyl 2-chlorovinyl ketones. The first method consists in the condensation of acid chlorides of α,β-unsaturated acids with acetylene in presence of aluminum chloride. The second method consists in the condensation of acid chlorides of α- and β-chloro acids with acetylene in presence of aluminum chloride and subsequent treatment of the reaction product with diethylaniline.

2. It was shown that alkenyl 2-chlorovinyl ketones react with 2-naphthol in presence of ferric chloride with formation of 3-(1-alkenyl)naphtho[2,1-b]pyrilium chloroferrates. This indicates the high mobility of chlorine in the alkenyl 2-chlorovinyl ketone molecule and proves the structure of these compounds.

SYNTHESIS AND PROPERTIES OF (TRIPHENYLSILOXY)SILANES AND THEIR HYDROLYSIS PRODUCTS

V. S. Chugunov

In the literature [1,2] only a few branched organic polysiloxanes of the types $Si(OSiR_3)_4$ and $R_nSi(OSiR_3)_{4-n}$ have been reported, in spite of their ready formation by the condensation of silicon tetrachloride with the corresponding sodium trialkyl- and dialkylaryl-siloxides.

We considered it to be of interest to prepare compounds of this type containing only aryl radicals. With this object we took sodium triphenylsiloxide as starting material; at 0° in a benzene medium, this condensed with silicon tetrachloride or tetrafluoride according to the equation:

$$Ph_3SiONa + SiX_4 = Ph_3SiOSiX_3 + NaX.$$

It was shown that reaction of sodium triphenylsiloxide with excess of silicon tetrachloride proceeded smoothly with formation in 72% yield of trichloro(triphenylsiloxy)silane [1,1,1-trichloro-3,3,3-triphenyldisiloxane], m.p. 47-48°. When chlorine was eliminated by hydrolysis with 0.1 N NaOH and this was followed by removal of solvent under reduced pressure and heating at 150-160°, a clear glassy polymer was formed; this softened at 65-70° and had the empirical formula $[(C_6H_5)_3SiOSiO_{1.5}]_n$. When reaction was between equimolecular proportions of trichloro(triphenylsiloxy)silane and sodium triphenylsiloxide, a 53% yield of dichlorobis(triphenylsiloxy)silane [3,3-dichloro-1,1,1,5,5,5-hexaphenyltrisiloxane], m.p. 134-135°, was formed in accordance with the equation:

$$(C_6H_5)_3SiOSiCl_3 + (C_6H_5)_3SiONa = [(C_6H_5)_3SiO]_2SiCl_2 + NaCl$$

Hydrolysis with 1N NaOH gave bis(triphenylsiloxy)silanediol [1,1,1,5,5,5-hexaphenyl-3,3-trisiloxanediol], m.p. 168-169°

It was further shown that reaction between silicon tetrachloride and excess of sodium triphenylsiloxide in boiling benzene gave a 29.5% yield of chlorotris(triphenylsiloxy)silane [3-chloro-1,1,1,5,5,5-hexaphenyl-3-(triphenylsiloxy)trisiloxane]; its hydrolysis product – tris(triphenylsiloxy)silanol [1,1,1,5,5,5-hexaphenyl-3-(triphenylsiloxy)-3-trisiloxanol] – melts at 241-242°. It is interesting that sodium triphenylsiloxide reacts already in the cold with silicon tetrafluoride with formation of fluorotris(triphenylsiloxy)silane [3-fluoro-1,1,1,5,5,5-hexaphenyl-3-(triphenylsiloxy)trisiloxane], m.p. 230-231°; this again gives tris(triphenylsiloxy)silanol on hydrolysis.

Our attempts to attach a fourth triphenylsiloxy group to silicon by boiling fluorotris(triphenylsiloxy)silane with excess of sodium triphenylsiloxide in benzene were not successful.

EXPERIMENTAL

Trichloro(triphenylsiloxy)silane

a) A mixture of 27.6 g of triphenylsilanol dissolved in 250 ml of dry benzene and 4 g of sodium was prepared in a round-bottomed flask fitted with a reflux condenser and protected from influx of moisture. The mixture was boiled for three hours in order to complete the formation of sodium triphenylsiloxide, and it was then

cooled with ice water. A solution of 20 g of silicon tetrachloride in 100 ml of benzene was then added, and the mixture was boiled for two hours. Precipitated sodium chloride was filtered off. Fractionation of the filtrate gave 28.4 g (72%) of trichloro(triphenylsiloxy)silane, b.p. 256-260° (30 mm), m.p. 47-48°. The product was readily soluble in ether, benzene, and other organic solvents; it was rapidly hydrolyzed by atmospheric moisture.

Found %: Si 12.9; 13.2; Cl 26.7; 26.5 $(C_6H_5)_3SiOSiCl_3$. Calculated %: Si 13.6; Cl 25.9. Found: M 410; 415 Calculated M 409.8

b) When 20 g of trichloro(triphenylsiloxy)silane was treated with 0.1 N NaOH, a viscous rubber-like polymer was formed which was readily soluble in ether, acetone, and benzene. When solvent was removed at 150-160° (30-35 mm), 14.5 g of a slightly yellowish transparent glass-like polymer (softening point 65-70°) was obtained.

Found %: C 65.71, 65.57; Si 16.41; 16.35; H 4.73; 4.87. $[(C_6H_5)_3SiOSiO_{1.5}]_n$. Calculated %: C 66.0 Si 17.1; H 4.6.

c) A solution of 1.2 g of trichloro(triphenylsiloxy)silane in 50 ml of benzene was cooled to 0° and 100 ml of a solution of phenyllithium (prepared from 15.7 g of bromobenzene in 85 ml of ether and 1.4 g of lithium) was added. The mixture was boiled for two hours, and the complex was then decomposed with dilute hydrochloric acid. Recrystallization from benzene gave 0.96 g of hexaphenyldisiloxane, m.p. 220°, which is in accord with the reported value [3].

Dichlorobis(triphenylsiloxy)silane

Sodium triphenylsiloxide was prepared from 1.2 g of sodium and a solution of 5.5 g of triphenylsilanol in 100 ml of benzene. This solution was cooled, and 7.8 g of trichloro(triphenylsiloxy)silane diluted with 50 ml of benzene was added. After two hours at the boil, the precipitate of sodium chloride was filtered off. The filtrate was warmed slightly and concentrated to 30 ml by the passage of dry air. Crystals of dichlorobis(triphenylsiloxy) silane separated and were recrystallized from petroleum ether. The finely crystalline dichloro(triphenylsiloxy) silane, amounting to 7.2 g (53%), melted at 134-135°.

Found %: Si 12.4; 12.2; Cl 10.9; 10.6. $[(C_6H_5)_3SiO_2]SiCl_2$ Calculated %: Si 12.9; Cl 11.0. Found M 636 Calculated M 649.8.

Bis(triphenylsiloxy)silanediol

Dichlorobis(triphenylsiloxy)silane (3 g) was dissolved in 30 ml of ethanol, and 1N NaOH was added gradually until there was an excess to phenolphthalein. The precipitate formed was filtered off and recrystallized twice from benzene. The product, 2.4 g (90.2%) of colorless crystals, was bis(triphenylsiloxy)silanediol, m.p. 168-169°.

Found %: C 70.46; 70.31; Si 13.88; 13.53; H 5.30; 5.19. $[(C_6H_5)_3SiO_2]Si(OH)_2$. Calculated %: C 70.54; Si 13.74; H 5.27.

Chlorotris(triphenylsiloxy)silane

Sodium triphenylsiloxide was prepared as before from 2 g of sodium and 27.6 g of triphenylsilanol dissolved in 200 ml of benzene. Silicon tetrachloride (3.5 g) was then added to the solution, and the mixture was boiled for four hours. Sodium chloride was separated from the benzene solution, and chlorotris(triphenylsiloxy)silane was isolated from the filtrate as a finely crystalline powder. Two crystallizations from benzene gave 8.6 g (29.5%) of product, m.p. 219-220°. Chlorotris(triphenylsiloxy)silane is difficultly soluble in ether, but fairly readily soluble in warm benzene and toluene.

Found %: Si 12.6; 12.1; Cl 4.02; 4.08. $[(C_6H_5)_3SiO]_3SiCl$. Calculated %: Si 12.6; Cl 3.98. Found: M 856; 870 (cryoscopically in camphor). Calculated: M 889.6.

Tris(triphenylsiloxy)silanol

To a solution of 3.2 g of chlorotris(triphenylsiloxy)silane in 50 ml of a 1:1 mixture of benzene and ethanol, 20 ml of 3% potassium hydroxide solution was added. The mixture was boiled in a water bath for 30 minutes. After being washed free from alkali, the isolated product was recrystallized from benzene. The product, amounting to 2.2 g (70%), was tris(triphenylsiloxy)silanol, m.p. 241-242°.

Found %: C 74.52; 74.45; Si 12.52; 12.50; H 5.15; 5.27 $[(C_3H_5)_3SiO]_3SiOH$. Calculated %: C 74.43; Si 12.88; H 5.32

Fluorotris(triphenylsiloxy)silane

A benzene solution of sodium triphenylsiloxide was prepared from 27.6 g of triphenylsilanol, 200 ml of benzene, and 4 g of sodium, and gaseous silicon tetrafluoride, prepared by the action of sulfuric acid on a mixture of 15 g of sodium fluosilicate and 5 g of glass powder, was passed through this solution at room temperature. When silicon tetrafluoride ceased to be evolved, the sodium fluoride formed was filtered from the solution, which was heated to the boil. Fluorotris(triphenylsiloxy)silane was isolated as a finely crystalline powder and was recrystallized from benzene. The yield of product, m.p. 230-231°, was 22.6 g (77.4%).

Found %: Si 12.9; 12.6. $[(C_6H_5)_3SiO]_3SiF$. Calculated % Si 12.86. Found: M 862; 869 (cryoscopically in camphor). Calculated: M 873.3.

Fluorotris(triphenylsiloxy)silane (3 g) was treated with alkali under the conditions used for the hydrolysis of chlorotris(triphenylsiloxy)silane, and a 65% yield of tris(triphenylsiloxy)silanol was obtained and identified by its melting point.

SUMMARY

1. It was shown that sodium triphenylsiloxide reacts with silicon tetrachloride with successive attachment of one, two, and three triphenylsiloxy groups to silicon.

2. It was shown that the complete exchange of the halogens of silicon tetrafluoride and silicon tetrachloride by triphenylsiloxy groups does not occur when the silicon halide is treated with sodium triphenylsiloxide in boiling benzene; the reaction stops at halotris(triphenylsiloxy)silane.

SYNTHESIS AND REACTIONS OF OXYGEN-CONTAINING ORGANOSILICON COMPOUNDS

COMMUNICATION 6. PREPARATION OF SECONDARY DIALKYL(OR ARYL)CHLOROSILANES AND DIALKYL(OR ARYL)SILANOLS AND SOME OF THEIR REACTIONS

M. F. Shostakovsky, D. A. Kochkin, and V. M. Rogov

The preparation of dialkyl(or aryl)silanols having silicon-attached hydrogen (general formula R_2SiOH) and the derived disiloxanes $R_2Si(H)-O-Si(H)R_2$ has not been described in the literature. Such organosilicon compounds are of definite interest in view of their considerable reactivity and the possibility of using them as starting materials in organic synthesis.

The present paper describes the preparation of diethyl-, ethylisobutyl-, and ethylphenyl-silanols and their derivatives: symmetrical tetraethyl-, diethyldiisobutyl-, and diethyldiphenyl-disiloxanes; also the symmetrical tetraethyldisilazane $(C_2H_5)_2Si(H)-NH-Si(H)(C_2H_5)_2$. The starting materials for the preparation of the silanols were the corresponding dialkyl(or aryl)chlorosilanes: chlorodiethyl-, chloroethylisobutyl-, and chloroethylphenyl-silanes, which we prepared with the aid of organomagnesium and organolithium compounds. Apart from chlorodiethylsilane, the properties of which have not been adequately described, the preparation and properties of these compounds have not been described in the literature. They were synthesized from dichloroethylsilane $C_2H_5SiHCl_2$, which we prepared by the action of ethyl chloride on a mixture of copper and silicon at 260-270° [1].

We showed in a series of investigations [2-4] that trialkyl(or aryl)silanols react with vinyl ethers with formation of organosilicon acetals of structure $CH_3CH(OR'')(OSiR_3)$. Secondary (i.e. having silicon-attached hydrogen) dialkyl(or aryl)silanols also react with vinyl ethers with formation of acetals. In the present paper we describe the reaction of ethylisobutylsilanol with ethyl vinyl ether with formation of acetaldehyde ethyl ethylisobutylsilyl acetal:

$$C_2H_5(i\text{-}C_4H_9)SiHOH + CH_2{=}CHOC_2H_5 \rightarrow CH_3CH(OC_2H_5)(OSiH(C_2H_5)(i\text{-}C_4H_9))$$

Secondary dialkyl(or aryl)silanols are mobile liquids having a pungent camphor odor. They react with sodium or potassium with formation of crystalline siloxides:

$$R_2Si(H)OH + Na(K) \rightarrow R_2Si(H)ONa(K) + H$$

Secondary dialkyl(or aryl)silanols are less stable compounds than trialkyl(or aryl)silanols, for keeping for only a few hours at room temperature results in condensation with formation of the corresponding disiloxanes:

$$R_2Si(H)OH + HOSi(H)R_2 \rightarrow R_2Si(H)-O-Si(H)R_2 + H_2O$$

Of the dialkyl(or aryl)silanols that we prepared, the most stable was ethylisobutylsilanol, which condensed with formation of 1,3-diethyl-1,3-diisobutyldisiloxane only after being kept for a long time. The stabilities of our dialkyl(or aryl)silanols can be arranged in the series:

$$C_2H_5- < C_6H_5- < i\text{-}C_4H_9-.$$

We did not isolate diethylsilanol in the pure state, although we prepared it by two methods: a) hydrolysis of chlorodiethylsilane with 1 N NaOH:

$$(C_2H_5)_2Si(H)Cl + NaOH \rightarrow (C_2H_5)_2Si(H)OH + NaCl$$

and b) hydrolysis of 1,1,3,3-tetraethyldisilazane with aqueous hydrochloric acid:

$$2(C_2H_5)_2SiCl + NH_3 \rightarrow (C_2H_5)_2Si(H)-NH-Si(H)(C_2H_5)_2 + 2HCl \quad (1)$$

$$(C_2H_5)_2Si(H)-NH-Si(H)(C_2H_5)_2 + 2HOH \xrightarrow{HCl} 2(C_2H_5)_2Si(H)OH + NH_3 \quad (2)$$

It must be pointed out that the introduction of an isobutyl radical into the chlorosilane and silanol molecules greatly increases their stabilities. Thus it is much more difficult to hydrolyze an alkylchlorosilane containing an isobutyl radical, boiling for 5-6 hours with 1 N NaOH being required for complete hydrolysis. This behavior of these sterically hindered compounds is to be explained by higher electron density in the chloroethylisobutylsilane and ethylisobutylsilanol molecules. The compounds with silicon-attached hydrogen – dialkyl(or aryl)silanols and the corresponding disiloxanes and disilazanes – reduce silver nitrate solution to metallic silver and decolorize potassium permanganate solution.

Some physicochemical properties of dialkyl(or aryl)chlorosilanes, dialkyl(or aryl)silanols, and the corresponding disiloxanes are given in Tables 1 and 2.

EXPERIMENTAL*

Preparation of chlorodiethylsilane $(C_2H_5)_2Si(H)Cl$. A mixture of 24.0 g (1 mole) of magnesium turnings (or 14.0 g of lithium shavings **) and 200 ml of ether was prepared in a three-necked flask fitted with a reflux condenser protected by a calcium chloride tube, a dropping funnel, and a mechanical stirrer. Cooling was applied while 109.0 g of ethyl bromide was dropped in. The resulting ethereal solution of ethylmagnesium bromide was added from a dropping funnel to 129.8 g of dichloroethylsilane with stirring and cooling. The reaction mixture was then boiled for five hours. After separation of the ethereal solution of reaction products and its fractionation through a column, 55.0 g (44.8%) of a product of b.p. 97-99° (750 mm) was isolated, and this corresponded in analysis to chlorodiethylsilane.

Preparation of 1,1,3,3-tetraethyldisilazane $(C_2H_5)_2Si(H)-NH-Si(H)(C_2H_5)_2$. A solution of 40.8 g (0.3 mole) of chlorodiethylsilane in 300 ml of dry ether was prepared in a two-necked one-liter flask fitted with a tube for the passage of gas and a reflux condenser. The flask was placed in a water bath at 5°, and a stream of dry ammonia

* Junior scientific worker A. M. Gutman took part in the work.

** The reaction with lithium was carried out in a nitrogen atmosphere.

TABLE 1

Some Physicochemical Properties of Dialkyl(or aryl)chlorosilanes

No.	Name of alkylchlorosilane	Formula	B.p. in °C (p in mm).	d_4^{20}	n_D^{20}	Analysis for Cl (alkaline hydrolysis)		MR	
						found	calc.	found	calc.
1	Dichloroethylsilane	$C_2H_5Si(H)Cl_2$	74.5 (752)	1.0849	1.4129	55.00 54.18	55.0	29.64	29.80
2	Chlorodiethylsilane	$(C_2H_5)_2SiCl$ H	97—99 (750)*	0.8731	1.4114	26.25 27.00 23.20	27.50	34.90	34.80
3	Chloroethylisobutylsilane	$C_2H_5(C_4H_9\text{-}i)SiCl$ H	138—140.0 (750)	0.9829	1.4250	23.40	23.53	43.57	44.06
4	Chloroethylphenylsilane	$(C_2H_5)(C_6H_5)SiCl$ H	204.0—207.5 (746.5)	1.0505	1.5205	19.77 20.00	20.77	49.39	49.99

The literature [5] gives b.p. 99° (741 mm); b.p. 99-100° (760 mm).

was passed for four hours. With passage of ammonia a white precipitate formed and some heat was evolved. At the end of the reaction the ethereal solution was decanted from the precipitate of ammonium chloride and filtered. Ether was distilled off, and two fractionations of the residue gave 40.0 g (63.5%) of 1,1,3,3-tetraethyldisilazane, b.p. 102-103° (50 mm); 183-186° (170 mm); n_D^{20} 1.4340; d_4^{20} 0.8035; Found MR 61.42; Calculated for $C_8H_{23}Si_2N$, MR 61.01.

Found %: C 50.82; 50.95; H 12.16; 11.93; Si 29.18; 29.24; N 6.69; 6.70. $C_8H_{23}Si_2N$. Calculated %: C 50.72; H 12.29; Si 29.57; N 7.38.

Hydrolysis of 1,1,3,3-tetraethyldisilazane. The hydrolysis was carried out in the above-described apparatus. A mixture of 18.8 g (0.1 mole) of the tetraethyldisilazane, 130.0 ml of ether, 45 ml of water, and a few drops of methyl orange was prepared in the flask. This mixture was then stirred and cooled while 66.9 ml of 0.41 N HCl was added dropwise from the dropping funnel. The end of the reaction, which was detected by the change in color of the methyl orange, occurred after 3-4 hours. The ether layer was separated in a separating funnel and was dried with potassium carbonate. Fractionation gave the following products:

Fraction I, b.p. 49.5-51.6° (96.5 mm); n_D^{20} 1.4120; 4.8 g

Fraction II, b.p. 91.0-92.5° (50 mm); n_D^{20} 1.4140; 10.0 g

Fraction III, high-boiling products, 3.6 g

Refractionation of Fraction I gave 3.6 g (34.6%) of diethylsilanol, b.p. 50-52° (45.0 mm); n_D^{20} 1.4170; d_4^{20} 0.829; Found MR 31.61; Calculated MR 31.08. Diethylsilanol is a mobile liquid having a pungent camphor-like odor; it is of low stability. Refractionation of Fraction II gave 9.4 g of 1,1,3,3-tetraethyldisiloxane, a mobile colorless liquid without any specific odor. It is soluble in ether, benzene, dioxane, and other solvents, but insoluble in water; it can be distilled without decomposition, and it reduces silver nitrate solution and decolorizes potassium permanganate solution.

Preparation of 1,1,3,3-tetraethyldisiloxane $(C_2H_5)_2Si(H)\text{-}O\text{-}Si(H)(C_2H_5)_2$. The hydrolysis was carried out in the apparatus described above. A mixture of 49.2 g of chlorodiethylsilane, 200 g of ether, and a few drops of phenolphthalein

indicator was prepared in the flask. The reaction mixture was then stirred and cooled while 1N NaOH was added until a pink coloration occurred. The temperature of the reaction mixture did not rise above + 2°. The ethereal solution was separated from the aqueous layer and washed with water until neutral, ether was removed, and the residue was vacuum-fractionated from a Favorsky flask. The product, amounting to 25.0 g (80.1%) was 1,1,3,3-tetraethyldisiloxane.

Preparation of chloroethylphenylsilane $(C_2H_5)(C_6H_5)Si(H)Cl$. The procedure and apparatus were as described for chlorodiethylsilane. Fractionation of the products of reaction between 129 g of dichloroethylsilane and phenylmagnesium bromide prepared from 157 g of bromobenzene and 24 g of magnesium gave 95.6 g (56.0%) of chloroethylphenylsilane, b.p. 204-207.5° (746.6 mm); d_4^{20} 1.0805; n_D^{20} 1.5205. Chloroethylphenylsilane is a mobile fuming liquid having a camphor odor. It decomposes somewhat when distilled at atmospheric pressure, and when heated strongly or exposed to light it explodes. In some experiments the high-boiling reaction products also exploded when heated.

Hydrolysis of chloroethylphenylsilane. Hydrolysis was carried out with aqueous 1N NaOH as described above for the preparation of tetraethyldisiloxane. Vacuum fractionation of the hydrolysis products from 34.0 g (0.2 mole) of chloroethylphenylsilane gave the following fractions:

Fraction I, b.p. 43.5-46.0° (6.0 mm); n_D^{20} 1.5196; 7.0 g

Fraction II, b.p. 136-144° (3 mm), n_D^{20} 1.5252; 15 g

Redistillation of Fraction I gave 6.0 g (18.9%) of a product having b.p. 62.3-64.0° (19.5 mm), n_D^{20} 1.5090, d_4^{20} 0.9495, which corresponded in analysis to ethylphenylsilanol. Ethylphenylsilanol is a clear mobile liquid having an ethereal odor; on standing, it is readily converted into 1,3-diethyl-1,3-diphenyldisiloxane. It reacts with sodium even at room temperature. Refractionation of Fraction II gave 14.3 g of 1,3-diethyl-1,3-diphenyldisiloxane.

Preparation of 1,3-diethyl-1,3-diphenyldisiloxane $C_2H_5Si(H)(C_6H_5)-O-Si(H)(C_6H_5)C_2H_5$. A sealed tube containing 76 g (0.05 mole of ethylphenylsilanol was heated in a water bath for three hours. Distillation from a Favorsky flask gave 5.7 g (80.6 %) of product of b.p. 140.5° (3 mm), n_D^{20} 1.5250; and d_4^{20} 0.9884, which was found to be 1,3-diethyl-1,3-diphenyldisiloxane.

Preparation of chloroethylisobutylsilane $C_2H_5-Si(H)(i\text{-}C_4H_9)-Cl$. A mixture of 24 g of magnesium turnings, 300 ml of dry ether, and a few milliliters of ethyl bromide was prepared in a three-necked flask. With constant stirring and cooling, 137.03 g (0.1 mole) of isobutyl bromide (b.p. 91.5°, d_4^{20} 1.264; n_D^{20} 1.4346) was added. The isobutylmagnesium bromide was added to 129.0 g (1 mole) of dichloroethylsilane. Fractionation of the reaction products gave 70.5 g (46.7%) of a fraction of b.p. 140° (756 mm).

Found %: C 47.25; 47.13; H 9.99; 10.03; Si 17.96; 18.27; Cl 23.96; 23, 3; (titration with alkali) 23.20; 23.40. $C_6H_{15}SiCl$. Calculated %: C 47.82; H 10.03; Si 18.62; Cl 23.53.

The chlorine content of the chloroethylisobutylsilane was determined both by combustion and by boiling a weighed amount with 1N NaOH and back-titrating the unchanged alkali. It was shown that to combine all the determinable chlorine long boiling (5-6 hours) is required. The contents of Si, C, H, and Cl were determined by combustion of a sample in a quartz tube according to the procedure developed in the Microanalysis Laboratory of the Institute of Organic Chemistry of the Academy of Sciences of the USSR.

Preparation of Ethylisobutylsilanol $C_2H_5-Si(H)(i\text{-}C_4H_9)-OH$. Ethylisobutylsilanol was prepared by the hydrolysis of chloroethylisobutylsilane with 1N NaOH the apparatus and procedure being as for the experiment on the hydrolysis

of chloroethylphenylsilane. Fractionation of the hydrolysis products from 30.1 g (0.2 mole) of chloroethylisobutylsilane from a Favorsky flask gave:

Fraction I, b.p. 70-76° (57.5 mm); n_D^{20} 1.4142

Fraction II, b.p. 126-136° (60.5 mm); n_D^{20} 1.4180

Fraction III, high-boiling products

Refractionation of Fraction I at a lower pressure gave 6.5 g (24.2%) of ethylisobutylsilanol, b.p. 53.0-55° (9 mm). Ethylisobutylsilanol is a colorless liquid having a camphor odor. It is soluble in ether, dioxane, and aromatic and aliphatic hydrocarbons. It reacts with sodium and potassium at room temperature.

Refractionation of Fraction II gave 9.6 g (34% calculated on ethylisobutylsilanol) of 1,3-diethyl-1,3-diisobutyldisiloxane; a clear mobile liquid of feeble odor. It can be distilled without decomposition, and it does not react with sodium or potassium at room temperature. B.p. 80.5° (11.5 mm) and 83.9° (12.5 mm).

Preparation of 1,3-diethyl-1,3-diisobutyldisiloxane $C_2H_5\underset{\underset{i\text{-}C_4H_9}{|}}{\overset{\overset{H}{|}}{Si}}-O-\underset{\underset{i\text{-}C_4H_9}{|}}{\overset{\overset{H}{|}}{Si}}C_2H_5$. A sealed tube containing 13.2 g of ethylisobutylsilanol (0.1 mole) and 1-2 drops of concentrated hydrochloric acid was heated in a boiling water bath for 2.5 hours. The reaction products were neutralized with potassium carbonate and fractionated. The product, amounting to 9.0 g (73.1%) was 1,3-diethyl-1,3-diisobutyldisiloxane.

Preparation of acetaldehyde ethyl ethylisobutylsilyl acetal. A mixture of 19.7 g (0.76 mole) of ethylisobutylsilanol, 10.8 g (0.75 mole) of ethyl vinyl ether (b.p. 36.5°; n_D^{20} 1.3760; d_4^{20} 0.7528), and one drop of concentrated hydrochloric acid was prepared in an ampoule cooled to a temperature of from − 3 to − 4°. The sealed ampoule was heated for five hours in a thermostat at 50-60°. The reaction products were treated with calcined potassium carbonate and then distilled from a Favorsky flask attached to a trap cooled in ice and salt. The following fractions were collected:

Fraction I, b.p. to 40° (760 mm); 7.2 g; n_D^{20} 1.4010

Fraction II, b.p. 100-106° (756 mm); 3.0 g; n_D^{20} 1.3810; d_4^{20} 0.8250

Fraction III, b.p. 178-181° (756 mm); 8.0 g; n_D^{20} 1.416; d_4^{20} 0.81388

Fraction IV, b.p. 85-101° (11 mm); 6.2 g; n_D^{20} 1.4220

Fraction V, high-boiling product – yellowish resin, 2.3 g

Fraction II contained the symmetrical diethyl acetal, for which the literature gives b.p. 103-104°; n_D^{20} 1.3820; d_4^{20} 0.8254.

Refractionation of Fraction III gave 4.5 g of a fraction of b.p. 181° (756 mm) and 98° (11 mm); this was found to be the ethyl ethylisobutylsilyl acetal, a clear mobile liquid having a pungent odor. It is soluble in ether, benzene, toluene, and aliphatic and aromatic hydrocarbons. Refractionation of Fraction IV gave 4.2 g of a fraction having b.p. 81.0° (9 mm), n_D^{20} 1.4190; and d_4^{20} 0.8099, which was found to be 1,3-diethyl-1,3-diisobutyldisiloxane. The structure of the acetal was confirmed by determining the acetaldehyde content of the hydrolysis products by the bisulfite method described previously [2].

The authors consider it their pleasant duty to express their thanks to members of the staff of the Microanalytical Laboratory, T. E. Shumilina and A. I. Guseva, for microanalytical determinations on the products synthesized.

SUMMARY

1. Dialkyl(or aryl)silanols containing silicon-attached hydrogen $R_2Si(H)OH$ and tetraalkyl(or aryl) disiloxanes of general formula $R_2\underset{\underset{H}{|}}{\overset{\overset{H}{|}}{Si}}-O-\underset{\underset{H}{|}}{\overset{\overset{H}{|}}{SiR_2}}$ were synthesized and characterized for the first time. Diethyl-,

ethylisobutyl-, and ethylphenyl-silanols and symmetrical tetraethyl-, diethyldiisobutyl-, and diethyldiphenyl-disiloxanes were prepared.

2. Chlorodiethyl-, chloroethylisobutyl-, and chloroethylphenyl-silanes were prepared for the first time.

3. It was shown dialkyl(or aryl)chlorosilanes (the example taken was chlorodiethylsilane) react with ammonia with formation of disilazanes $R_2Si-NH-SiR_2$. When hydrolyzed, 1,1,3,3-tetraethyldisilazane gives diethylsilanol and 1,1,3,3-tetraethyldisiloxane.

4. When dialkylsilanols react with vinyl ethers, organosilicon acetals of the following structure are formed:

(R^1 and R^2 are alkyl or aryl groups).

OPTICAL INVESTIGATION OF TETRAETHYLSILANE AND CHLORO(ETHYL)SILANES AND THE BEHAVIOR OF THESE COMPOUNDS IN CHLORINATION

M. I. Batuev, A. D. Petrov, V. A. Ponomarenko, and A. D. Matveeva

1. Study of the chlorination of tetraethylsilane $(CH_3CH_2)_4Si$, chlorotriethylsilane $(CH_3CH_2)_3SiCl$, dichlorodiethylsilane $(CH_3CH_2)_2SiCl_2$, dichloroethylsilane $CH_3CH_2SiHCl_2$, and trichloroethylsilane $CH_3CH_2SiCl_3$ with chlorine in presence of ultraviolet radiation [1] and with sulfuryl chloride in presence of benzoyl peroxide [2] revealed interesting regularities in the relative ease with which the hydrogens of C–H bonds in these compounds are replaced by chlorine atoms. Whereas in the chlorination of tetraethylsilane practically only the hydrogen atom of the C–H bond in the α-position to silicon is replaced by chlorine, as the ethyl radicals of tetraethylsilane are replaced by chlorine atoms, the activity of the α-C–H bond in this respect is considerably reduced and the activity of the β-C–H bond is greatly increased, becoming predominant in $CH_3CH_2SiCl_3$; the Cl_3Si group of this compound has a very marked β-orienting effect.

The variation in this activity in the α- and β-C–H bonds can be expressed schematically as follows:

$(CH_3CH_2)_4Si$	activity	of the α-C–H bond	$\gg$	activity	of the β-C–H bond
$(CH_3CH_2)_3SiCl$	"	of the α-C–H bond	$>$	"	of the β-C–H bond
$(CH_3CH_2)_2SiCl_2$	"	of the α-C–H bond	$\approx$	"	of the β-C–H bond
$CH_3CH_2SiHCl_2$	"	of the α-C–H bond	$<$	"	of the β-C–H bond
$CH_3CH_2SiCl_3$	"	of the α-C–H bond	$\ll$	"	of the β-C–H bond

The above-noted orienting effect of the Cl_3Si group is found also in the chlorination of trichloropropylsilane $CH_2CH_2CH_2SiCl_3$ [3]; the relative amounts of trichloro(1-, 2-, and 3-chloropropyl)silanes are 1:3.5:3.1.

The present paper gives the results of a Raman-spectrum study of various peculiarities of the structures of tetraethylsilane and chloro(ethyl)silanes; it is these peculiarities that mainly determine the above-described regularities in the chlorination of these compounds.

The spectra of the above organosilicon compounds and of some corresponding hydrocarbons were determined on a Soviet three-prism spectrograph (ISP-51) with a central camera. The exciting radiation was the mercury line at 4358 A. The Raman spectra of tetraethylsilane, chloro(ethyl)silanes, trichloroethylmethane [1,2,3-trichloropropane], and other organosilicon compounds and hydrocarbons are given below.

1. $(CH_3CH_2)_4Si$. $\Delta\nu(cm^{-1})$: 170(3), 233(0), 264(2), 299(5), 332(db), 392(1), 549(10), 564(4), 636(3b), 690(0), 713(1*), 731(5*) 744(4*), 974(6), 1007(4), 1022(5), 1234(6), 1276(0), 1297(0), 1331(0), 1379(1), 1418(6), 1466(8), 2734(2), 2821(3*), 2879(10*), 2908(9*), 2940(4*), 2955(5*), 2968(0*).

2. $(CH_3CH_2)_2SiCl_2$. $\Delta\nu(cm^{-1})$: 168(3*), 219(2*), 242(1db), 281(sh), 301(4*), 316(4*), 325(1), 461(4*), 478(6*), 592(6**), 607(3**), 729(3*), 745(3*), 977(5), 1006(4*), 1024(4*), 1239(4), 1379(0), 1416(4), 1467(7), 2692(0), 2741(2), 2825(2), 2882(9*), 2914(6*), 2941(2*), 2968(4*), 2979(0*). (The lines 168-316 are on the background of the wing of the Rayleigh line).

3. $(CH_3CH_2)_2SiCl_2$. $\Delta\nu$[cm^{-1}]: 111(1*), 126(1*), 167(*), 185(5*b, db), 227(1**), 239(2**), 251(1**), 297(5*), 311(5*), 330(0), 420(0), 457(10*), 473(2*), 493(0), 531(2*), 548(2*), 615(5), 688(2*), 708(2*), 738(2**), 740(2**), 976(4), 1008(5*), 1024(2*), 1056(0), 1227(1*), 1242(5*), 1268(0), 1290(0), 1319(0db), 1400(5), 1433(0), 1463(6), 2741(1), 2825(2), 2885(8*), 2919(3*), 2934(4*), 2967(3), 2983(0). (The lines 111-185 are on the background of the wing of the Rayleigh line).

4. $(CH_3CH_2)SiHCl_2$. $\Delta\nu$[cm^{-1}]: 177(5), 188(5*), 226(0), 264(0), 296(4), 493(10 b), 548(3*), 566(3*), 660(5), 708(4), 709(5*), 813(5*), 975(3 db), 1010(3db), 1073(0), 1093(0), 1236(4), 1405(3), 1463(4), 2204(9 m), 2747(1), 2829(1), 2889(7), 2914(2*), 2938(4*), 2973(3**), 2986(1**). (The lines 177-296 are on the background of the wing of the Rayleigh line).

5. $(CH_3CH_2)SiCl_3$. $\Delta\nu$[cm^{-1}]: 120(4*), 166(2*), 179(9*), 193(0), 225(7), 325(7), 447(10), 564(4*), 580(4*), 717(4 b), 973(2*), 985(2*), 1015(4), 1222(1), 1244(4*), 1389(3*), 1425(2*), 1465(6), 2750(1), 2848(1), 2895(7*), 2931(2*), 2946(6*), 2978(3), 2996(0). (The lines 120-225 are on the background of the wing of the Rayleigh line, which extends beyond the line 225).

6. $(CH_3CH_2)_4C$. $\Delta\nu$[cm^{-1}]: 175(2), 371(3), 405(10), 457(1), 664(6), 682(7), 770(6 b), 800(0), 912(7), 1013(0), 1057(2), 1089(8*), 1102(0*), 1124(3*), 1151(4*), 1174(*), 1198(4*), 1229(4), 1272(6), 1308(1), 1350(3), 1383(3), 1458(10 m), 2734(2), 2826(2), 2864(3*sh), 2888(10*sh), 2922(9*), 2945(1*), 2964(4*).

7. $(CH_3CH_2)CCl_3$. $\Delta\nu$[cm^{-1}]: 177(0*), 192(5*), 244(5*), 271(5*), 332(5**), 343(3**), 408(10), 530(10), 697(4), 778(4), 829(3), 931(2), 1056(4*), 1090(1*), 1112(1*), 1271(2), 1430(4), 1458(4), 1497(0), 1522(0), 2744(1db), 2842(1), 2888(3*), 2943(10* db, b), 2961(3*), 2989(5*), 3009(0). (The lines 177-271 are on the background of the wing of the Rayleigh line).

Notes. Intensity is expressed on a ten-degree scale. Other indications given with the intensity are b - broad line; sh - sharp line; db - doublet; the asterisks denote lines occurring on a background that is common to neighboring lines marked with the same number of asterisks.

The spectrum of the first compound has been published previously [4]; it has recently been published in a more precise form [5]. Our results add some further precision to the latter publication with respect to the resolution of certain frequencies and the detection of some lines of low intensity.

The spectra of Compounds 2-5 were also published recently [6], but in an incomplete form (only in the region 160-1460 cm^{-1}). The region of valency vibrations of C-H bonds, which, as we shall see below, is very important for the solution of our problems, is not investigated at all in the investigation cited; moreover, this publication contains many inaccuracies and mistakes in the determination of frequencies, so that it is impossible to make use of these spectra.

Before their Raman spectra were determined, the compounds were distilled twice through a 35-plate column. In the case of the readily hydrolyzable chloro(ethyl)silanes, precautions were taken against the ingress of atmospheric moisture into the vessels in which the substances for investigation were collected in the distillation (i.e., the cells used for the determination of the Raman spectra). The compounds investigated had the following boiling points: $(CH_3CH_2)_4Si$, 152.5° (754.1 mm); $(CH_3CH_2)_3SiCl$, 146° (750.4 mm); $(CH_3CH_2)_2SiCl_2$, 129.7° (751.9 mm); $(CH_3CH_2)SiHCl_2$, 74° (744 mm); $(CH_3CH_2)SiCl_3$, 97.4° (749.3 mm); $(CH_3CH_2)_4C$, 144° (760 mm); $CH_3CH_2)CCl_3$, 107.0° (750 mm).

2. In investigations on the hydroxy group in various compounds, one of us [7] has shown that the protonization of its hydrogen atom (in acids) results in a definite reduction in the O-H bond energy, increase in the interatomic distance in this bond, and reduction in the hydroxyl vibration frequency. On the other hand, electronization of this bond (in a transition to an OH^- ion) reduces the interatomic distance, raises the bondenergy, and so raises the vibration frequency. The range of variation of the vibration frequency of the hydroxy group is considerable - from 2500 cm^{-1} for the β-form of crystalline oxalic acid to 4200 cm^{-1} for the OH^- ion; the range of variation of the other parameters of this bond that we have indicated is also very great.

The concept of the protonization and electronization of X–H bonds in the sense of a lesser or greater involvement of the proton in the electron-orbital system of the X–H bond can be applied also to C–H bonds [7], but the electronization of the C–H bond, unlike that of the O–H bond, is accompanied by the tendency to form an ion (CH^-); the carbon atom remains bound to the rest of the molecule, but the proton enters more deeply into the electron-orbital system of the C–H bond.

Protonization of the C–H bond again leads to a reduction in its vibration frequency, whereas electronization leads to an increase in this frequency; the range of variation of the vibration frequency and other parameters (energy, interatomic distance) of the C–H bond is much narrower in known compounds than for the hydroxy group. Thus, the vibration frequencies of the six C–H bonds of the two methyls of ethane lie in the range 2700-2960 cm^{-1}, the four C–H bonds of ethylene in the range 3000-3100 cm^{-1}, and the two C–H bonds of acetylene in the range 3300-3400 cm^{-1}. The following are the frequencies of the C–H bonds in these compounds [8]:

Frequencies of 6 C–H bonds in ethane (C–C):	2730(3), 2791(2 b), 2880(10), 2940(10), 2960(5)
Frequencies of 4 C–H bonds in ethylene (C=C):	(2988), 3008(10), 3074(2), (3107)
Frequencies of 2 C–H bonds in acetylene (C≡C):	(3288), 3372

Note: The frequencies in parentheses are infrared frequencies (cm^{-1}) [8].

3. In the ethyl radicals of the compounds that we have investigated there are two kinds of C–H bonds: one occurs in methyl groups, and the other in methylene groups of ethyl radicals.

As experimental [9] and calculated [10] data for paraffin hydrocarbons have shown, the CH_2 and CH_3 groups present are largely independent in the sense that interaction with other frequencies in the molecule and also interaction between methyl and methylene groups has little effect on the vibration frequencies of these groups. The truth of this statement is evidenced, for example, by the fact that lengthening of a carbon chain in the series of normal paraffins does not give rise to any change in the characteristic frequencies of the methylene and methyl groups; in intensity, however, the lines due to C–H bonds of methylene groups, unlike those due to methyl groups, increase, because the number of methylene groups increases with lengthening of the carbon chain, whereas there are only two methyl groups in normal paraffins.

On the basis of experimental data for unbranched paraffins and of approximate calculations of the frequencies of "isolated" CH_2 and CH_3 groups [9, 10], the methylene and methyl groups are each characterized by two vibrations – symmetrical and antisymmetrical – the Raman frequencies of which are (cm^{-1}):

	Symmetrical vibration	Antisymmetrical vibration (degenerate in CH_3)
CH_2	2853	2908
CH_3	2879	2967

In the spectra observed for unbranched paraffins there is also a frequency of 2938 cm^{-1} that is attributable to the CH_3 group, and there are one or two frequencies in the region of 2740 cm^{-1} the assignment of which has not been finally decided (it is possible that the frequencies 2938 and 2967 cm^{-1} result from the splitting of the degenerate CH_3 frequency on account of the disturbance of the symmetry of this group in complex molecules [9-11].

A fact of importance for the further discussion is the high intensity of the line due to the symmetrical vibration of the methyl group as compared with that of the line due to the symmetrical vibration of the methylene group. This may be directly observed in the case of n-butane ($H_3C \cdot CH_2 \cdot CH_2 \cdot CH_3$), in which there are two methyl and two methylene groups (intensities on the visual scale) [12]:

	Frequency (cm^{-1})	Intensity
CH_2	2861	10
CH_3	2878	15

This is evidenced also by data on the intensities of C–H lines of the methyl and methylene groups of normal paraffins recalculated for equal numbers of scattering molecules: the intensity of the line for the symmetrical vibration of the methylene groups of n-octane (there are six such groups) is substantially less than that of the line for the symmetrical vibration of the methyl groups (of which there are only two) [9].

It will be seen from the above-cited data on the methylene and methyl lines of normal paraffins that, although the regions of the frequencies of their C–H bonds generally overlap, we may nevertheless speak of the greater protonization of C–H bonds of methylene groups as compared with methyl groups, the C–H bonds of which are more electronized. Actually, the frequency of the symmetrical vibration of the methylene group (2853 cm^{-1}) is lower than that of the symmetrical vibration of the methyl group (2879 cm^{-1}), and the antisymmetrical vibration of the methylene group has a lower frequency (2908 cm^{-1}) than that of the antisymmetrical vibration of the methyl group (2967 cm^{-1}, or 2938 and 2967 cm^{-1} – see above).

4. It would be a great mistake, however, to attempt to extend these characteristics of the lines of the methylene and methyl groups of normal paraffins to the methylene and methyl groups of compounds of all kinds. It is clear that the only assertion that we can make which holds largely irrespective of the kind of molecule in which the groups occur, is that vibrations of the methylene and methyl groups are mutually independent. As regards the effect of the rest of the molecule, its manifestation in the frequency characteristics of the methylene and methyl groups is small only in the normal paraffins, but is considerable already in branched hydrocarbons, and still more so in compounds that are even more complex in composition and structure. As a result, in some compounds the regions of the methyl and methylene frequencies may be greatly displaced with respect to one another and the C–H bonds of one group may be more electronized or protonized relative to the bonds of the other; there will be corresponding changes in the chemical nature and reactivity of the C–H bonds of these groups.

Thus, in the spectra of the compounds $H_3Si-CH_2-SiH_3$ (one methylene group and no methyl groups) and $H_3Si-CH_2-CH_2-SiH_3$ (two methylene groups, no methyl groups), which we investigated previously [13], the frequencies of the methylene groups were greatly displaced in the direction of higher frequencies, which indicates powerful electronization: in these compounds the electron system is greatly displaced toward the carbon atoms, for, according to Gordy, the electronegativity of the carbon atom (2.55) is considerably greater than that of the silicon atom (1.8). In ketene [14] $H_2C=C=O$, the frequency region of the CH_2 group is displaced still further in the direction of the higher frequencies and lies considerably higher than the frequency regions of both methylene and methyl groups of normal paraffins, i.e. the CH_2 group of ketene is much more electronized than the methylene and methyl groups of normal hydrocarbons (see Table 1).

Hence, although the vibrations of the C–H bonds of methyl and methylene groups are independent of one another, their frequencies may be greatly displaced with respect to one another to an extent dependent on the structure of the rest of the molecule and the kinds of atoms it contains; such behavior is of course indicative of changes in interatomic distances, bond energies, and reactivity of the C–H bonds of these groups.

We now turn our attention to the results of the optical investigation of tetraethylsilane and chloro(ethyl)-silanes with the object of interpreting the regularities observed in the chlorination of these compounds.

5. Table 2 gives the five principal frequencies of the valency vibrations of the C–H groups of methyl and methylene groups from the Raman spectra of tetraethylsilane and three chloro(ethyl)silanes in which one, two, and three ethyls of the tetraethylsilane are replaced by chlorine atoms.

The number of the principal frequencies of the methyl and methylene groups of all these compounds remains constant, but their relative positions in the spectrum varies substantially. As regards the frequencies of the methyl groups of tetraethylsilane, they are almost identical with those of the methyl groups of normal paraffins – in particular, n-butane (cm^{-1}):

Frequencies of the methyl groups of	tetraethylsilane	2879	2940	2955
" " "	n-butane [12]	2878	2939	2956
" " "	tetraethylmethane	2888	2945	2964

Of the two frequencies of tetraethylsilane – 2955 and 2968 cm^{-1} – the methyl frequency is to be identified with 2955 cm^{-1}, as can be seen not only from the above comparison, but also from a comparison of intensities (see above): the third methyl line is much more intense than that of the antisymmetrical vibration of the methylene group (2968 cm^{-1}). The symmetrical vibration of the methylene group of tetraethylsilane has the frequency

TABLE 1

Frequencies of the Methyl and Methylene Groups of Various Compounds

Compounds	Frequencies (cm^{-1})						
CH_3 Normal paraffins	—	2879 (10)	—	—	2938 (8)	2967 (5)	--
CH_2 Normal paraffins	2853 (8)	—	—	2908 (2)	—	—	—

TABLE 2

Frequencies of Valency-bond Vibrations of the Methyl and Methylene Groups of Tetraethylsilane and Chloro(ethyl)silanes.

Compound	Frequencies (cm^{-1})				
	1	2	3*	4*	5
1. $(CH_3CH_2)_4Si$	2879(10)	2908(9)	2940(4)	2955(5)	2968(0)
2. $(CH_3CH_2)_3SiCl$	2882(9)	2914(6)	2941(2)	2966(4)	2979(0)
3. $(CH_3CH_2)_2SiCl$	2885(8)	2916(3)	2934(4)	2967(3)	2983(0)
4. $(CH_3CH_2)SiCl_3$	2895(7)	2931(2)	2946(6)	2978(3)	2978(0)
Rise in frequency from 1 to 4	+ 16	+ 23	+ 6*	+23*	+ 28
			14*		
	(CH_3)	(CH_3)	(CH_2)	(CH_2)	(CH_2)

* If we regard the frequencies in the third and fourth columns as the result of the splitting of the degenerate CH_2 frequency (see above), we may make a rough estimation of this last frequency (that which it would have were it not degenerate) for Compounds 1-4, namely 2948, 2954, 2951, 2962 cm^{-1}; the rise from 1 to 4 will be + 14 cm^{-1}.

2908 cm^{-1}, and its intensity (in accordance with the above discussion) is somewhat lower than that of the symmetrical vibration of the C—H bond of the methyl groups.

Hence, the methylene frequencies of tetraethylsilane, unlike the methyl frequencies, are very high as compared with the frequencies of the corresponding groups of normal paraffins in general and of n-butane (and also tetraethylmethane) in particular (cm^{-1}):

Frequencies of the methylene groups of	tetraethylsilane	2908	2968
" " "	n-butane [12]	2861	2910
" " "	tetraethylmethane	2864	2922

Also, the frequency of the symmetrical vibration of the methylene groups of tetraethylsilane (2908 cm^{-1}) is higher than that of the symmetrical vibrations of its methyl groups (2879 cm^{-1}), and the frequency of the antisymmetrical vibration of methylene groups (2968 cm^{-1}) is higher than those of the two remaining frequencies

of its methyl groups (2940, 2955 cm^{-1}). This means that, in contrast to the case of the normal paraffins, the C–H bonds of the methylene groups of tetraethylsilane are more electronized than the C–H bonds of its methyl groups; such bonds in tetraethylsilane, unlike those in normal paraffins, are the more protonized.

Such relative positions of the frequencies of the C–H bonds of methyl and methylene groups in the tetraethylsilane spectrum result from the influence of the central silicon atom. Its electronegativity (1.8) is considerably less than the electronegativities of the carbon (2.55) and hydrogen (2.13 atoms). As a result, the electronic system is drawn from the silicon atom onto the carbon and hydrogen of the C–H bonds of the methylene groups; the latter are electronized and the frequencies are greatly raised. This effect of the silicon atom does not pass on as far as the C–H bonds of the methyl groups, so that the methyl frequencies remain unchanged (it is possible that the enhanced electronization of the methylene groups screens the effect of the silicon atom on the methyl groups).

6. Replacement of one, two, and finally three ethyl radicals by chlorine atoms results in an increase in the frequencies of the C–H bonds not only of the methylene groups, but also of the methyl groups; in chloro(ethyl) silanes the more electronegative chlorine atoms (2.97) (both with respect to silicon atoms (1.88) and also to carbon (2.55) and hydrogen (2.13) atoms) draw to themselves the valency-electron system of the molecule – "compacts" it – and together with the electrons (more accurately, by means of them) it attracts also hydrogen nuclei. As a result the C–H bond energies are increased, the bond lengths are reduced, and the vibration frequencies of these bonds are raised. The methylene groups, being nearer to the chlorine atoms than the methyl groups, are the more strongly affected by the chlorine atoms; in fact (Table 2), from the first to the fourth compound the frequency of the symmetrical vibration of methyl C–H bonds rises by 16 cm^{-1} and the antisymmetrical vibration by 14 cm^{-1}, whereas the frequencies of the methylene C–H bonds increase by 23 and 28 cm^{-1} respectively. Both the methylene and methyl groups are electronized under the influence of the chlorine atoms, but the methylene groups are affected to much the greater extent.

7. The above considerations make it possible for us to make some approach toward an understanding of the regularities observed in the readiness with which the various hydrogens of the C–H bonds of tetraethylsilane and chloro(ethyl)silanes are replaced by chlorine atoms.

Chlorination proceeds with separation of hydrogen chloride. In the chlorination of tetraethylsilane the preferential replacement of the hydrogens of the α-C–H bonds by chlorine is favored by the following circumstances.

The chlorine molecule, which is somewhat polarized under the influence of the second reactant and of the fluctuation factor, proceeds, with its positive end foremost, toward the more electronized α-C–H bond of a methylene group. A chlorine atom seizes the hydrogen of this bond and separates in the form of hydrogen chloride. This capture evidently occurs by a radical mechanism: a proton with one electron is torn from the bond – not a bare proton, nor a proton with two electrons, for in these cases we should have an ionic mechanism. This assumption is justified by a consideration of the chlorination conditions – treatment with chlorine in presence of ultraviolet radiation or treatment with sulfuryl chloride in presence of benzoyl peroxide. However, we do not propose to discuss these questions in this paper, for supplementary data are required for their solution. The other atom of the chlorine molecule combines with the tetraethylsilane residue. The approach of the positive end of the chlorine molecule to the α-C–H bond is favored not only by the higher electronization of this bond, but also by the screening of the positive silicon nucleus by its large electron envelope; moreover, this large electron envelope contributes in itself to the attraction of the positive end of the chlorine molecule to the α-bond.

As the ethyl radicals are replaced by chlorine atoms, electronization of α-C–H bonds continues, but there is a simultaneous gradual disappearance of the additional α-directing effect of the silicon atom on the chlorine molecule. In fact, with the replacement of the first, second, and particularly third ethyl radical by chlorine, the silicon atom itself becomes strongly polarized and its electron envelope gathers together toward the chlorine atoms; as a result of such a powerful polarization of the molecule, the rather considerable positive charge of the silicon atom is "bared", which, particularly in trichloroethylsilane, does not permit the positive end of the chlorine molecule to approach α-C–H bonds; an effect in the same direction is exerted on the negative end of the chlorine molecule by the negative pole of the organosilane molecule, which is concentrated in the region of the chlorine atoms. As a result, the chlorine molecule moves away to the β-C–H bonds, which are adequately electronized, and chlorinates them by the same mechanism.

As a result of the same circumstances, in trichloropropylsilane ($CH_2CH_2CH_2SiCl_3$) the β-C–H and the γ-C–H are almost equally active with respect to the replacement of hydrogen by chlorine; the activity of the β-bonds is, however, somewhat higher (see above), which is probably due to their somewhat higher electonization in comparison with the more remote γ-bonds.

Chlorination of $CH_3CH_2SiHCl_2$ proceeds in a more complex fashion than that of other chloro(ethyl)silanes owing to the presence in this compound of a very reactive polarized Si–H bond, which is the first to be attacked by chlorine; the chlorine molecule again approaches this bond with its positive end foremost. At this stage of the reaction the main product is $CH_3CH_2SiCl_2$, and further reaction consists in the chlorination of this compound. A subsidiary direction of reaction is the chlorination of C–H bonds of the ethyl of $CH_3CH_2SiHCl_2$ without effect on the Si–H bond. In this case we have to consider the action of two chlorine atoms on the one remaining ethyl radical, so that the electronization of C–H bonds of methylene and methyl groups is enhanced, as compared with the case of $(CH_3CH_2)_2SiCl_2$. For this reason, with respect to degree of electronization of C–H bonds, in Table 2 $CH_3CH_2SiHCl_2$ should be placed between $(CH_3CH_2)_2SiCl_2$ and $CH_3CH_2SiCl_3$, since this compound has the following C–H frequencies:

in CH_2	2889(7)	–	2938(4)	2973(3)	–
in CH_3	–	2914(2)	–	–	2986(1)

This complex course of the chlorination of $CH_3CH_2SiHCl_2$ is supported by the fact that the compound $CH_3CH(Cl)SiHCl_2$, which still preserves an Si–H bond, can be isolated from the chlorination product.

8. The large electron envelope of the silicon atom – $1s^2$, $2s^2$, $2p^3$, $3s^2$, $3p^2$ – undoubtedly acts somewhat as a screen in chloro(ethyl)silanes and so reduces the above-described effects of the chlorine atoms on the electron system of the ethyl radicals. On the other hand, the low electronegativity of the silicon atom, in which respect it approaches Group IV metals [13], favors the above-noted extreme polarization of Si–Cl bonds and, particularly in $CH_3CH_2SiCl_3$, hinders the approach of the chlorine molecule to α-C–H bonds of methylene groups in the chlorination process.

In trichloroethylmethane $CH_3CH_2CCl_3$, the central atom is carbon, which has a much smaller electron envelope ($1s^2$, $2s^2$, $2p^3$) than the silicon atom; it therefore has a smaller screening action on the effect of chlorine atoms on the electron system of ethyl radicals. This circumstance results in greater electronization of the C–H bonds of methylene and methyl groups in $CH_3CH_2CCl_3$ than in $CH_3CH_2SiCl_3$. In particular, the frequencies of the α-C–H bonds of the methylene groups of $CH_3CH_2CCl_3$ lie in a very high region (2943, 3009 cm^{-1}), so that these bonds are highly activated with respect to the replacement of their hydrogens by chlorine.

On the other hand, owing to the more favorable ratio of the electronegativities of carbon and chlorine atoms (0.86) as compared with this ratio for silicon and chlorine (0.61), the C–Cl bonds in $CH_3CH_2CCl_3$ are not so greatly polarized as the Si–Cl bonds in $CH_3CH_2SiCl_3$. The repelling effect of the central carbon atom and its attached chlorine atoms on the chlorine molecule approaching α-C–H bonds of $CH_3CH_2CCl_3$ is therefore less than that of the central silicon atom and its attached chlorine atoms in $CH_3CH_2SiCl_3$.

These two substantial differences between $CH_3CH_2CCl_3$ and $CH_3CH_2SiCl_3$ clearly account for the fact that in the chlorination of the first compound replacement of hydrogen atoms by chlorine proceeds to a considerable extent in the α-C–H bonds of the methylene groups [15], and not predominantly in the β-C–H bonds of the methyl groups, as occurs in the second compound.

M. F. Zulina took part in the experimental optical work, and L. L. Mkhitaryan and A. D. Snegova assisted in the preparation of the substances for investigation.

SUMMARY

1. In the chlorination of tetraethylsilane, replacement of hydrogen by chlorine occurs predominantly in the C–H bonds of the α-methylene groups owing to their great electronization and to the screening of the positive charge of the silicon nucleus by its considerable electron envelope.

2. As the ethyl radicals of tetraethylsilane are successively replaced by chlorine atoms, there occurs increasing electronization of C–H bonds, both in methylene groups (to the greater extent) and in methyl groups; and the repelling action on the chlorine molecule also increases. As a result, in $CH_3CH_2SiCl_3$ chlorination already occurs preferentially at the β-C–H bonds.

3. The phenomena of electronization and protonization of bonds are important factors in the determination of the chemical behavior of matter, but they must always be considered in their relation to other factors of chemical structure and to the conditions of reaction.

POLYENIC COMPOUNDS

COMMUNICATION 1. SYNTHESIS OF 1,5-DIARYL-1,3,5-HEXATRIENES

B. M. Mikhailov and G. S. Ter-Sarkisyan

The reactions of organolithium compounds with α,β-unsaturated ketones have not received much study, and their reactions with ketones having two conjugated double bonds have received almost no study at all, in spite of the fact that the study of these latter reactions is of interest for the synthesis of difficultly accessible hexatrienes. Unlike organomagnesium compounds, which generally show both 1,2- and 1,4-addition to the conjugated systems of α,β-unsaturated ketones, organolithium compounds generally show only 1,2-addition, so that it is possible to pass from ketone to alcohols, and then further to hydrocarbons.

In the present work we have investigated the reactions between a doubly unsaturated ketone – 3-methyl-6-phenyl-3,5-hexadien-2-one – and aryllithiums (phenyl-, 1-naphthyl-, and 9-fluorenyl-lithiums) with the object of preparing aryl-substituted 1,3,5-hexatrienes. The reactions were carried out in ethereal solution, the hexadienone – prepared in good yield from cinnamaldehyde and 2-butanone [1] – being added to the organolithium compound. The intermediate reaction product – the tertiary alcohol – was isolated only in one case, namely in the reaction between 3-methyl-6-phenyl-3,5-hexadien-2-one with phenyllithium:

3-Methyl-2,6-diphenyl-3,5-hexadien-2-ol is a crystalline substance that does not melt sharply, probably because it is partially dehydrated when heated. By the dehydration of this substance under various conditions we succeeded in preparing the four theoretically possible isomers of 4-methyl-1,5-diphenyl-1,3,5-hexatriene. When 3-methyl-2,6-diphenyl-3,5-hexadien-2-ol was heated with acetic anhydride in presence of anhydrous sodium acetate, an almost quantitative yield was obtained of a mixture of two hydrocarbons of m.p. 202-203° (I) and 185-186.5° (II). Vacuum distillation of the alcohol gave two other hydrocarbons, one of them a solid, m.p. 92.5° (III), and the other a liquid (IV).

When the 4-methyl-1,5-diphenyl-1,3,5-hexatriene of m.p. 92.5° was heated with acetic anhydride, it was converted into a mixture of the hydrocarbons of m.p. 202-203° and 185-186.5°; there can be no doubt, therefore, that the compounds (I), (II), and (III) are stereoisomers. As regards the geometric configurations of these hydrocarbons, the available data permit us to make only general observations.

The possible stereoisomers of 4-methyl-1,5-diphenyl-1,3,5-hexatriene A, B, C, and D differ among themselves in the disposition of the hydrogen atoms at one double bond and in the disposition of the extreme double bonds relative to the central double bond:

In conformity with the properties of the hydrocarbons (I), (II), (III), and (IV), it may be supposed that the 4-methyl-1,5-diphenyl-1,3,5-hexatriene of m.p. 202-203° (I) – which has the highest melting point and the lowest solubility in organic solvents – has the trans-trans configuration A. The configuration of the readily soluble hydrocarbon of m.p. 92.5° (III) probably corresponds to the cis-cis structure D, for this hydrocarbon is converted by heat into a mixture of high-melting isomers and it is known that in the thermal isomerization of substances of similar structure the transformation is generally from cis to trans; for example, when heated, cis-stilbene is converted into trans-stilbene [2] and cis-cis-1,4-diphenyl-1,3-butadiene is converted into the trans-trans isomer [3].

A study of the ultraviolet and infrared spectra of the 4-methyl-1,5-diphenyl-1,3,5-hexatriene isomers will probably enable us to make a closer approach to the question of their structures. It must be pointed out that the question of the stereoisomerism of aryl-substituted hydrocarbons has received little attention in the literature. Lunde and Zechmeister [4] found that, under certain conditions, 1,6-diphenyl-1,3,5-hexatriene can be converted into a mixture of isomeric hydrocarbons, of which only one was isolated in the pure state by the authors. Koelsch and Richter [5] state that two hydrocarbons that they prepared, m.p. 172-174° and 203-206°, were probably stereoisomers of 1,1,6,6-tetraphenylhexatriene.

In the reaction between 3-methyl-6-phenyl-1,3-hexadien-2-one and 1-naphthol we were unable to isolate the tertiary alcohol. Heating of the reaction product with acetic anhydride gave only one hydrocarbon, which corresponded in composition to 4-methyl-5-(1-naphthyl)-1-phenyl-1,3,5-hexatriene.

In reaction with 3-methyl-6-phenyl-3,5-hexadien-2-one, 9-fluorenyllithium reacts quite differently from phenyllithium and 1-naphthyllithium. In this case the substance isolated as the main product was not the tertiary alcohol, but an unsaturated ketone, which gave reactions characteristic for the carbonyl group. The formation of a ketone instead of an alcohol indicates that the addition of 9-fluorenyllithium to 3-methyl-6-phenyl-3,5-

hexadien-2-one differs from the usual 1,2-addition of organolithium compounds to unsaturated ketones and occurs either in the 1,4- or 1,6-positions, since there are two double bonds in the ketone under investigation.

It should be noted that several cases of the 1,4-addition of 9-fluorenyllithium to α,β-unsaturated ketones have been observed by Tucker and Whalley [6]. The reaction of 9-fluorenyllithium with ketones having two conjugated double bonds has not been studied previously.

In order to resolve the question of whether the reaction between 9-fluorenyllithium and 3-methyl-6-phenyl-3,5-hexadien-2-one proceeds through 1,4- or 1,6-addition, the unsaturated ketone that we obtained was subjected to ozonization. Acetic acid was isolated from the products, but no benzoic acid was obtained. A compound was obtained, in the form of its 2,4-dinitrophenylhydrazone, from the neutral products of the reaction, and in elementary composition this corresponded to the 2,4-dinitrophenylhydrazone of β-phenyl-9-fluorenepropionaldehyde. These results indicate that 9-fluorenyllithium undergoes 1,6-addition with 3-methyl-6-phenyl-3,5-hexadien-2-one, and the ketone then obtained is 6-(9-fluorenyl)-3-methyl-6-phenyl-3-hexen-2-one.

EXPERIMENTAL

3-Methyl-2,6-diphenyl-3,5-hexadien-2-ol. Over a period of 45 minutes, an ethereal solution of 17.3 g (0.093 mole) of 3-methyl-6-phenyl-3,5-hexadien-2-one [1] was added to an ethreal solution of phenyllithium prepared from 16 g of bromobenzene and 1.42 g of lithium. The reaction mixture was boiled for three hours, and on the next day it was decomposed with water. The ether layer was separated and dried, and the ether was distilled off. The residual viscous oil crystallized out on addition of ethanol. The precipitate was filtered off, washed with a little alcohol, and dried in a vacuum desiccator (19 g; m.p. 70-101°). A further 2.1 g of precipitate of m. p. 68-99° was isolated from the mother liquor. The yield of 3-methyl-2,6-diphenyl-3,5-hexadien-2-ol was 86%. After being crystallized from ethanol, aqueous methanol, or benzene, the substance was obtained in the form of white needles, m.p. 68-85°.

When vacuum-distilled, the crystalline alcohol was partially dehydrated. The fraction of b.p. 220-223° (8 mm) had the following elementary composition:

Found %: C 87.78; 87.84; H 7.63; 7.55. $C_{19}H_{20}O$. Calculated %: C 86.32; H 7.63.

4-Methyl-1,5-diphenyl-1,3,5-hexatriene stereoisomers of m.p. 203° (I) and 186.5° (II). A solution of 5 g of 3-methyl-2,6-diphenyl-3,5-hexadien-2-ol in 25 ml of acetic anhydride was boiled for 15 hours with 3 g of anhydrous sodium acetate. The reaction mixture was then poured into water. The precipitate that formed was filtered off and dried in a vacuum desiccator. The product, amounting to 4.5 g, was a yellow crystalline substance, m.p. 143-167°. The yield of the mixture of hydrocarbons (I) and (II) was almost quantitative. When 1.4 g of the substance was crystallized from a 1 : 2 mixture of ethanol and benzene, a white substance (0.44 g) of m.p. 187-196° was obtained; crystallization of this from benzene and then from glacial acetic acid gave 4-methyl-1,5-diphenyl-1,3,5-hexatriene (I) in the form of fine white rhombs, m.p. 202-203°; the substance is of low solubility in alcohols.

Found %: C 92.73; 92.68; H 7.38; 7.44. $C_{19}H_{18}$. Calculated %: C 92.68; H 7.32.

Dilution of the main mother solution with ethanol gave 0.47 g of white crystals, m.p. 170-181°, and repeated recrystallization of these from glacial acetic acid gave gleaming white crystals of 4-methyl-1,5-diphenyl-1,3,5-hexatriene (II), m.p. 185-186.5°. In admixture with the 4-methyl-1,5-diphenyl-1,3,5-hexatriene of m.p. 202-203°, this substance melted at 169-178°.

Found %: C 92.85; 92.73; H 7.31; 7.33. $C_{19}H_{18}$. Calculated %: C 92.68; H 7.32.

4-Methyl-1,5-diphenyl-1,3,5-hexatriene isomers (III) and (IV). The oil (23.5 g) obtained as described above from 18.6 g (0.1 mole) of 3-methyl-6-phenyl-3,5-hexadien-2-one and phenyllithium was vacuum-distilled without first isolating the tertiary alcohol as a solid. The fractions obtained were:

Fraction I, b.p. 200-230° (14 mm); 5.25 g
Fraction II, b.p. 230-240° (14 mm); 8.0 g
Fraction III, b.p. 240-250° (14 mm); 2.25 g
Residue 5.5 g

Fraction I partially crystallized out. The crystals (1.75 g, m.p. 68-75°) were separated from the oil and recrystallized from methanol; 0.9 g of substance of m.p. 87-91° was obtained. When ether was added to Fraction II (a viscous oil), a further 1 g of substance of m.p. 87-91° was isolated. Recrystallization of this substance from methanol gave white plates, m.p. 92-92.5°; this substance – 4-methyl-1,5-diphenyl-1,3,5-hexatriene (III) – is readily soluble in organic solvents.

Found %: C 92.57; 92.65; H 7.52; 7.46. $C_{19}H_{18}$. Calculated %: C 92.68; H 7.32.

Redistillation of Fraction II (after separation of the hydrocarbon of m.p. 92.5°) gave 1.5 g of a light-yellow liquid, b.p. 170-173° (3 mm), n_D^{22} 1.6243. This, according to analysis, was 4-methyl-1,5-diphenyl-1,3,5-hexatriene.

Found %: C 92.51; 92.55; H 7.48; 7.45. $C_{19}H_{18}$. Calculated %: C 92.68; H 7.32. Found: M 242; 251. Calculated: M 246.33.

Isomerization of 4-methyl-1,5-diphenyl-1,3,5-hexatriene of m.p. 92.5°. a) A solution of 0.5 g of 4-methyl-1,5-diphenyl-1,3,5-hexatriene of m.p. 92.5° in 2.5 ml of acetic anhydride was boiled with 0.3 g of anhydrous sodium acetate for 15 hours. The reaction mixture was poured into water, and the precipitate that formed was filtered off. The precipitate (0.43 g; m.p. 142-167°) was crystallized from a mixture of ethanol and benzene, and then from glacial acetic acid, as indicated above. The products isolated were 4-methyl-1,5-diphenyl-1,3,5-hexatriene of m.p. 196-200° (undepressed by admixture of the hydrocarbon (I) obtained previously) and 4-methyl-1,5-diphenyl-1,3,5-hexatriene of m.p. 181-185° (undepressed by admixture of the hydrocarbon (II) obtained previously).

b) It was found that 4-methyl-1,5-dipheny-1,3,5-hexatriene of m.p. 92.5° underwent the same transformation into two isomeric hydrocarbons when it heated for four hours at 150-155°.

4-Methyl-5-(1-naphthyl)-1-phenyl-1,3,5-hexatriene. An ethereal solution of 14.9 g (0.08 mole) of 3-methyl-6-phenyl-1,3-hexadien-2-one was added over a period of 40 minutes to an ethereal solution of 1-naphthyllithium prepared from 19 g of 1-bromonaphthalene and 1.28 g of lithium. The reaction mixture was boiled for four hours, and on the next day it was decomposed with water. The usual treatment and removal of ether gave a dark-brown viscous oil (23.5 g), from which naphthalene was removed by steam-distillation and the residual solid resin was extracted with hot ethanol. When the alcoholic solution was cooled, perylene crystallized out (0.1 g; m.p. 272-275°). After removal of alcohol the residual resin-like solid (13.6 g) was dehydrated with acetic anhydride under the conditions described above. The product (12.8 g) was a dark-colored powder, m.p. 60-105°; crystallization of this from a 1 : 1 mixture of ethanol and ethyl acetate gave 2.9 g of white crystals, m.p. 219-225°, yield 12%. After being recrystallized from ethyl acetate and then from a mixture of benzene and ethanol, 4-methyl-5-(1-naphthyl)-1-phenyl-1,3,5-hexatriene formed very small white crystals, m.p. 230-231°.

Found %: C 93.21; 93.23; H 6.79; 6.83. $C_{23}H_{20}$. Calculated %: C 93.20 H 6.80.

6-(9-fluorenyl)-3-methyl-6-phenyl-3-hexen-2-one. An ethereal solution of 13 g (0.07 mole) of 3-methyl-6-phenyl-3,5-hexadien-2-one was added over a period of 45 minutes to an ethereal solution of 9-fluorenyllithium prepared from 12.8 g (0.077 mole) of fluorene and phenyllithium. The reaction mixture was boiled for two hours, and on the next day it was decomposed with water. After the usual treatment and removal of ether, there remained a red oil (27.5 g), from which a crystalline precipitate formed when methanol was added. The yield of crystals, m.p. 98-101°, was 10.6 g (43%). After being twice recrystallized from ethanol, 6-(9-fluorenyl)-3-methyl-6-phenyl-3-hexen-2-one was obtained as white plates, m.p. 102-103.

Found %: C 88.38; 88.42; H 6.83; 6.82. $C_{26}H_{24}O$. Calculated %: C 88.60; H 6.86.

The 2,4-dinitrophenylhydrazone of this ketone was prepared in ethanol solution in presence of traces of concentrated hydrochloric acid; it was obtained as orange-yellow crystals, m.p. 153-155°.

Found %: C 72.03; H 5.25; N 10.74. $C_{32}H_{28}N_4O_4$. Calculated %: C 72.19; H 5.30; N 10.53.

The residue remaining after the removal of solvent from the main mother liquor was fractionally distilled, and subsequent crystallization gave fluorene (3.1 g), difluorenylethane (0.65 g), m.p. 242-243°, and a hydrocarbon (0.3 g), m.p. 143-156°, the composition of which differed from that of 1-fluorenyl-2,3-dimethyl-6-phenyl-1,3,5-hexatriene.

Found %: C 93.99; H 5.85. $C_{33}H_{32}$. Calculated %: C 93.37; H 6.83.

Ozonization of 6-fluorenyl-3-methyl-6-phenyl-3-hexen-2-one. A solution of 5 g of the ketone in 30 ml of dry chloroform was ozonized for 11 hours with oxygen containing 6% of ozone. After the usual treatment, 0.5 g of acetic acid, b.p. 115-118°, was isolated from an acid medium. The 2,4-dinitrophenylhydrazone of 5-phenyl-5-fluorenepropionaldehyde was prepared from the neutral ozonization products (4 g of a viscous yellow oil), and after being recrystallized several times from glacial acetic acid, it melted at 225-227°.

Found %: C 69.56; H 4.61; N 11.65. $C_{28}H_{22}N_4O_4$. Calculated %: C 70.28; H 4.63; N 11.71.

The neutral ozonization products yielded also the 2,4-dinitrohydrazone of 9-fluorenone, m.p. 290°, undepressed by admixture of synthesized fluorenone 2,4-dinitrophenylhydrazone.

SUMMARY

1. Phenyllithium and 1-naphthyllithium undergo 1,2-addition to the conjugated system of 3-methyl-6-phenyl-3,5-hexadien-2-one with formation of the corresponding tertiary alcohols, which give arylhexatrienes by further reaction. On the other hand, 9-fluorenyllithium undergoes 1,6-addition with this ketone with formation of the unsaturated ketone 6-fluorenyl-3-methyl-6-phenyl-5-hexen-2-one.

2. By the dehydration of 3-methyl-2,6-diphenyl-3,5-hexadien-2-ol, four stereoisomeric 4-methyl-1,5-diphenyl-1,3,5-hexatrienes can be prepared.

REACTION OF SILACYCLOPENTANES AND SILACYCLOHEXANES WITH CONCENTRATED SULFURIC ACID

A. F. Plate, N. A. Belikova, and Yu. P. Egorov

We have shown previously [1] that concentrated sulfuric acid opens the rings of silacyclopentanes quantitatively at the Si–C bond. When the sulfuric ester that is formed at first is treated with water, a disiloxane is obtained in 94% yield:

where R=CH_3 and C_2H_5

The methyl or ethyl group is not eliminated. In the present investigation we have shown that this reaction can be extended to other cyclic systems containing silicon as a hetero member of the ring, namely, bistetramethylenesilane (I) – a spiran containing two five-membered rings – and the silacyclohexane compound dimethyl(pentamethylene)silane (II).

In the case of the spiran (II) reaction proceeds just as readily as with other silacyclopentanes, but under the given conditions only one ring is broken and the dibutylbistetramethylenedisiloxane (III) is obtained in 90% yield:

The higher stability of the five-membered ring in the sulfuric ester derivative formed is probably to be explained by the presence of an Si–O bond, which stabilizes the Si–C bond in the ring. However, under more severe conditions, this ring is also opened, this being shown for the case of diethylbistetramethylenedisiloxane (IV), which we prepared previously. When the usual excess of sulfuric acid was increased tenfold and the treatment after decomposition with water was made more prolonged, this disiloxane yielded a new cyclic siloxane – symmetrical tetrabutyltetraethylcyclotetrasiloxane (V):

Thus, on the basis of five examples, it was shown that silacyclopentanes react with sulfuric acid with quantitative scission of the ring at the Si–C bond.

The silacyclohexane dimethyl(pentamethylene)silane (II) was prepared in 26.7% yield by the reaction:

It reacts differently with concentrated sulfuric acid. Reaction proceeds in two directions: with scission of the six-membered ring at the Si–C bond, and with elimination of methyl group from the silicon atom. Moreover, these two reactions proceed at the same rate, as can be judged from the amount of methane evolved. However, the rate at which the six-membered cycle reacts with sulfuric acid is about one-twentieth of the rate of five-membered cycles, which indicates the higher stability of the six-membered silicon-containing ring under the given conditions.

This new interesting reaction, in which a methyl group is eliminated from a silicon atom under the action of sulfuric acid, was known for organosilicon compounds containing a functional group [of the type $(CH_3)_3Si(CH_2)_nX$] [2], but was not known for aliphatic hydrosiliconcarbons.

Hence, as a result of scission with sulfuric acid, a mixture of equal amounts of two sulfuric esters is obtained, and by treatment with water these can give three different siloxanes (VI), (VII), and (VIII):

We did not succeed in separating this mixture into its components owing to the closeness of the boiling points of these siloxanes. Chromatography on silica gel also failed to separate them. Of the disiloxanes that can be formed in this reaction, only (VII) has been described [3]. In order to determine the composition of the mixture obtained, we specially synthesized the siloxane (VI). From a comparison of the physical constants of the siloxanes (VI) and (VII) (including molecular refraction) and from analysis and determinations of molecular weight and the amount of methane evolved in the reaction, it may be assumed that all three possible disiloxanes are present in the reaction mixture and the contents of the groups

in the mixture are equal.

In order to confirm these results on the composition of the mixture we made use also of Raman spectra obtained, on the one hand, for the mixture of disiloxanes and, on the other hand, separately for dimethyl(pentamethylene)silane (II) and symmetrical tetramethyldipentyldisiloxane (VI).

A comparison of data in the literature on Raman spectra shows that silanes of the structures $(CH_3)_3SiR$ and $(CH_3)_2SiRR'$ (R and R' being aliphatic) are characterized by a series of stable frequencies lying in the regions 680-705, 830-840, 1250-1262, 1410-1415, about 2900, and about 2960 cm^{-1} and attributable to vibrations in CH_3 groups attached to silicon [4, 5]. In the spectra of the silane (II) and of the disiloxane (VI), which are given below, these frequencies are indeed found: the silane (II) gives 694, 833, 1251, 1408, 2900, and 2965 cm^{-1}, and

the disiloxane (VI) gives 705, 838, 1268, 1410, 2904 and 2965 cm^{-1}. It is found that characteristic frequencies are to be attributed to other aliphatic radicals attached to silicon, e.g. C_3H_9, C_3H_7, C_4H_9, and C_5H_{11}, the most characteristic being four frequencies, which are displaced in a regular fashion as the chain is lengthened [5]. Thus for silicon-attached C_3H_9, the following frequencies are always observed: 972-978, 1010-1020, 1230-1240, and 1460-1470 cm^{-1}, of which the first two are to be attributed to valency vibrations ν (C–C) and the last two to deformational vibrations δ (C–H). With lengthening of the chain to C_5H_{11}, the first two are raised to about 1030 and about 1067 cm^{-1}, and the second two are lowered to 1200 and 1455 cm^{-1}. With further lengthening of the chain this process is continued to 1050, 1080 cm^{-1} and 1192, 1445 cm^{-1} for C_6H_9 and about 1070, about 1100 cm^{-1} and 1185, 1440 cm^{-1} for C_8H_{11}. In the spectrum of the disiloxane (VI) such frequencies can indeed be found: 1070, 1102, 1186, and 1443 cm^{-1}.

It must be pointed out that the Raman spectrum of the silane (I) contains the same set of frequencies as that indicated in our paper [6] as characteristic for a five-membered ring containing silicon; in the silane (I) the intensities of these lines are almost double. In the spectrum of the silane (II), apart from the frequencies due to the CH_3 groups attached to silicon, three intense narrow lines are observed (794, 908, and 1006 cm^{-1}); these stand out quite sharply amongst the other lines of the spectrum.

On analogy with naphthenes, for which the presence of 3-4 sharp intense lines in this frequency region is characteristic – e.g. in the spectra of 1,1-dimethylcyclohexane (706, 828, and 1028 cm^{-1}) and ethylcyclohexane (754, 795, and 1034 cm^{-1}) – we consider that these frequencies are characteristic of a six-membered ring containing a silicon atom.

Turning to the spectrum of the mixture under investigation, we first note the presence of three intense sharp lines coinciding in position with the frequencies noted for the six-membered ring containing silicon, i.e. 800, 909, and 1007 cm^{-1}, their relative intensities being the same as for the silane (II). Similarly, in the region of C–H vibrations we have a group of five lines, 2846, 2872, 2906, 2930, and 2960 cm^{-1}, of which 2906 cm^{-1} is the most intense, 2846 and 2960 cm^{-1} are also intense, and 2872 and 2930 cm^{-1} are the least intense, the character of the distribution of intensities being the same as for the silane (II). This gives us grounds to assert the existence in the mixture of the group

Also, the spectrum contains frequencies of the pentyl group, 1070, 1100, 1187, and about 1451 cm^{-1} (the last line broad) and frequencies of the methyl group, 686, 846, 1256, and 1406 (broad) (the frequencies of 2900 and 2960 cm^{-1} are discussed above). These facts again allow us to consider that the mixture contains a compound with the grouping:

The results of spectrum analysis therefore confirm the results of the physicochemical investigation.

EXPERIMENTAL

Sulfuric acid of density 1.830 was used in all experiments.

Bistetramethylenesilane (I). This was prepared from 60.5 g of 1,4-dibromobutane, 9.0 g of lithium, and 35.8 g of dichloro(tetramethylene)silane in accordance with West's method [3]. The spiran was purified by distillation over sodium and chromatography on silica gel. The yield was 26.6%. The product had b.p. 173-174° (750 mm); n_D^{20} 1.4863; d_4^{20} 0.9043; m.p. –52°; Found MR 44.56; Calculated for C_8SiH_{16} MR 44.54. The literature [3] gives b.p. 178.5° (760 mm); n_D^{25} 1.4860; d_4^{25} 0.899; m.p. < –70°.

Reaction of bistetramethylenesilane (I) with sulfuric acid. A mixture of 4.3 g (0.03 mole) of the spiran (I) and 11.7 g (0.12 mole) of sulfuric acid was shaken for six hours at room temperature. The mixture was treated with water, and the upper layer was separated, washed with sodium carbonate solution, and dried with calcium

chloride. The product, amounting to 4.0 g (90%), was dibutylbistetramethylenedisiloxane (III), b.p. 293.5-294.0° (751 mm); n_D^{20} 1.4670; d_4^{20} 0.9125; found M (cryoscopically in benzene) 288.2; 295.3. Calculated M 298.55. Found MR 90.78; Calculated for $C_{16}Si_2H_{34}O$, MR 90.96.

Found %: C 64.19; 64.07; H 11.64; 11.54; Si 18.84; 18.41. $C_{16}Si_2H_{34}O$. Calculated %: C 64.36; H 11.48; Si 18.80.

Reaction of diethylbistetramethylenedisiloxane (IV) with sulfuric acid. A mixture of 2.8 g (0.011 mole) of the disiloxane (IV) (prepared by method in [6]; b.p. 140.5-141.0° (34 mm); n_D^{20} 1.4641; d_4^{20} 0.9280) and 25.5 g (0.25 mole) of sulfuric acid was shaken for ten hours at room temperature. The mixture was diluted with water, and the upper layer was separated and again shaken with 16.5 g of sulfuric acid for ten hours. The mixture was diluted with water, and the upper layer was washed with sodium carbonate solution and dried with calcium chloride. The product, amounting to 1.8 g (60%) was tetrabutyltetraethylcyclotetrasiloxane (V), b.p. 194-196° (10 mm); n_D^{20} 1.4422; d_4^{20} 0.9286; Found M (cryoscopically in benzene) 506.4; 528.3; Calculated M 520.93; Found MR 148.50; Calculated for $C_{24}Si_4H_{52}O_4$ MR 148.64.

Found %: C 55.53; 55.27; H 10.79; Si 20.99; 21.29. $C_{24}Si_4H_{52}O_4$. Calculated %: 55.33; H 10.83; Si 21.54.

Dimethylpentamethylenesilane (II). A solution of 161 g (0.7 mole) of 1,5-dibromopentane in 500 ml of ether was added to 37 g (1.5 g-atom) of magnesium in 150 ml of ether. The mixture was boiled for two hours; it was then cooled to 5° and a solution of 90 g (0.7 mole) of dichlorodimethylsilane in 1 liter of ether was added in one portion. The mixture was boiled for 15 hours, and the precipitate was then decomposed with water. The ether layer was separated, and the aqueous layer was extracted with two portions of ether. The combined ether solutions were dried with calcium chloride. Ether was distilled off, and the residue then came over at 125-136°. After being distilled over sodium through a 25-plate column and being subjected to chromatography on silica gel, the dimethylpentamethylenesilane had the following properties: b.p. 131.2-131.3° (740 mm); n_D^{20} 1.4428; d_4^{20} 0.8111; Found MR 41.92; Calculated for C_7SiH_{16}, MR 42.04 Calc. 23.9 g (26.7% theory.).

The literature gives: b.p. 133-134° (752.9 mm); n_D^{20} 1.43940; d_4^{20} 0.8039[7] and b.p. 133°, n_D^{25} 1.4380; d_4^{25} 0.798 [3].

Symmetrical tetramethyldipentyldisiloxane (VI). Chlorodimethylpentylsilane (b.p. 166-168°) was prepared in 50% yield from 1.0 mole of dichlorodimethylsilane and 1.0 mole of n-$C_5H_{11}MgBr$ by the Grignard-Wurtz reaction. When 20 g (0.12 mole) of the product was shaken, first with 50 ml of water for ten minutes and then with dilute sulfuric acid, 13 g (77%) of tetramethyldipentyldisiloxane was obtained; b.p. 249.0-249.5° (758 mm); n_D^{20} 1.4226; d_4^{20} 0.8128; Found MR 85.94; Calculated for $C_{14}Si_2H_{34}O$, MR 85.96.

Found %: C 60.96; 61.02; H 12.69; 12.51; Si 20.58; 20.41. $C_{14}Si_2H_{34}O$. Calculated %: C 61.25; H 12.48; Si 20.44.

Reaction of dimethylpentamethylenesilane (II) with sulfuric acid. A mixture of 4.7 g (0.036 mole) of the silane (II) and 10.0 g (0.094 mole) of sulfuric acid was shaken for 13.5 hours at room temperature. There was evolution of gas (425 ml at 0° and 760 mm), and this was found by analysis to be pure methane. The viscous solution formed was treated with water, and the upper layer was washed with sodium carbonate solution and dried with calcium chloride. The experiment was repeated three times, and altogether 12.0 g (85%) of a mixture of disiloxanes was obtained; it had b.p. 245-252°; n_D^{20} 1.4430; d_4^{20} 0.8681; M (cryoscopically in benzene) 257.0, 249.5; Found MR 78.95; Calculated for $C_{14}Si_2H_{34}O$, MR 85.96; for $C_{12}Si_2H_{30}O$ – 73.87; for $C_{15}Si_2H_{32}O$ – 79.20; Calculated M 274.53, 242.18, 258.49 respectively.

Found %: C 60.11; 60.05 H 11.43; 11.65; Si 21.68; 21.52.

$C_{14}Si_2H_{34}O$ (VI). Calculated %: C 61.25; H 12.48; Si 20.44
$C_{12}Si_2H_{30}O$ (VII). Calculated %: C 59.47; H 10.82; Si 23.17
$C_{15}Si_2H_{32}O$ (VIII). Calculated %: C 60.39; H 11.69; Si 21.71

For dimethylbispentamethylenedisiloxane (VI) the literature [3] gives: b.p. 253°; n_D^{25} 1.4640; d_4^{25} 0.927.

Raman spectra (cm^{-1}); the intensities (in parentheses) are estimated visually. For dimethylpentamethylenesilane and bistetramethylenesilane the intensities are given on a scale such that the intensity of the 802 cm^{-1} line of cyclohexane is 250 units.

Bistetramethylenesilane (I) $\Delta\nu$: 242(15), 305(60), 591(25), 618(55), 668(15), 726(10), 757(5), 782(5), 854(60), 946(30), 1026(35), 1068(12), 1156(20), 1200(7), 1254(25), 1340(5), 1414(25), 1457(35), 2854(120), 2870(35), 2895(135), 2945(275).

Dimethylpentamethylenesilane (II) $\Delta\nu$: 105(15 background), 146(30), 203(70), 238(18), 253(15), 334(25 sh), 371(10), 482(10), 585(200), 632(5), 663(2), 694(15), 724(15), 741(5), 794(40 sh), 833(3 b), 908(30), 950(3), 990(8), 1006(40 sh), 1037(2), 1080(12), 1098(10), 1134(15 b), 1180(18), 1193(15), 1251(15), 1268(12), 1291(15), 1333(7), 1408(25), 1445(25), 1460(10), 2846(75), 2874(20), 2900(125 b), 2928(15), 2965(50).

Symm. tetramethyldipentyldisiloxane (VI) $\Delta\nu$: 170(2b), 200(4 b), 479(1), 540(6 b), 652(5), 682(5), 705(3), 763(1), 767(1), 838(0), 895(4), 922(1), 956(4), 1026(3), 1070(3 b), 1102(43a), 1135(4 b), 1186(6 b), 1245(4), 1262 (1), 1304(6), 1336(1), 1380(1), 1410(5), 1443(7), 1456(5), 2858(5 b), 2882(5 b), 2904(10), 2965(10 sh).

Mixture of (VI), (VII), and (VIII) $\Delta\nu$: 184(4 b), 204(4 b), 378(5), 481(1), 520(3), 556(6 b), 658(4 b), 686(2), 717(4 b), 750(1), 767(0), 800(6 sh), 846(0), 878(2), 896(2), 909(6 sh), 956(2), 1007(6 sh), 1042(3), 1070 (4 b), 1100(4 b), 1135(3 b), 1187(4), 1204(4), 1256(4), 1275(1), 1304(5 b), 1336(3 b), 1406(6 b), 1451(6 b), 2846 (10), 2872(5), 2906(10 b), 2930(5), 2960(7).

SUMMARY

1. Bistetramethylenesilane, dimethylpentamethylenesilane, and symmetrical tetramethyldipentyldisiloxane were synthesized.

2. It was shown that silacyclopentanes and their derivatives undergo quantitative scission at the Si–C bond in the ring when treated with concentrated sulfuric acid, the examples taken being bistetramethylenesilane and diethylbistetramethylenedisiloxane.

3. It was shown that, when silacyclohexanes (the example taken being dimethylpentamethylenesilane) react with concentrated sulfuric acid, reaction proceeds in two directions: scission of the Si–C bond in the ring and elimination of a methyl group from the silicon atom.

STEREOCHEMISTRY OF CYCLIC COMPOUNDS

COMMUNICATION 13. SYNTHESIS AND STEREOCHEMISTRY OF ISOMERIC DECAHYDRO-1,2-NAPHTHALENEDICARBOXYLIC ACIDS

I. N. Nazarov, V. F. Kucherov, and V. M. Andreev

As we showed in a previous communication [1], the hydrogenation of the isomeric adducts (III) and (IV) formed by 1-vinyl-1-cyclohexene with maleic anhydride proceeds in a sterically selective manner with addition of hydrogen at the double bond from the less screened side (opposite to the carboxyls), so that it is possible to obtain the isomeric cis-syn-cis- and trans-anti-cis-decahydro-1,2-naphthalenedicarboxylic acids (I) and (II) quite readily in almost quantitative yield:

The steric nonequivalence of the carboxyls in the isomeric 1,2,3,5,6,7,8,8a-octahydro-1,2-naphthalenedicarboxylic acids (III) and (IV) made it possible for us to prepare the corresponding four isomeric monoesters [2], the hydrogenation of which also proceeds in a sterically selective manner from the side opposite to the carboxyls with formation of four isomeric saturated monoesters (V), (IX), (XIII), and (XVII). These monoesters served us as starting materials for the preparation of new stereoisomers of decahydro-1,2-naphthalenedicarboxylic acid.

For this purpose we used the reaction of isomerization of the monoesters with sodium methoxide, which, as is well known, occurs at the esterified carboxyl and gives dicarboxylic acids with a trans arrangement of carboxyl groups.

It was found that the cis-syn-cis monoester (V) with an esterified carboxyl at C-2 is very readily isomerized with sodium methoxide with almost quantitative formation of cis-syn-trans-decahydro-1,2-naphthalenedicarboxylic acid (VI), which readily gives the corresponding cis-syn-trans anhydride (VII) and the crystalline cis-syn-trans diester (VIII).

By analogous isomerization at the 1-carboxyl, the isomeric cis-syn-cis monoester (IX) is converted quantitatively into cis-anti-trans-decahydro-1,2-naphthalenedicarboxylic acid (X), which gives the cis-anti-trans anhydride (XI) and the cis-anti-trans diester (XII). The cis-anti-trans acid (X) is readily obtained also by the isomerization of the cis-syn-cis diester (XXVII).

The isomeric monoesters of the trans-anti-cis series (XIII) and (XVII) were also subjected to isomerization with sodium methoxide. It was found, however, that only the trans-anti-cis monoester (XIII), which is esterified at the 2-carboxyl, is isomerized under these conditions, and this gives a good yield of trans-anti-trans decahydro-1,2-naphthalenedicarboxylic acid (XIV), which gives the trans anhydride (XV) and the trans diester (XVI).

The isomeric trans-anti-cis monoester (XVII), which is esterified at the 1-carboxyl, was found to be incapable of undergoing isomerization with sodium methoxide; under such conditions it was quantitatively hydrolyzed into the original trans-anti-cis acid (II).

Yet another stereoisomer of decahydro-1,2-naphthalenedicarboxylic acid was obtained in a study of the thermal isomerization of the cis-syn-cis anhydride (XVIII).

It was found that this anhydride, like the previously studied anhydride of the unsaturated acid (III) [1], is able to undergo thermal isomerization into the more stable cis-anti-cis anhydride (XIX). Similar thermal isomerizations have been described previously for a series of anhydrides of monocyclic o-dicarboxylic acids [3]. Hydrolysis of the cis-anti-cis anhydride (XIX) readily gives cis-anti-cis-decahydro-1,2-naphthalenedicarboxylic acid (XX), from which we prepared the corresponding diester (XXI). The spatial configuration of the cis-anti-cis acid (XX) was proved by studying the isomerization of the corresponding isomeric monoesters (XXII) and (XXIII) in presence of sodium methoxide. These monoesters were prepared by a method described previously [4] – addition of methanol to the cis-anti-cis anhydride (XIX) and partial hydrolysis of the cis-anti-cis diester (XXI).

It was found that, as in the case of the unsaturated acids (III) and (IV) [2], these reactions proceed in a sterically selective manner, and by the action of methanol on the anhydride (XIX) the cis-anti-cis monoester (XXII) with its esterified carboxyl at C-2 was formed, whereas partial hydrolysis of the diester (XXI) gave mainly the isomeric cis-anti-cis monoester (XXIII) with its esterified carboxyl at C-1. The structure of the monoester (XXII) was proved by lengthening of the carbon chain in an Arndt-Eistert reaction and dehydrogenation of the 2-carboxydecahydro-1-naphthaleneacetic acid (XXIV) obtained to 1-methylnaphthalene. The structure of the isomeric monoester (XXIII) was proved by the fact that it was converted by hydrolysis into the original cis-anti-cis acid (XX).

When the monoester (XXII) was boiled with sodium methoxide, isomerization at the esterified 2-carboxyl occurred with formation of the cis-anti-trans acid (X), already obtained from the cis-syn-cis monoester (IX). The same acid (X) is readily prepared also by the isomerization of the diester (XXI). On the other hand, the monoester (XXIII) with an esterified 1-carboxyl reacts under these conditions with formation of the cis-syn-trans acid (VI), identical with the acid obtained previously by the isomerization of the cis-syn-cis monoester (V). It is not difficult to see that such transformations can occur only if the acid (XX) has a cis-anti-cis configuration.

With the object of synthesizing other possible isomers of decahydro-1,2-naphthalenedicarboxylic acid, we studied the hydrogenation of the previously described [2] isomeric syn-trans- and anti-trans-1,2,3,5,6,7,8,8a-octahydro-1,2-naphthalenedicarboxylic acids (XXV) and (XXVI). It was found, however, that of these acids only the syn-trans acid (XXV) is hydrogenated selectively, when it gives the above-described cis-syn-trans-decahydro-1,2-naphthalenedicarboxylic acid (VI).

The anti-trans acid (XXVI) is hydrogenated to a mixture of saturated acids, and by fractional crystallization of this mixture was isolated only a small amount of the cis-anti-trans acid (X). These results are strictly in accordance with molecular models [2], from which it follows that in the acid (XXV) the carboxyls have a screening effect, whereas in the acid (XXVI) such screening is absent.

We have thus prepared six out of the eight theoretically possible isomers of decahydro-1,2-naphthalenedicarboxylic acid, four of these, (I), (VI), (X), and (XX), belonging to the cis-decahydronaphthalene series, and the other two, (II) and (XIV), to the trans-decahydronaphthalene series. The preparation of these isomers by stereospecific mutual transformations leaves no doubt about the correctness of the configurations attributed to them. Moreover, the steric structures of trans-anti-cis- and trans-anti-trans-decahydro-1,2-naphthalenedicarboxylic acids (II) and (XIV) were recently rigorously proved by special synthesis via decahydro-4-oxo-1,2-naphthalenedicarboxylic acid [5].

An examination of molecular models of isomeric decahydro-1,2-naphthalenedicarboxylic acids confirms our conclusions regarding their spatial configurations derived from a study of the thermal transformations of these acids and the isomerization of the corresponding esters in presence of sodium methoxide. As the models show, the isomerization of the cis-syn-cis acid (I) [in the form of its monoester(V)] with sodium methoxide at the polar 2-carboxyl and the analogous isomerization of the cis-anti-cis acid (XX)[in the form of its monoester (XXIII)] at the polar 1-carboxyl will readily give the same cis-syn-trans acid (VI) with a diequatorial (trans) arrangement of carboxyls. In a similar way, the trans-anti-cis acid (II) [in the form of its monoester (XIII)] is readily isomerized at its polar 2-carboxyl into the trans-anti-trans acid (XIV), which also has a diequatorial (trans) arrangement of carboxyls.

(e) – equatorial arrangement of substituent
(p) – polar arrangement of substituent

Different behavior is found in the isomerization of the monesters (IX) and (XXII) with sodium methoxide [corresponding to the transformation of the acids (I) and (XX) at the equatorial 1- and 2-carboxyls]. In this case isomerization should lead to an unstable acid with a dipolar (p – p) arrangement of carboxyl groups, and, owing to the mobility of the cis-decahydronaphthalene system, this acid will undergo spontaneous rearrangement into the stable cis-anti-trans acid (X) with a diequatorial (trans) arrangement of carboxyls. A similar rearrangement of rings occurs also in the case of the diesters (XXVII) and (XXI) [corresponding to the acids (I) and (XX)], which in isomerization with sodium methoxide are converted not into the cis-syn-trans acid (VI), but into the stable cis-anti-trans acid (X).

Hence, the isomerization of the diesters (XXVII) and (XXI) appears to occur at equatorial carboxyls with subsequent rearrangement of the rings with formation of the more stable cis-anti-trans configuration.

In a similar way, under the conditions of isomerization with sodium methoxide, the trans diester (XIII), which corresponds to the cis-syn-trans acid (VI), is partially converted into the cis-anti-trans acid (X). In the stable trans-decahydronaphthalene series such a rearrangement of rings cannot occur, so that isomerization of the trans-anti-cis acid (II) at the 1-carboxyl does not occur and the monoester (XVII) is merely hydrolyzed to the original acid (II) under these conditions.

Study of thermal transformations showed that, of the four acids of the cis-decahydronaphthalene series, the most stable thermally is the cis-anti-cis acid (XX), the anhydride of which (XIX) is the product obtained when the other three acids of the cis-decahydronaphthalene series (I), (VI), and (X) are heated at 250°. Similarly, the trans-anti-trans acid (XIV) is readily isomerized at 250° into the anhydride of the trans-anti-cis acid (II). All these data on the mutual transformations of the six isomeric decahydro-1,2-naphthalenedicarboxylic acids that we have prepared are in full accord with previously established facts concerning the higher stability of the anti configuration at the 1–8a bond [6] and the higher thermal stability of the cis configuration of a five-membered anhydride ring [7].

Some supplementary data on the stereochemistry of isomeric acids of the cis-decahydronaphthalene series were obtained in a study of the partial hydrolysis of the isomeric diesters (XXVII) and (XXVIII). It was found that both of these esters are isomerized to a considerable extent when hydrolyzed with one molecular equivalent of potassium hydroxide, the products being the crystalline monoesters (XXIX) and (XXX) with a trans arrangement of carboxyls; the spatial configurations of these products were proved by their conversion into the above-described diesters (XII) and (XVI) with the aid of sodium methoxide.

When subjected to Arndt-Eistert chain lengthening, the monesters (XXIX) and (XXX) gave the isomeric 1-carboxydecahydro-2-naphthaleneacetic acids (XXXI) and (XXXII), dehydrogenation of which gave 2-methylnaphthalene. This proved that both trans monoesters (XXIX) and (XXX) have the esterified group at C-1, so that even under mild conditions (1 molecular equivalent of potassium hydroxide) the cis-syn-cis diester (XXVII) is readily isomerized and, owing to rearrangement of the bicyclic system, gives a cis-anti-trans configuration with a diequatorial (e–e) arrangement of carboxyls. On the other hand, in hydrolysis with one molecular equivalent of potassium hydroxide, the trans-anti-cis diester (XXVIII) undergoes only isomerization at the polar 2-carboxyl.

EXPERIMENTAL

cis-syn-trans-Decahydro-1,2-naphthalenedicarboxylic acid (VI). To a solution of 5 g of sodium in 120 ml of absolute methanol, 2 g of the cis-syn-cis monoester (V), m.p. 144° [2], was added, and the mixture was boiled for 15 hours. Methanol was distilled off under reduced pressure and the residue was dissolved in 100 ml of water. The solution was filtered and was evaporated on a water bath to a thick slurry. The precipitate of salts was filtered off, washed with absolute methanol, and dissolved in 50 ml of water. Acidification of the filtered solution with hydrochloric acid gave 1.75 g of the cis-syn-trans acid (VI), m.p. 213-215°, raised to a constant value of 217-218° (with decomposition) by crystallization from acetone.

Found %: C 63.85; 63.64; H 7.99; 8.91. $C_{12}H_{18}O_4$. Calculated %: C 63.68; H 8.02.

The diphenacyl ester, prepared in the usual way, melted at 98-99° after recrystallization from alcohol.

Found %: C 72.61; 72.92; H 6.56, 6.55. $C_{22}H_{30}O_6$. Calculated %: C 72.71; H 6.54.

cis-syn-trans Anhydride (VII). A solution of 0.5 g of the cis-syn-trans acid (VI) in 5 ml of acetyl chloride was boiled for one hour, and the volatile products were distilled off under reduced pressure. The liquid residue was evaporated with benzene under reduced pressure, treated with petroleum ether, and left overnight at 0°. The crystalline product was washed on the filter with petroleum ether, and 0.4 g of the anhydride (VII), m.p. 70-73°, was obtained. After two recrystallizations from petroleum ether, the anhydride (VII) had a constant melting point of 75-76°.

Found %: C 68.97; 69.17; H 7.67; 7.56. $C_{22}H_{26}O_3$. Calculated %: C 69.21; H 7.74.

Hydrolysis of the cis-syn-trans anhydride (VII) with aqueous sodium hydroxide (5%) at the boil gave pure original cis-syn-trans acid (VI), m.p. 215-216°.

cis-syn-trans Diester (VIII). The cis-syn-trans acid (VI) (0.7 g) was treated with ethereal diazomethane, ether was distilled off, and the residue was washed with petroleum ether. A yield of 0.65 g of (VIII), m.p. 63-65°, was obtained; after crystallization from petroleum ether it melted at 72-73°.

Found %: C 66.23; 66.20; H 8.67; 8.55. $C_{14}H_{22}O_4$. Calculated %: C 66.12; H 8.72.

cis-anti-trans-Decahydro-1,2-naphthalenedicarboxylic acid (X). To a solution of 4.2 g of sodium in 100 ml of absolute methanol, 1.7 g of the cis-syn-cis monoester (IX), m.p. 121° [2], was added, the mixture was boiled for 16 hours, and methanol was distilled off under reduced pressure. The residue was dissolved in 30 ml of water, the solution was evaporated on a water bath, and the precipitate of salts was filtered off and washed with methanol. Dissolution of the product in water and acidification with hydrochloric acid gave 1.6 g of the cis-anti-trans acid (X), m.p. 196-198°. Crystallization from 25% acetone gave the pure acid, m.p. 202-203°.

Found %: C 63.74; 63.75; H 8.01; 8.18. $C_{12}H_{18}O_4$. Calculated %: C 63.68; H 8.02.

cis-anti-trans Anhydride (XI). A solution of 0.5 g of the cis-anti-trans acid (X) in 5 ml of acetyl chloride was boiled for 40 minutes, the volatile products were distilled off under reduced pressure, and the residue crystallized when treated with petroleum ether. The product, amounting to 0.4 g, was the cis-anti-trans anhydride (XI), m.p. 135-137°; crystallization from a 1:2 mixture of benzene and ether gave the pure anhydride, m.p. 137-138°.

Found %: C 69.07; 69.17; H 7.57; 7.70. $C_{12}H_{16}O_3$. Calculated %: C 69.21; H 7.74.

Hydrolysis with 5% sodium hydroxide solution gave a quantitative yield of the original cis-anti-trans acid (X), m.p. 201-202°.

cis-anti-trans Diester (XII). A suspension of 1.5 g of the cis-anti-trans acid (X) in ether was treated with ethereal diazomethane, ether was distilled off, and the crystalline residue was washed on the filter with petroleum ether. The product, amounting to 1.3 g, was the cis-anti-trans diester (XII), m.p. 39-42°, raised to 43-44° by crystallization from petroleum ether.

Found %: C 65.97; 65.72; H 8.70; 8.74. $C_{14}H_{22}O_4$. Calculated %: C 66.12; H 8.72.

trans-anti-trans-Decahydro-1,2-naphthalenedicarboxylic acid (XIV). To a solution of 6.5 g of sodium in 220 ml of absolute methanol, 2.7 g of the trans-anti-cis monoester (XIII), m.p. 85° [2], was added, the mixture was boiled for 17 hours, methanol was distilled off under reduced pressure, and the residue was dissolved in 60 ml of water. The solution was filtered and evaporated in a porcelain dish on a water bath. The precipitate of salts was filtered off, washed with methanol, and dissolved in 15 ml of water. Acidification of the solution with hydrochloric acid gave 2.4 g of the trans-anti-trans acid (XIV), m.p. 194-196°, raised to 199-200° by crystallization from 25% acetone; it gave a marked depression of melting point (to 175-190°) in admixture with the acid (X).

Found %: C 63.69; 63.58; H 7.98; 7.92. $C_{12}H_{18}O_4$. Calculated %: C 63.68; H 8.02.

trans-anti-trans anhydride (XV). Boiling with acetyl chloride in the usual way converted 0.5 g of the trans-anti-trans acid (XIV) into 0.43 g of the trans-anti-trans anhydride (XV), m.p. 113-115°; after crystallization from a mixture of diethyl ether and petroleum ether it melted at 114-115°.

Found %: C 68.98; 69.20; H 7.75; 7.54. $C_{12}H_{16}O_3$. Calculated %: C 69.21; H 7.74.

Hydrolysis of (XV) with boiling 5% sodium hydroxide converted it quantitatively into the original trans-anti-trans acid (XIV), m.p. 198-199°.

trans-anti-trans Diester (XVI). One g trans-anti-trans acid (XIV) was treated with ethereal diazomethane giving 1 g trans-anti-trans diester (XVI), m.p. 49-51°, which after crystallization from petroleum ether had constant m.p. 54-55°.

Found%: C 66.14; 66.31; H 8.65; 8.75. $C_{14}H_{22}O_4$. Calculated %: C 66.12; H 8.72.

Attempt to isomerize the trans-anti-cis monoester (XVII). To a solution of 6.5 g of sodium in 220 ml of absolute methanol, 2.7 g of the trans-anti-cis monoester (XVII), m.p. 103° [2], was added, and the mixture was boiled for 17 hours. The usual treatment gave 2.4 g of the trans-anti-cis acid (II), m.p. 147-148°, raised to 151-153° by crystallization from 25% acetone. There was no depression of melting point in admixture with the previously described sample [2].

cis-anti-cis Anhydride (XIX). The cis-syn-cis anhydride (XVIII) (17.4 g), m.p. 76° [2], was heated for one hour in a stream of nitrogen at 245-255° and then for a further ten minutes at 275°. Vacuum distillation of the product gave 13.2 g of the cis-anti-cis anhydride (XIX) in the form of a thick oil, b.p. 195-196° (14 mm). It gradually crystallized to a solid of m.p. 46-50°, raised to 59-60° by crystallization from a 1 : 5 mixture of diethyl ether and petroleum ether.

Found %: C 69.04; 69.16; H 7.57; 7.70. $C_{12}H_{16}O_3$. Calculated %: C 69.21; H 7.74.

cis-anti-cis-Decahydro-1,2-naphthalenedicarboxylic acid (XX). A mixture of 7.1 g of the cis-anti-cis anhydride (XIX) and 80 ml of 5% sodium hydroxide solution was boiled for ten minutes. Acidification with hydrochloric acid gave 7.5 g of the cis-anti-cis acid (XX), m.p. 187-190°, raised to 197-198° by crystallization from 70% acetone.

Found %: C 63.85; 63.98; H 8.34; 8.24. $C_{12}H_{18}O_4$. Calculated %: C 63.68; H 8.02.

cis-anti-cis Diester (XXI). The cis-anti-cis acid (XX) (4.5 g) was treated with a preparation of ethereal diazomethane, ether was distilled off, and the liquid residue was vacuum-distilled. The product, amounting to 4.6 g, was the cis-anti-cis diester (XXI), b.p. 131-132° (2 mm); n_D^{20} 1.4874; d_4^{20} 1.1241; MR 65.11, Calc. MR 65.48

Found %: C 66.06; 66.04; H 8.70; 8.86. $C_{14}H_{22}O_4$. Calculated %: C 66.12; H 8.72.

cis-anti-cis Monoester (XXII). A mixture of 5.5 g of the cis-anti-cis anhydride (XIX) and 25 ml of absolute methanol was boiled for one hour, methanol was distilled off under reduced pressure, and the crystalline residue was washed on the filter with petroleum ether. The product, amounting to 4.8 g was the cis-anti-cis monoester (XXII), m.p. 86-89°, raised to 92-93° by crystallization from a 1 : 3 mixture of diethyl ether and petroleum ether.

Found %: C 64.85; 65.04; H 8.28; 8.39. $C_{13}H_{20}O_4$. Calculated %: C 65.01; H 8.33.

When subjected to isomerization with sodium methoxide according to the above-described procedure, 2.1 g of the cis-anti-cis monoester (XXII) gave 1.9 g of an acid of m.p. 193-195°, raised to 200-202° by crystallization from 25% acetone; it showed no depression of melting point in admixture with a pure sample of the cis-anti-trans acid (X).

cis-anti-cis Monoester (XXIII). The cis-anti-cis diester (XXI) (4.6 g) was added to a solution of 0.99 g of potassium hydroxide in 16 ml of water and 50 ml of methanol, and the mixture was boiled for two hours. Methanol was distilled off under reduced pressure, and the aqueous solution was extracted with ether and acidified with hydrochloric acid. The oil that separated was extracted with ether, the ether extract was dried with sodium sulfate, and the ether was distilled off. The liquid product was dissolved in 15 ml of petroleum ether, a small amount of heterogeneous high-melting substance was filtered off, and the solution was evaporated to small bulk and left at 0° overnight. The crystals that separated were filtered off and washed with cold petroleum ether. The product, amounting to 2.2 g, was the cis-anti-cis monoester (XXIII), m.p. 88-91°, raised to a constant value

of 95-96° by crystallization from a mixture of diethyl ether and petroleum ether. A mixture with the isomeric cis-anti-cis monoester (XXII) melted at 65-75°.

Found %: C 64.90; 64.96; H 8.19; 8.45. $C_{13}H_{20}O_4$. Calculated %: C 65.01; H 8.33.

When subjected to isomerization with sodium methoxide according to the above-described procedure, 1 g of the cis-anti-cis monoester (XXIII) gave 0.88 g of the cis-syn-trans acid (VI), m.p. 210-212°, raised to 217-218° by crystallization from acetone; it gave no melting point depression with sample prepared previously.

cis-anti-cis-2-Carboxydecahydro-1-naphthaleneacetic acid (XXIV). A mixture of 3 g of cis-anti-cis monoester (XXII), 20 ml of dry benzene, and 1 ml of oxalyl chloride was heated at 60° for two hours. Benzene was distilled off under reduced pressure, and the liquid acid chloride was dissolved in 15 ml of dry ether. The solution was added with cooling and stirring to a solution of 4 g of diazomethane in 200 ml of dry ether and left overnight. Ether was distilled off, and the residue was dissolved in 60 ml of absolute methanol. Freshly prepared silver oxide (1 g) was added, and the mixture was boiled for five hours. The precipitate was filtered off, methanol was distilled off, and the liquid residue was vacuum-distilled. The product, amounting to 2.4 g, was the dimethyl ester of 2-carboxydecahydro-1-naphthaleneacetic acid (XXIV), b.p. 156° (4 mm) and on n_D^{20} 1.4860.

Found %: C 67.23; 67.37; H 8.86; 8.77. $C_{15}H_{24}O_4$. Calculated %: C 67.16; H 9.01.

In order to hydrolyze the ester of (XXIV), 2.2 g was boiled with 12 ml of 20% potassium hydroxide solution for four hours. Acidification with hydrochloric acid gave 1.7 g of the acid, m.p. 145-160°. Two crystallizations from 50% aqueous acetone gave 1.1 g of cis-anti-cis-2-carboxydecahydro-1-naphthaleneacetic acid (XXIV) having a constant melting point of 180-182°.

Found %: C 65.00; 65.09; H 8.32; 8.33. $C_{13}H_{21}O_4$. Calculated %: C 65.01; H 8.33.

In order to dehydrogenate the acid (XXIV), 1.05 g was heated as a solution in 20 ml of benzene with 0.5 g of palladized charcoal (10% Pd) for 16 hours at 360-370°. Distillation gave 0.4 g of dehydrogenation product, b.p. 210-232°, n_D^{20} 1.5574. The product formed a picrate of m.p. 137-138°, undepressed by admixture of pure 1-methylnaphthalene picrate (138-140°).

Hydrogenation of syn-trans-1,2,3,5,6,7,8,8a-octahydro-1,2-naphthalenedicarboxylic acid (XXV). In the hydrogenation of 2.2 g of the syn-trans acid (XXV) as a solution in 20 ml of absolute methanol in presence of platinum oxide, one molecular equivalent (230 ml at 0° and 760 mm) of hydrogen was absorbed. Methanol was distilled off under reduced pressure, and the crystalline product was washed on the filter with a little 50% aqueous acetone. The product, amounting to 2.1 g, was pure cis-syn-trans acid (VI), m.p. 216-217°, undepressed by admixture of the sample described above.

Hydrogenation of anti-trans-1,2,3,5,6,7,8,8a-octahydro-1,2-naphthalenedicarboxylic acid (XXVI). In the hydrogenation of 2.5 g of the anti-trans acid (XXVI) as a solution in 25 ml of methanol in presence of platinum oxide, one molecular equivalent (260 ml) of hydrogen was absorbed. After removal of methanol there remained a liquid product which solidified when treated with water (2.2 g, m.p. 170-185°). As a result of two fractional crystallizations of this mixture from 40% aqueous acetone, 0.9 g of the cis-anti-trans acid (X) was isolated; it had m.p. 200-202°, undepressed by admixture of the above-described sample.

We did not suceed in isolating any other pure substances.

Thermal transformations of isomeric decahydro-1,2-naphthalenedicarboxylic acids. a) The cis-anti-trans acid (X) (0.5 g) was heated in a stream of nitrogen for 45 minutes at 250-255° and then for a further five minutes at 270-275°. Vacuum distillation of the product gave 0.4 g of a viscous liquid having b.p. 185-190° (10 mm) and n_D^{20} 1.5110, which was hydrolyzed at the boil with 5 ml of 5% sodium hydroxide solution. The crystals formed on acidification (0.3 g, m.p. 185-188°) were crystallized from 70% aqueous acetone. They then melted at 196-197° and were found to be identical with the cis-anti-cis acid (XX).

b) In a similar way, 0.9 g of the cis-syn-trans acid (VI) gave 0.6 g of a liquid anhydride, which, after hydrolysis and crystallization of the product from 50% acetone, gave 0.5 g of pure cis-anti-cis acid (XX), m.p. 197-198° and identical with the samples described above.

c) The trans-anti-trans acid (XIV) (0.9 g) was heated in a stream of nitrogen for 45 minutes at 250-255° and the product was vacuum-distilled. The isomerization product solidified when distilled; it was washed with ether. The product, amounting to 0.6 g, was the anhydride of the trans-anti-cis acid (II), m.p. 126-127° and identical with the substance obtained previously [1]. Hydrolysis with aqueous sodium hydroxide gave the pure trans-anti-cis acid (II), m.p. 151-153°, undepressed by admixture of an authentic sample.

cis-anti-trans Monoester (XXIX). The cis-syn-cis diester (XXVII) (11.6 g) was added to a solution of 2.5 g of sodium hydroxide in 125 ml of methanol and 40 ml of water, and the mixture was boiled for two hours. Methanol was distilled off under reduced pressure, and the aqueous solution was extracted with ether and acidified with hydrochloric acid. The crystalline product was filtered off and carefully washed with a 2:1 mixture of ether and acetone. The product, amounting to 4.2 g, was the cis-anti-trans monoester (XXIX), m.p. 160-162°, raised to a constant value of 165-166° by crystallization from acetone.

Found %: C 64.95; 64.79; H 8.34; 8.43. $C_{19}H_{28}O_4$. Calculated %: C 65.01; H 8.33.

When the cis-anti-trans monoester (XXIX) was treated with ethereal diazomethane, the cis-anti-trans diester (XII) of m.p. 43-44° described above was obtained in quantitative yield.

trans-anti-trans Monoester (XXX). By similar partial hydrolysis, 6 g of the trans-anti-cis diester (XXVIII) gave 2.1 g of the trans-anti-trans monoester (XXX), m.p. 120-122°, raised to 124-125° by crystallization from a 1:1 mixture of diethyl ether and petroleum ether.

Found %: C 64.81; 64.76; H 8.26; 8.31. $C_{19}H_{28}O_4$. Calculated %: C 65.01; H 8.33.

Treatment of this monoester with diazomethane gave the trans-anti-trans diester (XVI), m.p. 52-53° and identical with the sample obtained previously.

cis-anti-trans-1-Carboxyldecahydro-2-naphthaleneacetic acid (XXX). A mixture of 3.1 g of the cis-anti-trans monoester (XXIX), 20 ml of dry benzene, and 1 ml of oxalyl chloride was heated at 50° for three hours. Benzene was distilled off under reduced pressure, and the resulting liquid acid chloride was dissolved in 15 ml of dry ether. This solution was added slowly with cooling to a dry solution of 4.5 g of diazomethane in 150 ml of ether, and the solution was left overnight at room temperature. On the next day ether was distilled off and the residue was dissolved in 60 ml of absolute methanol; 1 g of silver oxide was added, and the mixture was boiled for seven hours. Silver oxide was filtered off, methanol was distilled off under reduced pressure, and the residue was vacuum-distilled, yielding 2.9 g of the dimethyl ester of the acid (XXXI), b.p. 145-146° (3 mm) and n_D^{23} 1.4836.

Found %: C 67.15; 66.96; H 9.03; 8.93. $C_{15}H_{24}O_4$. Calculated %: C 67.16; H 9.01.

In order to hydrolyze the ester, 2.6 g was boiled with 14 ml of 20% sodium hydroxide solution for four hours. The oil formed on acidification rapidly solidified, and in this way 2.2 g of an acid of m.p. 175-185° was obtained. Two crystallizations from 50% aqueous acetone gave 1.8 g of the acid (XXXI) having a constant melting point of 198-199°.

Found %: C 64.95; 65.02; H 8.33; 8.32. $C_{13}H_{21}O_4$. Calculated %: C 65.01; H 8.33.

In order to dehydrogenate the acid (XXXI), a mixture of 1.2 g of the acid, 20 ml of benzene, and 0.5 g of palladized charcoal (10% Pd) was heated in a nitrogen atmosphere at 360-370° for 16 hours. Distillation gave 0.55 g of the dehydrogenation product, b.p. 210-235° and n_D^{20} 1.5510. The picrate prepared from this had m.p. 114-115°, undepressed by admixture of a known sample of 2-methylnaphthalene picrate.

trans-anti-trans-1-Carboxydecahydro-2-naphthaleneacetic acid (XXXII). In a similar way, 2 g of the trans-anti-trans monoester (XXX) was submitted to the Arndt-Eistert reaction and gave, after distillation, 1.6 g of the dimethyl ester of the acid (XXXII), b.p. 148-150° (3 mm); n_D^{20} 1.4814.

Found %: C 67.26; 67.28; H 8.05; 9.08. $C_{15}H_{24}O_4$. Calculated %: C 66.12, H 8.72.

Hydrolysis of 1.5 g of this diester by treatment with a solution of 3.5 g of potassium hydroxide in 5 ml of water at the boil gave 1.2 g of the acid (XXXII), m.p. 212-215°, raised to 218-220° by crystallization from 50% acetone.

Found %: C 64.99; 65.11; H 8.43; 8.35. $C_{12}H_{21}O_4$. Calculated %: 65.01; H 8.23.

In order to dehydrogenate the acid (XXXII), 1.1 g was heated as a solution in 20 ml of benzene with 0.5 g of palladized charcoal (360-370°, 18 hours). Distillation gave 0.45 g of dehydrogenation product, b.p. 220-235° and n_D^{20} 1.5554. The picrate of the product had m.p. 115-116°, undepressed by admixture of known 2-methylnaphthalene picrate.

Isomerization of the cis-syn-cis diester (XXVII). The cis-syn-cis diester (XXVII) (4.0 g) was added to a solution of 9.7 g of sodium in 250 ml of absolute methanol, and the mixture was boiled for 18 hours. The above described treatment gave 3.2 g of the cis-anti-trans acid (X), m.p. 190-192°, raised to 202-203° by crystallization from 25% aqueous acetone; there was no depression of melting point in admixture with the sample prepared previously (above).

Isomerization of the cis-anti-cis diester (XXI). In the same way, 0.8 g of the cis-anti-cis diester (XXI) was isomerized with a boiling solution of 1.9 g of sodium in 50 ml of absolute methanol for a period of 17 hours. The product, amounting to 0.6 g, was the cis-anti-trans acid (X), m.p. 189-193°, raised to 202-203° by crystallization from 30% acetone; there was no depression of melting point in admixture with a known sample.

Isomerization of the cis-syn-trans diester (VIII). In the same way, after the isomerization of 1.0 g of the diester (VIII) by boiling it for 16 hours with a solution of 2.5 g of sodium in 60 ml of absolute methanol, 0.75 g of an acid of m.p. 187-190° was obtained. Two crystallizations from 30% aqueous acetone gave 0.25 g of the cis-anti-trans acid (X), m.p. 200-202°, undepressed by admixture of samples prepared previously (above).

SUMMARY

1. Six of the eight theoretically possible isomers of decahydro-1,2-naphthalenedicarboxylic acid (I), (II), (VI), (X), (XIV), and (XX) are described, and in each case a rigorous determination of spatial configuration is made.

2. A study is made of the chemical transformations of all the synthesized isomeric decahydro-1,2-naphthalenedicarboxylic acids and of the cis-trans isomerization of the corresponding mono- and di-esters in presence of sodium methoxide. It is shown that the isomers obtained are relatively stable both to heat and to alkaline reagents.

3. On the basis of the theory of equatorial-polar bonds in the cyclohexane molecule and of an examination of molecular models, all the peculair features of the mutual transofrmations of the six isomeric decahydro-acids and their esters can be explained.

HYDROGENATION OF ISOPROPENYLCYCLOPROPANE IN PRESENCE OF PLATINUM BLACK

B. A. Kazansky, M. Yu. Lukina, A. I. Malyshev, V. T. Aleksanyan, and Kh. E. Sterin

We have observed previously [1] that in the hydrogenation of isopropenylcyclopropane in alcholic solution at room temperature in presence of palladium black addition of two molecules of hydrogen occurs with formation of 2-methylpentane:

A study of this reaction showed that 2-methylpentane is formed by the hydrogenation of the first-formed 2-methyl-1-pentene and 2-methyl-2-pentene. It was suggested that these methylpentenes are formed as a result of 1,3- and 3,4-addition of hydrogen to isopropenylcyclopropane, in which the double bond is conjugated with the three-membered ring:

We did not succeed in establishing the positions in which addition of hydrogen occurred (1,4 or 3,4 or both simultaneously), for it was found that in presence of palladium black under the experimental conditions used 2-methyl-1-pentene and 2-methyl-2-pentene are isomerized into one another with formation of an equilibrium mixture. No 1,2-addition of hydrogen occurred; the product of such addition, isopropylcyclopropane, was not detected either as a final product or as an intermediary. Continuing the study of this reaction, we carried it out under the same conditions but with platinum black as catalyst in place of palladium black. We then found that in presence of platinum black the amount of hydrogen absorbed by one molecular proportion of isopropenylcyclopropane was not two molecular proportions, but only 1.3; absorption then ceased, and no further absorption occurred when a new portion of catalyst was added. The bromine water test indicated absence of unsaturated compounds in the catalyzate. Fractionation through a 40-plate column showed that the catalyzate consisted of a mixture of hydrocarbons of similar boiling points, so that we could not separate them by distillation. The physical constants of the product indicated that it was a mixture of isopropylcyclopropane and 2-methylpentane, and a Raman-spectrum study confirmed this view; the catalyzate consisted of 70% of isopropylcyclopropane and 30% of 2-methylpentane.

In order to elucidate the mechanism of the hydrogenation, we carried out a series of experiments in which the addition of hydrogen to isopropenylcyclopropane was discontinued as soon as 0.65 or 1 molecular proportion of hydrogen had been absorbed. Raman-spectrum investigations on the catalyzates showed that, apart from

isopropenylcyclopropane, isopropylcyclopropane, and 2-methylpentane, 2-methyl-1-pentene and 2-methyl-2-pentene were also present.

In order to determine whether isopropenylcyclopropane underwent isomerisation under the conditions of hydrogenation, we carried out experiments in which the addition of hydrogen was stopped as soon as 0.2 of a molecular proportion had been absorbed. Investigation with the aid of Raman spectra showed that the catalyzate consisted mainly of unchanged isopropenylcyclopropane together with some isopropylcyclopropane and traces of 2-methyl-2-pentene.

It was established by special experiments that, in contrast with the behavior found for palladium black, in presence of platinum black 2-methyl-1-pentene and 2-methyl-2-pentene are not isomerized into one another. It was established also that under the given conditions in presence of either catalyst, hydrogen does not add to isopropylcyclopropane, i.e the three-membered ring remains intact. On the basis of all these results we may suppose that the hydrogenation of isopropenylcyclopropane in presence of platinum black proceeds in accordance with the following scheme:

Hence, in presence of platinum black, isopropylcyclopropane (I) and 2-methylpentane (II) are formed simultaneously but at different rates. In the first case only 1,2-addition of hydrogen occurs, and conjugation of of the three-membered ring with the double bond is not observed; in the second case, as in the case of the hydrogenation of isopropenylcyclopropane in presence of palladium black, there is conjugation of the three-membered ring and the double bond and 1,4- and 3,4-addition of hydrogen occurs. When we consider the amounts of hydrogen added in the two reactions, it becomes clear why absorption ceases after the addition of 1.3 of a molecular proportion in presence of platinum.

EXPERIMENTAL

1. Hydrocarbons and Catalysts

Isopropylcyclopropane was prepared by the hydrogenation of isopropenylcyclopropane over a copper chromate catalyst, the product being distilled through a 100-plate column. The purity of the hydrocarbon so obtained was estimated at about 97% on the basis of its refractive index and specific volume: b.p. 58.4° (760 mm); n_D^{20} 1.3859; d_4^{20} 0.6968; aniline point 34.9°. Raman spectrum: *

$\Delta\nu$ (cm^{-1}) 237(2), 260(0), 296(14), 339(17), 440(2), 465(39), 708(12), 737(45), 798(8), 818(16,b), 872(71), 904(18), 922(6), 951(8), 961(2), 991(0), 1014(2), 1041(7), 1065(1), 1096(7), 1123(15), 1135(12), 1161(0), 1174(2), 1193(92), 1209(11), 1219(15), 1284(4), 1311(11), 1331(3), 1372(2), 1387(18), 1427(18), 1453(28,b), 1467(24,b), 2713(30), 2753(5), 2870(130), 2912(65), 2940(30, background), 2959(90), 2990(50,b), 3004(140), 3065(60), 3074(60).

* Laboratory worker V. M. Gorokhova took part in the investigation of the Raman spectra.

Isopropenylcyclopropane, 2-methyl-1-pentene, and 2-methyl-2-pentene were synthesized by the methods described previously [1]. In the same paper the constants and Raman spectra of these compounds were given. The reported constants of isopropenylcyclopropane and the hydrocarbons that can be obtained from it by hydrogenation are given in Table 1.

TABLE 1

Hydrocarbon	B.p. (°C)	n_D^{20}	d_4^{20}
Isopropylcyclopropane [2]	58.37	1.38639	0.69829
Isopropenylcyclopropane [2]	70.33	1.42550	0.75153
2-Methyl-1-pentene [3]	60.7	1.3915	0.6817
2-Methyl-2-pentene [3]	67.29	1.4004	0.6863
3-Methylpentane [3]	60.271	1.37145	0.65315

Platinum Black was prepared by Zelinsky's method [4]. The same batch of catalyst was used in all the experiments.

Palladium Black was prepared from palladous chloride by Zelinsky's method [4].

2. Experimental Procedure

Hydrogenation was carried out in a 100-ml hydrogenation flask of the usual type at 18-20°. In each experiment a fresh 0.4 g portion of catalyst was used, and reaction was with electrolytic hydrogen in 40 ml of distilled ethanol. Catalyst was filtered off, and the hydrogenation product was distilled as an azeotropic mixture with alcohol through a column with a glass packing. It was then washed with water, dried, and fractionated through a 40-plate column with a copper packing. In all these fractionations through a column, 7 ml of heptane (n_D^{20} 1.3877) was added as a displacer.

Isomerization experiments were carried out under the same conditions as the hydrogenation experiments, 20% of the hydrogen theoretically necessary for hydrogenation being added. The catalyzate was isolated in the same way.

3. Description of Experiments

Hydrogenation. Experiment 1. The amount of hydrogen absorbed by 11.5 g (15.4 ml) of isopropenylcyclopropane in presence of 0.4 g of platinum black was 4060 ml (1.3 mol. prop.)* (one molecular proportion of hydrogen would be 3135 ml). The yield of catalyzate was 10.7 g (15.3 ml). The fractionation results are given in Table 2.

Judging from the constants of the fractions given in Table 2, addition of 1.3 molecular proportions of hydrogen to isopropenylcyclopropane gives a mixture of isopropylcyclopropane and 2-methylpentane. The fractions of Experiment 1 were mixed together and the Raman spectrum of the mixture was determined:

$\Delta\nu$ (cm^{-1}) 167(1), 229(2), 279(1), 296(3), 322(1), 339(4), 386(1), 444(2), 464(6), 503(0), 692(1), 708(3) 737(7), 793(2), 815(5), 873(8, sh), 904(3, b), 921(2, background), 952(4), 1010(2,b), 1040(3,b), 1066(1), 1099(3,b), 1123(4,b), 1172(2, diffuse), 1193(9, sh), 1219(3), 1239(2, background), 1290(3,b), 1311(3,b), 1336(2,b), 1367(2), 1388(5, b), 1426(4), 1446(6,b), 1460(6,b).

Experiment 2. The amount of hydrogen absorbed by 22.6 g (30.0 ml) of isopropenylcyclopropane in presence of 0.4 g of platinum black was 4000 ml (0.65 mol. prop.) (one molecular proportion of hydrogen would be 6160 ml). The yield of catalyzate was 21.3 g (30.0 ml). The fractionation results are given in Table 3.

Judging from the data in Table 3, the catalyzate may contain all of the hydrocarbons listed in Table 1. Raman spectra:

* In all experiments the volume of hydrogen is reduced to STP.

Mixture of Fractions I and II:

$\Delta\nu$ (cm^{-1}): 299(5), 341(5), 445(2,b), 467(8,b), 710(4), 739(10,sh), 800(4,sh), 818(5, b), 874(10), 908(4, background), 954(4), 984(1), 1018(½), 1042(4,b), 1068(0), 1094(2, background), 1105(2, background), 1124(4, background), 1164(1), 1175(1), 1194(10), 1212(1, background), 1221(4), 1240(2), 1289(2, background), 1315(5, background), 1336(2,b), 1391(7, sh), 1429(5,sh), 1454(7,b), 1469(7,b), 1653(2,b). [923(3, background), also recorded].

Fraction IV:

$\Delta\nu$ (cm^{-1}): 234(2,b), 267(6,b), 333 (1), 356(1), 394(4), 415(5), 474(9, sh), 485(2), 530(4,b), 656(0), 695(2,b), 713(7,sh), 730(4), 762(0), 794(2,b), 818(5,b), 841 (1), 888(9,b), 901(9, sh), 961(9, sh), 995(4, sh), 1021(4), 1087(4), 1098(4), 1172(2,b), 1193(10,b), 1237(3, v.b.), 1294(5 sh), 1315(0), 1342(2), 1379(4), 1427(6,b), 1461(6,b), 1506(0), 1635(10, sh), 1650(10, sh), 1674(2,b), 1701(0).

TABLE 2

Fraction No.	B.p. (°C)	Amount (g)	n_D^{20}	d_4^{20}	Aniline point (°C)
I	58.3—58.4	1.1	1.3843	0.6820	41.7
II	58.4—58.5	1.9	1.3839	0.6904	—
III	58.5—58.6	3.5	1.3830	0.6890	43.5
IV	58.6—59.2	2.5	1.3815	0.6840	—
V	59.2—59.3	0.7	1.3795	—	53.9
Losses	—	1.0	—	—	—

TABLE 3

Fraction No.	B.p. (°C)	Amount (g)	n_D^{20}	d_4^{20}
I	57.6—57.9	3.6	1.3842	0.6940
II	57.9—58.7	6.6	1.3840	0.6927
III	58.7—68.8	3.7	1.3950	0.6959
IV	68.8—70.1	6.7	1.4240	0.7492
Losses	—	0.7	—	—

Fraction III could not be investigated in detail owing to its powerful fluorescence, but visual examination showed that it contained isopropylcyclopropane, 2-methyl-1-pentene, 2-methyl-2-pentene, and a smaller amount of isopropenylcyclopropane.

Experiment 3. The amount of hydrogen absorbed by 21.4 g (29.0 ml) of isopropenylcyclopropane in presence of 0.4 g of platinum black was 5850 ml (about 1 mol. prop.) (one molecular proportion of hydrogen would be 5835 ml). The yield of catalyzate was 19.1 g (27.5 ml). The fractionation results are given in Table 4.

TABLE 4

Fraction No.	B.p. (°C)	Amount (g)	n_D^{20}	d_4^{20}
I	58.5—59.7	13.5	1.3837	0.6800
II	59.7—70.5	4.6	1.4080	0.7175
Losses	—	1.0	—	—

The results of the fractionation indicate that, as in Experiment 2, a mixture of hydrocarbons was obtained. Raman spectra:

Fraction I

$\Delta\nu$ (cm^{-1}): 296(3), 340(4), 385(0), 444(2), 465(7), 615(0), 654(0), 709(3), 738(9), 800(3), 817(6), 873(10), 886(1), 905(4), 923(2), 953(4), 1016(1,b), 1042(3), 1097(2,b), 1122(4), 1194(10), 1210(2), 1219(4), 1239(1), 1287(2,b), 1314(3), 1336(2,b), 1388(6,sh), 1428(5,sh), 1451(6,b), 1465(6,b), 1652(1).

Fraction II:

$\Delta\nu$ (cm^{-1}): 236(1,b), 267(4,b), 323(0), 340(0), 358(0), 395(2), 414(4), 445(1), 473(6,sh), 487(1, background), 530(2, background), 587(0), 696(1), 714(5), 727(2), 736(2), 798(1), 817(5, b), 873(3), 899(8,v.b.), 952(0), 962(6), 995(2), 1020(4), 1043(2), 1063(2), 1088(2,b), 1103(2,b), 1135(2), 1173(2), 1193(10,b), 1219(1), 1241(1), 1265(1), 1294(4), 1306(1), 1339(1), 1381(5,b), 1391(5,b), 1428(8), 1459(8), 1640(10), 1652(10), 1678(8).

When an attempt was made to hydrogenate isopropylcyclopropane under the same conditions over platinum black and over palladium black, no absorption of hydrogen was observed.

Isomerization. Experiment 1. The amount of hydrogen absorbed by 11.5 g (15.2 ml) of isopropenylcyclopropane in presence of 0.4 g of platinum black was 600 ml (0.2 mol. prop.) (one molecular proportion of hydrogen would be 3135 ml). The catalyzate, amounting to 10.2 g (14.0 ml), had b.p. 65.5-69.5° (754.6 mm); n_D^0 1.4122; d_4^{20} 0.7386. Raman spectrum:

$\Delta\nu$ (cm^{-1}): 234(1,b), 267(6), 297(1), 338(1), 394(4), 415(5), 474(8, sh), 486(3, background), 530(3,b), 696(2), 713(7, sh), 728(4), 738(4), 799(2), 818(5,b), 873(5), 894(9,b), 902(10), 963(8), 995(4,sh), 1020(5), 1047(2), 1087(4), 1100(4), 1172(2), 1193(10), 1221(2), 1237(3,4), 1293(5,sh), 1315(1), 1342(3,b), 1380(1), 1393(6,b), 1428(10), 1461(10), 1504(0), 1638(10,sh), 1651(10,sh), 1673(0-1).

Experiment 2. The amount of hydrogen absorbed by 11.4 g (15.2 ml) of isopropenylcyclopropane in presence of 0.4 g of palladium black was 600 ml (0.2 mol. prop.). The catalyzate, amounting to 10.0 g (13.8 ml), had b.p. 66.5-69.6° (754.6 mm); n_D^{20} 1.4175; d_4^{20} 0.7326. Raman spectrum:

$\Delta\nu$ (cm^{-1}): 205(1), 228(1), 266(6,b), 331(1), 352(1), 394(4), 415(5), 474(7), 486(2), 533(3), 695(3), 713(6, sh), 728(4), 786(2), 798(2), 818(6,b), 836(2,b), 889(3), 898(9, b), 962(7), 994(4), 1020(5), 1045(2), 1061(2), 1088(4), 1104(3), 1170(2, background), 1193(10,b), 1221(2), 1240(9,b), 1293(5), 1307(3, background), 1321(2), 1340(3,b), 1377(3), 1387(5, background), 1428(8,b), 1459(8,b), 1510(0), 1636(10), 1650(10), 1676(6,sh).

Experiment 3. The amount of hydrogen absorbed by 11.02 g (16.0 ml) of 2-methyl-2-pentene in presence of 0.4 g of platinum black was 600 ml, the theoretical amount required for complete hydrogenation being 2930 ml. The catalyzate, amounting to 10.0 g (14.7 ml), had b.p. 62.0-66.2° (743.3 mm); n_D^{20} 1.3945.

Experiment 4. The amount of hydrogen absorbed by 5.2 g (7.5 ml) of 2-methyl-2-pentene in presence of 0.4 g of platinum black was 280 ml, the theoretical amount required for complete hydrogenation being 1380 ml. The catalyzate, amounting to 3.9 g (5.5 ml), had b.p. 60.3-60.7° (747.5 mm); n_D^{20} 1.3862.

The fractionation and Raman-spectrum results obtained in Experiments 3 and 4 show that 2-methyl-1-pentene and 2-methyl-2-pentene do not isomerize into one another under the given conditions.

4. Discussion of the Results of the Analysis of the Raman Spectra

In the analysis of the Raman spectra of the fractions, we made use of the frequencies and intensities for isopropylcyclopropane * given above, those for isopropenylcyclopropane and 2-methylpentenes, which we studied previously [1], and also the data in the literature for 2-methylpentane prepared under conditions similar to ours [5].

* For analysis accurate to within ± 5-10%, an admixture of 2-3% of 2-methylpentane in the isopropylcyclopropane could not have a substantial effect on the results of quantitative analysis.

The determination of 2-methyl-1-pentene in presence of isopropenylcyclopropane presents great difficulties, for when its content is low the only line remaining suitable for photometric estimation is 1651 (76), on which the line 1649 (90) of isopropenylcyclopropane is superimposed. In such a case the 2-methyl-1-pentene content of the fraction can be estimated only very approximately from the increase in the intensity of the line 1649. Most of the intense analytical lines of 2-methylpentane coincide with lines of 2-methylpentenes and cyclopropanes, which makes its determination in mixtures very difficult. For this reason, in all experiments except that on the addition of 1.3 molecular proportion of hydrogen the 2-methylpentane content was determined by difference after the contents of the remaining components had been found. Hence, the analytical results are most reliable for the main components of the fractions – isopropyl- and isopropenyl-cyclopropanes – and also for 2-methyl-2-pentene.

The contents of the individual components of the catalyzates obtained in Experiments 1, 2, and 3 on hydrogenation and Experiments 1 and 2 on isomerization are given in Table 5.

TABLE 5

Catalyst	Amount of hydrogen added (molecules per molecule of hydrocarbon)	B.p. (°C)	Composition of catalyzate (%)					Accounted for (%)
			Isopropenyl-cyclopropane	Isopropyl-cyclopropane	2-Methyl-1-pentene	2-Methyl-2-pentene	2-Methyl-pentane	
Pt	1.3	58.3-59.3	–	70	–	–	30	100

Pt	0.65	57.6-58.7	–	82	3	–	15	100
		58.7-68.8	+	++	++	++	–	–
		68.8-70.1	85	–		5	–	90
Pt	0.2	–	72	25	–	3	–	100
Pd	0.2	–	80	–	–	20	–	100

SUMMARY

1. It was found that, in the hydrogenation of isopropenylcyclopropane in alcoholic solution at room temperature and atmospheric pressure in presence of platinum black, 1.3 molecular proportions of hydrogen are added and a mixture of 70% isopropylcyclopropane and 30% 2-methylpentane is formed.

2. It was shown that the 2-methylpentane present in the catalyzate is formed under these conditions by the hydrogenation of 2-methyl-1-pentene and 2-methyl-2-pentene formed as intermediate products.

3. It was shown that isopropylcyclopropane is not hydrogenated under these conditions.

4. It was found that isomerization of 2-methyl-1-pentene and 2-methyl-2-pentene into one another does not occur in presence of platinum, whereas such isomerization was observed in experiments with palladium black.

INVESTIGATION OF THE COMPOSITION OF THE NAPHTHENE PART OF THE KEROSENE FRACTION OF TUIMAZIN (DEVONIAN) PETROLEUM

A. V. Topchiev, L. M. Rozenberg, M. M Kusakov, and M. V. Shishkina

The investigation of the hydrocarbon composition of sulfur-containing petroleums is associated with considerable difficulties in that the selective removal of sulfur compounds is accompanied by the loss of an appreciable amount of aromatic hydrocarbons [1]. Naphthene hydrocarbons, which form one of the main hydrocarbon components of most petroleums, have not yet received adequate study, particularly for fractions boiling above 150°. The more detailed study of the hydrocarbons of this class is, however, of great scientific and practical importance.

EXPERIMENTAL*

In the present work we studied naphthenes of the decalin and cyclohexane series by the method of analytical dehydrogenation [2] with subsequent isolation and identification of the aromatic hydrocarbons formed. The kerosene fraction (b.p. 180-310°) of Tuimazin (Devonian) petroleum was subjected to dearomatization and simultaneous desulfurization by five successive treatments under cooling with an equal volume of 100% sulfuric acid. The neutralized, washed, and dried product was passed through a column of silica gel (100-150 mesh) in order to remove traces of resinous and sulfur-containing compounds. The dearomatized kerosene was not fractionated into narrow fractions since preliminary experiments had shown that the secondary aromatics isolated from narrow fractions of the dehydrogenation product did not contain condensed aromatic hydrocarbons. The product, now free from aromatics and sulfur compounds, was treated with urea in the way described previously [3] in order to remove paraffins, and it was then subjected to exhaustive dehydrogenation over a platinum-iron catalyst. The properties of the kerosene after successive removals of individual classes of hydrocarbons are given in Table 1.

Part of the dehydrogenation product was fractionated into fractions corresponding in boiling point to naphthalene and its homologs, the possibility of the formation of azeotropic mixtures being taken into account [4]. Preliminary experiments showed that treatment of the narrow fractions of the dehydrogenation product with picric acid did not yield picrates, and the secondary aromatic hydrocarbons separated on silica gel had low refractive indices and densities characteristic for monoalkyl derivatives (Table 2). The data in Tables 1 and 2 enable us to conclude that decalin and its homologs are absent in the kerosene of Tuimazin petroleum. For this reason the further separation of aromatic hydrocarbons from the dehydrogenation product was carried out on the wider kerosene fraction (b.p. 182-310°).

Study of the ultraviolet absorption spectrum of the dehydrogenation product from Tuimazin kerosene showed that it contained some naphthalene hydrocarbons, but their content in the aromatic fractions was very small, varying from 0.01 to 0.001%. This low content of condensed aromatic hydrocarbons lies outside the limits of the picrate method. It is therefore to be recommended that the determination of very small amounts of naphthalene and its homologs in fractions by the picrate method be carried out on the aromatic concentrates.

In the study of the cyclohexane hydrocarbons of the kerosene fractions of Tuimazin petroleum by the methods of dehydrogenational catalysis, it was shown that the analytical dehydrogenation of these fractions was complicated by side reactions, which resulted in the formation of unsaturated compounds and the elimination of methyl groups [5-8]. However, the part played by these reactions was relatively insignificant. The product obtained by the dehydrogenation of a wide kerosene fraction, b.p. 195-300, at 305-310° with a space velocity of 0.5-0.62 hour^{-1} had an iodine value of 6-7. In order to determine the effect of the space velocity on the extent to which

*Senior laboratory workers I. S. Genekh and P. A. Nikitina took part in the experimental work.

TABLE 1

Properties of Kerosene at Different Stages of its Investigation

side reactions occurred, the wide kerosene fraction was dehydrogenated at various space velocities: 1.0, 0.75, 0.65, and 0.50 hour^{-1}. The results showed that, irrespective of space velocity, the dehydrogenation product contained unsaturated compounds and the gas contained methane hydrocarbons.

The kerosene fractions are more complex in chemical composition than the gasoline fractions and their dehydrogenation proceeds with greater difficulty. Even after being passed repeatedly over the catalyst at a space velocity of 0.9-1.0 hour^{-1}, the kerosene fractions were only slightly dehydrogenated. Under these conditions a considerable change was generally observed in the temperature conditions in the reaction zone, so that the initial temperature had to be 30-35° higher than usual. The product obtained before stationary temperature conditions were established (305-310°) was disregarded, and after that the dehydrogenation product was collected.

The presence of unsaturated compounds in the dehydrogenation product and of methane hydrocarbons in the gas (Table 3) shows that the dehydrogenation of Tuimazin kerosene over a platinum-iron catalyst is complicated by destructive side reactions that are independent of space velocity.

It follows from the data presented in Table 3 that the contents of methane hydrocarbons in the gas and the iodine values of the dehydrogenation products are almost constant. The maximum content of aromatic hydrocarbons in the dehydrogenation product was obtained at a space velocity of 0.65 hour^{-1}. For the preparation of the fractions for investigation, the product, freed from aromatic hydrocarbons and normal paraffins, was subjected to exhaustive dehydrogenation at a space velocity of 0.65 hour^{-1} under the conditions described above. Two dehydrogenation treatments on 1500 g of product gave 1440 g of the dehydrogenation product (96% yield, 4% loss). The dehydrogenation product had the following properties: d_4^{20} 0.8095; n_D^{20} 1.4524; iodine value 5.7; content of sulfonatables 16.0%; content of aromatics 12.7%.

TABLE 3

Effect of Space Velocity on the Formation of Unsaturated and Methane Hydrocarbons

Space velocity ($hour^{-1}$)	n_D^{20}	Iodine value	Content of aromatic hydrocarbons (%)	Analysis of gas	
				H_2 %	C_nH_{2n+2}
1.00	1.4491	6.8	6.3	96.0	4.0
0.75	1.4497	8.0	8.0	—	—
0.65	1.4510	6.5	10.0	95.5	4.5
0.50	1.4512	6.6	—	94.0	6.0

Chromatography of the dehydrogenation product was carried out in a column of ASM silica gel (Voskresensk Chemical Combine; 100-150 mesh; activity to benzene 14) by the method described previously [9]. The intermediate fraction, separated on silica gel after the petroleum ether distillate, had an iodine value of 75 and was studied in detail. Only secondary aromatic hydrocarbons were investigated. Our previous investigations have shown that aromatic hydrocarbons boiling over a very narrow range (1-3°) can be multicomponent mixtures which give several fractions with different refractive indices when subjected to chromatography on silica gel. For the separation of these aromatic hydrocarbons advantage was taken of the fact that each type of these hydrocarbons has its own characteristic range of refractive indices. By repeated fractionation on silica gel a series of fractions was obtained in narrow ranges of refractive indices; the properties of these fractions are given in Table 4. The further separation of each of these fractions according to boiling point was not practicable owing to their small amounts. The densities and refractive indices of the first ten fractions (Table 4) are very close to the corresponding values given in the literature for alkyl derivatives of benzene [10]. Apart from polyalkylbenzenes, the other fractions probably contain more complex structures, as indicated by their higher densities and refractive indices. It should be noted that, on standing, the fraction of b.p. 292-302° (n_D^{20} 1.5279) gave a small amount of crystalline precipitate, which we did not succeed in extracting from the thick mass for identification. When this fraction was cooled strongly, no increase in the amount of the solid was observed. A chloroform solution of the crystalline product was treated with benzaldehyde in presence of sulfuric acid and gave first a green, and then a stable reddish-violet, coloration, characteristic for acenaphthene [11]. In order to study the ultraviolet absorption spectrum of this fraction, a solution was prepared in isooctane in which the crystals dissolved and the thick yellow mass remained insoluble. A well defined absorption spectrum, identical with that of pure acenaphthene, was obtained (Fig. 1; the spectrum of acenaphthene was determined previously on the same spectrograph under the same conditions). The identification of the aromatic hydrocarbons formed after the dehydrogenation of Tuimazin kerosene by chemical methods was not carried out owing to the small amount of product and its complex composition (Table 4).

The investigation of the compositions of the types of secondary aromatic hydrocarbons was carried out with the aid of ultraviolet absorption spectra. The absorption spectra of aromatic fractions in the near ultraviolet were determined by the method of photographic photometry. The spectra were photographed on a medium quartz spectrograph. The weakening of the light passing through the solution was carried out with the aid of a rotating sector. The absorption spectra of the first six fractions of secondary aromatic hydrocarbons from Tuimazin kerosene showed a close resemblance, both with respect to the position of the bands and with respect to their relative intensities (Fig. 2). Since the differences in the spectra of the first three fractions were within the limits of error of measurement, the absorption spectra of Fractions I-III are represented by a single curve in Fig. 2. The most intense maxima are at wavelengths of 2650 and 2685 A; notable maxima occur at 2600, 2620, and 2730 A; also, at 2780 A is a point of inflection (shoulder) that is characteristic for all five absorption spectra. The positions and forms of the absorption bands indicate that the fractions are substituted benzenes.

The absorption spectra of subsequent fractions are similar in form to those of the first six fractions. From Fraction I onwards, the absorption spectra were calculated with the aid of characteristic curves (without taking account of the contrast factor for different parts of the spectrum). This method of calculation somewhat modified

the form of the absorption curve. The absorption spectra of Fractions VII and VIII have in general the same peculiar features as those observed in the spectra of the preceding fractions (Fig. 3).

Comparison of the absorption spectra of eight fractions of Tuimazin kerosene with the spectra of pure alkylbenzenes showed that these fractions contained alkylbenzenes in which the substituents occupied different positions. In order to determine the presence of one or other type of alkylbenzene, not only were the positions of the maxima and their relative heights taken into account, but also the absolute values of the absorption coefficients for each type of alkylbenzene. It is known [12] that monoalkylbenzenes have the lowest absorption coefficients, o- and m-dialkylbenzenes have somewhat higher values, and p-di-, 1,2,4-tri-, and 1,2,4,5-tetra-alkylbenzenes have extremely high absorption coefficients; 1,2,3-tri-, 1,3,5-tri-, 1,2,3,4-tetra-, 1,2,3,5-tetra-, penta-, and hexa-alkylbenzenes have absorption coefficients of the same order as the o- and m-dialkylbenzenes. In the paper [13], which is devoted to an investigation of polyalkylbenzenes containing 9-10 carbon atoms, data are given on the ultraviolet absorption spectra of 15 pure alkylbenzenes boiling in the range 150-180°. The absorption spectra of these hydrocarbons are classified according to types: Type A, monosubstituted; Type B, m- and o-di- and 1,2,3- and 1,3,5-tri-substituted; Type C, p-disubstituted and 1,2,4-trimethylbenzene. Each of these types is characterized not only by the constancy of the positions of the principal absorption maxima, but also by close mean values of the absorption coefficients for all absorption bands.

In order to interpret the absorption spectra of fractions of secondary Tuimazin aromatic hydrocarbons, use was made of the data in the paper [13] and data in the literature on the absorption spectra of alkylbenzenes boiling in the range 100-300° [12,14-20]. It was found that the positions of the absorption maxima and mean values of ε_λ for alkylbenzenes boiling in the range 100-300° are constant, so that the mean "type" absorption spectra established in the paper [13] may be used to establish the main types of substitution of the alkylbenzenes in the fractions boiling in the range 200-300°. The problem of determining the relative amounts of the various types of alkylbenzenes in the kerosene fractions investigated is at present insoluble, since the available data on the absorption spectra of the individual aromatic hydrocarbons are extremely incomplete and have been obtained with various types of apparatus.

The ultraviolet absorption spectra of fractions of the dehydrogenation product of Tuimazin kerosene indicates the presence of the following benzene homologs:

1) monoalkylbenzenes, mainly having branched alkyl chains (maximum 2600 A, shoulder 2540-2550 A);

2) p- and m-dialkylbenzenes (maxima 2600, 2650, 2680, and 2730 A);

Fig. 1. Absorption spectra: 1) pure acenaphthene; 2) acenaphthene fraction.

3) 1,3,5-trialkylbenzenes (maxima 2625, 2650, 2680 A);

4) 1,2,3,5- and 1,2,3,4-tetraalkylbenzenes (maxima 2680, 2730, 2770 A and 2650, 2680, 2735, 2780 A, respectively).

From the absorption spectra none of the following were detected in the fractions of secondary Tuimazin aromatics: o-dialkylbenzenes, 1,2,4- and 1,2,3-trialkylbenzenes, 1,2,4,5-tetramethylbenzene, pentamethylbenzene, and hexamethylbenzene.

Some fractions (II-V, VII-X), which were available in amounts of 6-8 ml, were investigated with the aid of Raman spectra. As a rule, the higher gasoline fractions are already becoming difficult to investigate by means of Raman spectra owing to their bright fluorescence. However, the Raman spectra of the kerosene fractions had an insignificant background, so that up to 30-40 lines could be measured in their spectra. It is possible that repeated passage of the product through silica gel had freed it from the impurities causing the fluorescence.

Fig. 2. Absorption spectra: 1) Fraction VI; 2) Fraction IV; 3) Fractions I-III.

The Raman spectra of all the investigated fractions contained lines of the same frequencies and similar intensities, which indicates the closeness of the fractions in composition (Table 5). Analysis of the Raman spectra showed that the fractions of secondary Tuimazin aromatic hydrocarbons contained a small amount of monoalkylbenzenes, some m- and p-dialkylbenzenes, and some polyalkylbenzenes. No. 1, 2,3-trialkylbenzenes were detected by the Raman spectra, and no o-dialkylbenzenes could be found. Hence, the conclusions derived from absorption spectra concerning the principal types of alkylbenzenes present in the fractions of secondary aromatic hydrocarbons are in close accord with those derived from the Raman spectra.

Note: The exciting radiation was the mercury line 4358 A (blue). Intensities were estimated visually and are given in parentheses. sh denotes "sharp", df "diffuse", b "broad", and db "double". In the comparison spectra, the roman numerals in parentheses indicate intensity. The characteristic Raman lines are taken from the paper [22], in which they are represented diagrammatically. The heights of the lines in the spectrum of an individual type of molecule indicate approximate relative intensities. The most intense line in each given spectrum is indicated by the numeral I, a less intense line by II, and so forth. Intensities denoted by the same numerals in different spectra are not comparable. For 1,2,4,5-tetramethylbenzene and all succeeding pure hydrocarbons, intensities are given on a 10-degree visual scale. No lines for 1,2,3-trisubstituted benzenes are found in the spectrum (the line 1600 cm^{-1} is absent). Lines indicated by an asterisk can be explained as Raman lines 2650-3060 cm^{-1} due to violet excitation.

The absorption spectrum of Fraction IX (Fig. 3) has anomalously high absorption coefficients, and the positions of the principal maxima are somewhat different than those for the preceding fractions, which cannot be explained by superposition of the absorption spectra of different alkylbenzenes. In order to determine whether naphthalene and its homologs were present in this fraction, its absorption spectrum was determined in the long-wave region (3000-3300 A) at a concentration of 0.7% by weight. Four absorption maxima were found in the region 3100-3250 A: 3140, 3190, 3220, and 3242 A. Exactly the same maxima were found in the spectra of Fractions X-XIII at concentrations of 0.6% and in the spectra of Fractions XIV-XVII at concentrations of 0.06%. The absorption spectra of Fractions XV and XVII are given in Fig. 4. The observed absorption maxima indicate that the naphthalene homologs detected in these fractions of the dehydrogenation product from Tuimazin kerosene are very close in composition.

By comparing the observed absorption maxima (Fig. 4) with the absorption spectra of individual naphthalene derivatives [21], we found that the Tuimazin secondary aromatic hydrocarbons very probably include 1,6-, 1,7- and 2,6-dimethylnaphthalenes and 1,3,5-trimethylnaphthalene; the possibility is not excluded that 2-methylnaphthalene and 1,2- and 1,3-dimethylnaphthalenes may be present in these fractions. It can be said with certainty that 1,4-, 1,5-, 1,8-, 2,3-, and 2,7-dimethylnaphthalenes are absent in the fractions investigated. The absorption spectrum of Fraction XII differs somewhat from the absorption spectra of the other fractions containing naphthalenes. It may be expected that 1,3,7- and 1,2,5-trimethylnaphthalenes will be present in this fraction. The absorption spectra enable us to make an approximate estimate of the amounts of naphthalenes in the fractions investigated, namely, 0.001% for Fractions IX-XII and 0.01% for Fractions XV-XVII.

The repeated separation of the aromatic hydrocarbons on silica gel ensured that fractions were obtained in narrow ranges of refractive index, and to a considerable extent it concentrated them into types. This facilitated their investigation by means of absorption spectra and enabled us to obtain satisfactory Raman spectra. It is very desirable that in future work separation according to boiling point should be performed on fractions selected according to refractive index.

SUMMARY

1. As it is found that, under the given dehydrogenation conditions, cyclohexane hydrocarbons apparently undergo no appreciable change in structure, it may be considered that the aromatic hydrocarbons obtained correspond to the naphthene hydrocarbons.

2. An investigation by means of ultraviolet absorption spectra of the aromatic hydrocarbons isolated from the dehydrogenation product from the kerosene of Tuimazin (Devonian) petroleum showed that this kerosene contains:

a) alkyl derivatives of cyclohexane, including branched-chain monoalkyl derivatives, p- and m-dialkylcyclohexanes, 1,3,5- and 1,2,4-trialkyl derivatives, and tetraalkyl derivatives, mainly 1,2,3,4 and 1,2,3,5; the possibility of the presence of penta- and hexa-methylcyclohexanes cannot be excluded;

b) hydrogenated acenaphthene (found in Tuimazin petroleum for the first time);

c) decalin and its homologs (about 1% on the total amount of the fractions).

3. No bicyclohexyl and its homologs were detected in the kerosene of Tuimazin petroleum.

COPOLYMERIZATION OF DIENIC HYDROCARBONS WITH VINYL ETHERS

COMMUNICATION 1. PECULIAR FEATURES OF THE COPOLYMERIZATION OF CHLOROPRENE WITH VINYL ETHERS

S. P. Mitsengendler, V. N. Krasulina, and L. B. Trukhmanova

In each of the systems investigated, the component monomers stand at opposite ends of the average-activity series [1]. Chloroprene is the most active of all known monomers: its rate of polymerization is about one thousand times as high as the rates for butadiene and isoprene [2]. This great difference in rate of polymerization and the exceptional tendency for exclusive 1,4-addition to occur are to be attributed to strong polarization of the C=C bonds of the monomer under the action of the chlorine atom. In fact, of all known dienic hydrocarbons and halo hydrocarbons, chloroprene has the highest dipole moment. Chloroprene (M_2) actively copolymerizes both with monomers containing positive substituents (styrene, vinyl ethers) [3,4], and also with monomers containing negative substituents (acrylates) (M_1) [5]. In all cases, chloroprene, being the most active component, predominates in the copolymer, and the copolymers are definitely non-alternating in structure ($r_1 > 1$; $r_2 < 1$). On the other hand, under conditions under which copolymerization proceeds by a cationic mechanism (in presence of Friedel-Crafts catalysts), chloroprene is a component of low activity and makes an insignificant contribution to the copolymer [6].

Alkyl vinyl ethers stand together with vinyl esters in the last group of the average-activity series [1]. In contrast with vinyl esters, the main peculiarity of vinyl ethers is the absence of any tendency to polymerize by the radical mechanism. However, presence of a negative C=C bond tends to cause active copolymerization with monomers containing a positive C=C bond (acrylates, maleic anhydride, acrylonitrile) [7,8]. If there is no polar effect in a system containing alkyl vinyl ethers, copolymerization proceeds extremely slowly, forming products of low weight. It is known that alkyl vinyl ethers can act as polymerization controllers [1,8].

Another important peculiarity of alkyl vinyl ethers is their ability to polymerize very rapidly in presence of traces of hydrogen halide, halides, and catalysts of the Friedel-Crafts type. In a series of investigations, Shostakovsky [9] showed that the polymerization of alkyl vinyl ethers in presence of acids proceeds under the influence of an active molecule that is formed, and a proton-catalyzed process occurs as follows:

The present investigation had the object of studying the effect of chloroprene on the behavior of vinyl ethers under the conditions of radical copolymerization.

EXPERIMENTAL

Chloroprene, prepared in the laboratory, was dried with calcium chloride and distilled through a 1-meter column; b.p. 59.4°. The alkyl vinyl ethers were purified in the usual way [9]; the boiling point of isopropyl vinyl ether was 58.5°. Emulsion copolymerization was carried out at 40° [2] and at from −2 to −5°, using an oxidation-reduction system containing ferrous sulfate, glucose, and pyrophosphate [10]. Homogeneous copolymerization was carried out at 65° in presence of benzoyl peroxide and 2,2'-azobis[2-methylpropionitrile]. The polymerization product was a white mass and was extremely heterogeneous in composition and properties. The product was fractionated by gradual addition of three parts of acetone to one part of a 3-5% benzene solution, and then further gradual addition of methanol. The widest fraction was separated by direct addition of a threefold amount of methanol (Fraction I). In the course of a day a liquid layer separated from the residual solution. After being separated from the solvent and dried, this product was found to be a white elastic macromolecular substance, which contained up to 93-98% of the ether (Fraction II). After the separation of Fraction II, a greasy product containing 0.5-2% of chloroprene (Fraction III) remained in solution. All the fractions were reprecipitated three times, and, after being dried at room temperature in a vacuum, they were analyzed for chlorine content by the Carius method. In special cases the products were fractionated. The molecular weights of the separate fractions were determined with an osmometer.

I. Low-temperature Emulsion Copolymerization

An investigation of the emulsion copolymerization of chloroprene and isopropyl vinyl ether (Table 1) showed that chloroprene copolymerizes very rapidly with vinyl ethers and predominates in the copolymer, which is in accord with the values of the copolymerization constants r_1 and r_2 for this system. As required by modern theory, the compositions of the copolymers vary little with the copolymerization temperature (by about 2%) (Table 2).

TABLE 1

Composition of Copolymers Obtained in the Oxidation-Reduction System at −2°

Composition of original mixture (mole %)		Duration of polymerization (hours)	Yield of copolymer (%)	Composition of copolymer (mole %)	
Chloroprene	Ether			Chloroprene	Ether
50	50	3.0	17.5	94.5	5.5
50	50	17.0	47.4	94.4	5.6
66	34	19.0	67.3	96.3	3.7
75	25	4.5	13.0	96.2	3.8

TABLE 2

Effect of Temperature on the Compositions of Copolymers Obtained by the Emulsion Method.

Composition of original mixture (mole %)		Temperature (°C)	Yield of copolymer (%)	Composition of copolymer (mole %)	
Chloroprene	Ether			Chloroprene	Ether
50	50	40	40.0	96.5	3.5
50	50	40	35.0	96.4	3.6
50	50	−2	47.4	94.4	5.6

Owing to the instability of vinyl ethers in alkaline* and in particularly acid media, it was impossible to carry out investigations at ether concentrations of above 50%, even at low temperature.

* According to data in the literature [2], the pH of the aqueous phase is always lower by 2-3 units after the reaction owing to the elimination of a very small amount of hydrogen chloride.

II. Homogeneous Copolymerization

1. Anomaly observed in the mass copolymerization of chloroprene with alkyl vinyl ethers. The first experiments on the mass copolymerization of chloroprene with isopropyl vinyl ether and with ethyl vinyl ether showed that, unlike emulsion copolymerization, this process does not proceed by a radical mechanism. For almost any proportions of the components, the inactive ether monomer predominates over the active chloroprene monomer in the copolymer. For example, for equimolecular proportions of monomers, the chloroprene content of the copolymer is 22-36%, as against 95% for emulsion copolymerization (Table 3).

TABLE 3

Homogeneous Copolymerization of Chloroprene and Isopropyl Vinyl Ether at 65°.

Composition of original mixture (mole %)		Time (hours)	Yield (% by weight)	Mean composition of copolymer (mole%)	
Chloroprene	Ether			Chloroprene	Ether
9	91	24.0	63.5	11.4	88.6
20	80	–	20.0	20.3	79.7
34	66	2.0	57.0	8.8	91.2
50	50	2.0	25.5	21.8	78.2
50	50	12.0	41.2	36.0	64.0
66	34	2.0	25.1	32.3	67.7

In contrast to the case of radical copolymerization, the compositions of the copolymers were extremely unstable and changed according to the polymerization conditions. For example, presence of air in the system resulted in an increased content of the ether in the copolymer. On the other hand, polymerization in a nitrogen atmosphere increased the chloroprene content. A similar change in the composition of the product occurred when benzoyl peroxide was replaced by 2,2'-azobis[2-methylpropionitrile], which gives nitrogen when it decomposes (Table 4).

2. Formation of an "azeotropic" mixture. The course of the process is very interesting when the molar ratio of ether to chloroprene is 4:1. Under these conditions the composition of the product is identical with that of the original mixture at all stages of the transformation, i.e. the components are used up in a uniform manner during the process and an "azeotropic" copolymer formed. At a higher ether concentration, e.g. at a molar ratio of ether to chloroprene of 9:1, the composition of the product is fairly close to that of original mixture. "Azeotrope" formation occurs also in the case of ethyl vinyl ether (Table 5).

3. Comparison of composition curves for radical and cationic copolymerization. Fig. 1 illustrates the different mechanisms of the processes occurring in emulsion and in mass copolymerization of chloroprene with isopropyl vinyl ether. Fig. 2 illustrates the results of Foster [6] on the radical and cationic copolymerization of chloroprene with styrene. For this system the chloroprene content is 88% in the case of radical copolymerization and 7% in the case of cationic copolymerization. As already pointed out, in processes proceeding by the cationic mechanism, chloroprene is extremely inactive as compared with monomers containing electropositive substituents. Comparison of Figures 1 and 2 indicates similar courses for the composition curves of the systems chloroprene-styrene and chloroprene-isopropyl vinyl ether. We may thus conclude that the anomaly observed in the compositions of copolymers obtained by mass copolymerization in presence of benzoyl peroxide is associated with the occurrence of the process by a cationic mechanism (characteristic for catalysts of the Friedel-Crafts type, some cation-forming substances, and also hydrogen acids).

4. Possibility of cationic copolymerization under the conditions of our investigation. Williams and Walker [11] showed that traces of water remain in chloroprene dried with calcium chloride, and these, and also air, have an effect on the polymerization of the chloroprene. The chloroprene that we used was dried with calcium chloride and undoubtedly contained traces of moisture, which, by reaction with the chloroprene, gave rise to the hydrogen chloride referred to above. As is well known, alkyl vinyl ethers polymerize very rapidly in presence of traces of hydrogen chloride. According to Shostakovsky's scheme, the initial polymerization centers are positively charged molecules of the ether. From Foster's data, given above, it is seen that chloroprene is also able to add to a chain that terminates with a carbonium ion, though to a considerably lower extent. These data from the literature enable us to explain the possibility of cationic copolymerization under the conditions of our investigation.

TABLE 4

Effect of Copolymerization Conditions on the Composition of the Copolymer Obtained (molar ratio of chloroprene to ether of 1:1).

Duration of polymerization (hours)	Yield %	Initiator	Atmosphere	Mean composition of copolymer %		Fraction I		Fraction II		Fraction III	
				Chloroprene	Ether	Yield (%)	Amount of chloroprene (%)	Yield (%)	Amount of chloroprene (%)	Yield (%)	Amount of chloroprene (%)
12	41.2	Benzoyl peroxide	Air	36.0	64.0	15.8	89.7	16.2	2.1	9.2	2.9
2	25.5	Benzoyl peroxide	Air	22.0	78.0	8.2	65.5	8.8	1.3	8.5	1.6
2	38.7	2,2'-Azobis[2-methylpropionitrile]	Air	67.0	33.0	25.4	96.0	4.2	8.5	7.2	5.0
33.0	26.8	Benzoyl peroxide	Nitrogen	50.6	49.4	15.4	88.6	8.6	2.0	2.8	2.0
10.5	12.5	Benzoyl peroxide	Nitrogen	38.3	61.7	5.7	81.6	6.8	1.8	---	---

TABLE 5

Constancy of the Composition of the Copolymer for Varying Progress of Reaction for the Case of an "Azeotropic" Original Mixture

Ether	Chloroprene content (mole %)		Yield of product (%)	Note
	of original mixture	of product		
Isopropyl vinyl	20	20.3	20	The experiments were carried out at 60° in presence of benzoyl peroxide
	20	19.6	39	
	20	17.8	85	
Ethyl vinyl	9	9.5	20	
	9	9.7	22	
	20	19.0	15	

5. Fractionation of the copolymerization products. Fractionation of the copolymers showed that they are mixtures of copolymers differing greatly both in composition and in properties and therefore readily separated from one another (Table 4). For equimolecular proportions of the components, one copolymer (Fraction I) corresponds both in composition and in properties to the product of radical copolymerization. The average chloroprene content of this fraction is 65-90%; the copolymer is not soluble in acetone. The second copolymer – the main product – corresponds in composition and properties to the product of cationic copolymerization. The chloroprene content is 1-2%, and the copolymer is readily soluble in acetone (Fractions II and III). The fractionation of the "azeotropic" copolymer is of very great interest: its overall composition is the same as that of the original mixture for all values of the progress of reaction (Table 6).

The copolymer was fractionated into ten fractions (Table 6 and Fig. 3). It was found that the fractionation curve for this "azeotrope" was again typical for a mixture of copolymers varying greatly in composition. The curve for the composition of (I) is typical for a copolymer of a radical type, and the curve for the composition of (II) is typical for a copolymer of a cationic type. The peculiar feature of this process of dual copolymerization is that the component that is inactive for one process is extremely active for the other. This relationship between

Fig. 1. Composition curves for copolymers obtained: I) in an emulsion; II) in the mass.

Fig. 2. Composition curves for chloroprene-styrene copolymers (according to Foster): 1) radical copolymerization ($r_1 = 6.3$; $r_2 = 0.005$); 2) cationic copolymerization ($r_1 = 0.24$; $r_2 = 15.6$).

TABLE 6

Fractionation of the "Azeotropic" Copolymer with a Mean Composition of 19.6% of Chloroprene and 80.4% of the Ether.

Fraction	Content of fraction (mole %)	Composition of Fraction		Molecular weight
		chloroprene	Ether	
I	9.05	98.5	1.5	60 000
II	0.67	95.6	4.4	
III	0.73	93.0	7.0	
IV	2.40	74.5	25.5	45 000
V	4.60	69.4	30.6	
VI	1 80	60.5	39.5	
VII	7.60	5.0	95.0	90 000
VIII	34.90	6.2	93.8	
IX	19.20	2.0	98.0	60 000
X	19.25	0.5	99.5	Fluid low-molecular-weight product

the two parallel processes means that, for each of these processes, the concentration of the active component in the original mixture is initially at a minimum and increases during the process.

It may be considered therefore that the minimum chloroprene content on the composition curve for copolymer (I) corresponds to the initial composition of the radical copolymer (I). This composition corresponds to the values obtained for the constants r_1 and r_2 for the radical copolymerization of the system: $r_1 = 0.164$; $r_2 = 11.45$ (Table 7). The minimum content of the ether on the composition curve for the copolymer (II) will probably correspond to the initial composition of the copolymer (II) (these points are marked in Fig. 3 as I_0 and II_0).

Fig. 3. Variation in composition of fractions during precipitation.

The increase in the consumption of the ether in the course of the process due to the formation of the copolymer (II) is apparently counterbalanced by the reduction in the consumption of the ether due to the formation of the copolymer (I). This is the explanation of the uniform overall consumption of monomers during the process when the original mixture is "azeotropic".

Hence, the term "azeotrope" refers not to the separate copolymers (I) and (III), but to the overall product. The formation of an "azeotropic" copolymer indicates that both processes proceed simultaneously. The simultaneous occurrence of parallel processes is indicated also by the simultaneous variation of the contents of Fractions I, II, and III with increase in the progress of reaction (Table 4).

Table 8 gives data on the fractionation of a copolymer prepared from an original mixture of 91 moles % of the ether and 9 moles % of chloroprene (close to the "azeotropic" mixture).

Fraction III corresponds to the initial composition of the radical copolymer, in accord with the values of the copolymerization contants r_1 and r_2 (Table 7). With increase in the progress of reaction, the radical copolymer becomes enriched in chloroprene (to above 90%) owing to the enrichment of the original mixture in chloroprene, which is again the result of simultaneous cationic copolymerization in which the ether is the main component consumed.

TABLE 7

Experimental Data for the Calculation of r_1 and r_2 for the System at 80° in Presence of 2,2'-Azobis[2-methylpropionitrile] as Initiator.

Experiment	Initial composition of the reaction mixture (mole %)		Yield of copolymer (%)	Chloroprene content of copolymer (mole %)	Final composition of reaction mixture (mole %)	
	Chloroprene M_2^0	Ether M_1^0			Chloroprene M_2	Ether M_1

IV	"	55.0	2.0	98.0
V	"	24.0	0.5	99.5

Direct Proof of the Simultaneous Occurrence of the Radical and Cationic Mechanisms of Copolymerization

If radical and cationic copolymerization really do take place simultaneously under the conditions of our investigation, then we may direct the process in the desired direction by inhibiting one of the processes. Actually,

when 1% of an inhibitor for radical copolymerization (quinone) was added to a reaction mixture prepared from equimolecular amounts of monomers, then, as in the cationic copolymerization of chloroprene with styrene, a product typical for the cationic mechanism was obtained; the average percentage of chloroprene was 7-12, depending on the progress of reaction (Experiments 2 and 3, Table 9).

TABLE 9

Change in the Direction of the Process, as Affected by the Nature of the Added Inhibitor

Ampoule	Addition of quinone	Addition of alcohol	Duration of polymerization (hours)	Yield of copolymer (%)	Mean composition of copolymer (moles %)	
					Chloroprene	Ether
1	–	–	12.0	41.2	36.0	64.0
2	+	–	15.5	46.2	7.6	92.4
3	+	–	24.0	50.0	12.4	87.6
4*	–	+	6.5	16.8	98.5	1.5
5**	–	+	6.5	32.5	98.3	1.7

* Initiator – 2,2'-azobis[2-methylpropionitrile]; temperature – 80°.

** Emulsion copolymerization.

Fig. 4. Dependence of the change of the direction of the process on the nature of the added inhibitor: 1) addition of alcohol (inhibitor for cationic copolymerization); 2) no addition; 3) addition of quinone (inhibitor for radical copolymerization).

When about 10% of inhibitor for cationic copolymerization of alkyl vinyl ethers (alcohol) was added, a copolymer typical for the radical mechanism was obtained, as in emulsion copolymerization (Experiments 4 and 5, Table 9; Fig. 4). This complex process can therefore be controlled so as to obtain macromolecular products enriched with respect to the ether or with respect to chloroprene.

Effect of Chloroprene Units (M_2) on the Activity of the Polymeric Radical of Isopropyl Vinyl Ether (M_1)

A basic assumption of the modern theory of copolymerization is that the activity of the polymeric radical depends only on the structure of the last monomer unit and not on the remaining units in the chain. However, various observations on the hundreds of systems already investigated have indicated that the other units of the chain, particularly the penultimate unit, also have an effect [12-15]. This effect is particularly notable when a monomer containing polar groups is present.

Much earlier, in an investigation of the copolymerization of vinyl acetate (M_1) with maleic anhydride and its derivatives [12-13], one of us showed that the polar monomer unit of vinyl acetate (M_1) affected the activity of the polymeric radical (M_2) and its participation in the formation of the M_2-M_2 link in the copolymer chain. In the radical copolymerization of chloroprene with isopropyl vinyl ether in presence of alcohol we observed an analogous phenomenon: The process is not described by the equation

$$\frac{dM_1}{dM_2} = 1 + \frac{1}{r_2} \cdot \frac{M_1}{M_2}$$

which is for the particular case when $K_{M_1M_1}\delta = 0$, but is described by the equation for the general case with participation of four elementary reactions:

$$\frac{dM_1}{dM_2} = \frac{M_1}{M_2} \cdot \frac{r_1 M_1 + M_2}{r_2 M_2 + M_1}.$$

The values that we obtained for the copolymerization constants – $r_1 = 0.164 \pm 0.043$ and $r_2 = 11.45 \pm 0.54$ – indicate the considerable activity of the radical (M^0_1), which stands in contrast with its behavior with other monomers. As is well known, in all previously investigated systems in which an alkyl vinyl ether (M_1) takes part, the constant r_1 is zero. In accordance with our calculated values of the constants of the system, it is possible to obtain copolymers containing more than 50% of ether monomer units * (Table 7). It is probable that such a change in the properties of alkyl vinyl ethers is to be attributed to the presence of the strongly polarized chloroprene molecule.

Principal Properties of the New Copolymers Obtained

The copolymers – both those produced by radical copolymerization and those produced by cationic copolymerization – are white elastic substances having molecular weights of 60,000-90,000. An exception is formed by the last low-molecular-weight fraction, which is isolated after removal of solvent; it contains 99.0-99.5% of ether units and 0.5-1% of chloroprene units. Copolymers of both types, when they contain 80-90% of chloroprene in the one case and when they contain 2-6% in the other case, lose their elasticity in the course of time. When they are heated, the elasticity is restored. This is probably to be related to the readiness with which crystallization occurs with formation of a regular structure [16], as in the case of polychloroprene itself. The products of cationic copolymerization are particularly interesting. The presence of 2% of chloroprene units in the polyether chain gives macromolecular elastic products that differ sharply from the products of the polymerization of the alkyl vinyl ether alone, which are fluid substances of low molecular weight [17]. Preliminary determinations of the physicomechanical properties shows that these copolymers are highly elastic rubbers of good stability to oil, but their mechanical strength is extremely low.

SUMMARY

1. An investigation was made of the emulsion and mass copolymerization of chloroprene with isopropyl vinyl ether at various temperatures.

2. In presence of initiators for radical copolymerization, two mechanisms operate simultaneously: a) copolymerization by the radical mechanism, and b) copolymerization by the cationic mechanism.

3. The relative amounts of copolymers of the radical and cationic types are considerably dependent on the polymerization conditions. Under all conditions the copolymer of the cationic type predominates.

4. Conditions were found which make it possible for the process to be directed in a single direction with formation of copolymers containing up to 95-98% of the vinyl ether (molecular weight 60,000-90,000) or 80-90% of chloroprene (molecular weight 60,000).

5. The radical-copolymerization constants of the system were determined: $r_1 = 0.164 \pm 0.043$; $r_2 = 11.45 \pm 0.54$. The existence of two constants is explained as the result of the effect of the penultimate monomer unit (M_2).

6. The emulsion copolymers corresponded in composition to a mechanism of radical copolymerization.

OPTICAL METHOD OF INVESTIGATING HYDROCARBONS

COMMUNICATION 9.* RAMAN SPECTRA OF SOME NAPHTHENES

P. A. Bazhulin, A. I. Sokolovskaya, N. A. Belikova

A. L. Liberman, and A. F. Plate

In the present communication we present some new data on the Raman spectra of five naphthene hydrocarbons and one aromatic hydrocarbon. Most of these hydrocarbons are difficult to synthesize.

EXPERIMENTAL RESULTS

All the measurements were carried out on an ISP-51 spectrograph with a camera of f = 270 mm. The procedure for the determination of frequencies and intensities was the same as in the preceding papers [1-7].

We give the data on the frequencies and intensities for the six hydrocarbons below. For each hydrocarbon the method of preparation is outlined and its principal constants (boiling point, density, and refractive index) are given. All data on intensities in this communication are expressed on a scale somewhat improved in accuracy [8]. Abbreviations for characteristics of the lines are: b (broad), sh (sharp), bk (line is on background of considerable intensity), db (doublet), (?) (line may be repeat from another exciting frequency).

cis-1-Butyl-2-methylcyclopentane. This was synthesized together with the trans isomer by reaction of 2-methylcyclopentanone with butylmagnesium bromide, dehydration of the alcohol formed, and hydrogenation of the resulting butylmethylcyclopentene in the cold in presence of platinized charcoal activated with palladous chloride. After purification of the product by chromatographic adsorption on silica gel, the mixture of stereoisomers was separated by distillation under reduced pressure through an 80-plate column [9]: b.p. 175° (760 mm); 78.7° (28 mm); n_D^{20} 1.4381; d_4^{20} 0.7980; Found MR 46.15; Calculated for $C_{10}H_{20}$ MR 46.18. The individual stereoisomer was prepared for the first time.

$\Delta\nu$: 277 (8, b), 297 (8, b), 372 (5), 382 (5), 423 (3, b), 460 (1, b), 501 (3), 511 (2), 520 (2), 724 (1), 758 (9), 778 (11), 805 (5), 820 (5), 836 (8), 869 (6), 888 (29, b, db), 922 (12), 960 (0), 980 (10, b), 1018 (8), 1054 (15, db) 1088 (12), 1120 (9), 1150 (5), 1191 (8, b, db), 1240 (2), 1268 (8, b), 1300 (18, b, db), 1350 (4, b), 1446 (50), 1460 (70), 1472 (20, b), 2813 (0), 2855 (150), 2871 (300), 2895 (150, bk), 2908 (280, bk), 2932 (280), 2960 (290).

trans-1-Butyl-2-methylcyclopentane. This was prepared together with the cis isomer and was separated by distillation through an 80-plate column (see above): b.p. 169.4-169.5°; 74.0-74.1° (28 mm); n_D^{20} 1.4321; d_4^{20} 0.7847; Found MR 46.37; Calculated for $C_{10}H_{20}$ MR 46.18. The individual stereoisomer was prepared for the first time.

$\Delta\nu$: 237 (7, b), 248 (7, b), 288 (7, b), 333 (5), 378 (6), 404 (0), 424 (4), 504 (9), 525 (3), 552 (4), 600 (4, b), 762 (2), 777 (7), 798 (2), 813 (6, b) 873 (8, b, db), 895 (24, sh), 905 (10), 925 (3), 987 (2, b), 1001 (8), 1033 (4), 1059 (9), 1084 (11), 1093 (11), 1138 (9, b, db), 1185 (7, b), 1220 (2, b), 1242 (0), 1270 (3), 1296 (13, b), 1343 (8), 1377 (4), 1441 (30), 1450 (50), 1461 (40), 2731 (5, b), 2854 (200), 2868 (300), 2908 (240, bk), 2923 (200, bk), 2940 (240, bk), 2960 (270).

cis-1-Ethyl-4-methylcyclohexane. This was synthesized together with the trans isomer from p-bromotoluene, which was converted into 1-ethyl-4-methylbenzene by the Wurtz reaction, the product being then hydrogenated over platinized charcoal at 175°. The 1-ethyl-4-methylcyclohexane so obtained was then purified by

* Communication 8 was published in Bull. Acad. Sci. USSR, Physics Series [8].

chromatographic adsorption on silica gel, and the cis and trans isomers were separated by distillation through an 80-plate column [10]: b.p. 152.6°; n_D^{20} 1.4374; d_4^{20} 0.7969; Found MR 41.53; Calculated for C_9H_{18} MR 41.56. The individual stereoisomer was isolated for the first time.

$\Delta\nu$: 202(2,b), 305(0), 368(15), 392(3), 410(3), 443(10), 468(5), 489(4), 590(1), 631(31), 738(15,sh), 753(34), 766(15), 781(32), 817(20), 896(4), 909(2), 951(5), 966(10), 1004(10,b), 1028(8), 1044(8), 1059(31), 1103(10,b,db), 1163(19), 1195(6), 1206(6), 1264(37), 1288(3), 1308(3), 1348(19), 1439(46), 1459(46), 2853(220), 2880(100,bk), 2905(100,bk), 2924(200,b), 2930(270,b), 2959(50).

trans-1-Ethyl-1-methylcyclohexane. This was prepared together with the cis isomer and was separated by distillation through an 80-plate column (see above): b.p. 149.1°; n_D^{20} 1.4304; d_4^{20} 0.7798; Found MR 41.85; Calculated for C_9H_{18} MR 41.56. The individual stereoisomer was prepared for the first time.

$\Delta\nu$: 201(0), 242(0), 280(2), 306(5), 345(38), 378(1), 402(2), 441(2), 454(27), 477(23), 508(0), 754(65), 778(43), 841(3), 913(8), 967(5), 991(8), 1014(5), 1031(10), 1069(65), 1108(3,b), 1166(26), 1175(23), 1195(0,b), 1251(41), 1275(2), 1306(11), 1345(24), 1354(30), 1442(36,b), 1457(60), 2672(3,b), 2846(290), 2873(160,b), 2909(160,b), 2932(240), 2959(100,b).

Hexylcyclohexane. This was synthesized by reaction between hexylmagnesium bromide and cyclohexanone, dehydration of the alcohol formed, and hydrogenation of the product in the cold in presence of platinized charcoal activated with chloroplatinic acid. The product was purified by chromatographic separation on silica gel and was vacuum-distilled through a 40-plate column: b.p. 123.5-123.7° (40 mm); n_D^{20} 1.4464; d_4^{20} 0.8077; Found MR 55.61; Calculated for $C_{12}H_{24}$ MR 55.42. The literature [11] gives b.p. 224.0°; n_D^{20} 1.4462; d_4^{20} 0.8076.

$\Delta\nu$: 228(4,b,bk), 255(4,b,bk), 406(2,b), 446(8), 495(0), 510(0), 524(0), 744(2), 776(19), 793(19), 811(4,b), 844(21), 894(4,b), 931(2,b), 979(5,b), 1033(36), 1053(6,bk), 1082(10), 1104(6,b), 1120(6,b), 1157(8,b,db), 1182(2,b), 1203(0), 1261(28,b), 1301(16,b,db), 1348(11), 1366(4), 1393?(2), 1445(75), 1460(10,b), 2667(5,b), 2728(2,b), 2842(260,b), 2853(260,b), 2875(100), 2892(100,bk), 2919(170), 2933(170), 2959(50).

Hexylbenzene. This was synthesized by reaction between pentylmagnesium bromide and benzaldehyde, conversion of the resulting 1-phenyl-1-hexanol into its acetic ester, and pyrolysis of this at 425° into 1-phenyl-1-hexene, which was hydrogenated in the cold over palladized charcoal activated with palladium chloride. The product was vacuum-distilled through a 40-plate column: b.p. 126.8-126.9° (39 mm); n_D^{20} 1.4872; d_4^{20} 0.8576. The literature [11] gives b.p. 226.1°; n_D^{20} 1.4864; d_4^{20} 0.8575.

$\Delta\nu$: 233(25,b,bk), 259(5,b), 353(0,b), 394(0,b), 510(0,b), 526(0,b), 569(2,b), 594(2,b), 622(37), 749(23), 786(10), 802(5), 816(20), 842(6), 864(4), 892(7), 902(8), 938(0), 1003(250), 1031(60), 1065(8), 1076(8), 1113(14,b), 1155(22), 1183(15,db), 1202(38), 1304(24,b), 1339(0), 1444(38,b), 1453(30,b), 1584(20), 1606(65), 2857(110), 2879(60,bk), 2904(130,b,bk), 2935(120,bk), 2965(30), 3050(50,b), 3065(140), 3075(100,b).

DISCUSSION OF RESULTS

In this investigation the Raman spectra of the stereoisomers (cis and trans) of 1-ethyl-4-methylcyclohexane and 1-butyl-2-methylcyclopentane were studied for the first time. Table 1 gives a comparison of the frequencies and intensities of the most intense lines of the cis and trans isomers of 1-ethyl-4-methylcyclohexane.

As can be seen from Table 1, these two stereoisomers have many frequencies in common, but there are some fairly intense lines which differ from one another. The most intense characteristic lines distinguishing one form from the other are: for the cis form 368(15), 631(31), 738(15,sh), 766(15), 817(20) cm^{-1}; for the trans form 345(38), 454(27), 1069(65), 1175(23), 1251(41), 1354(30) cm^{-1}. These data provide a basis for determining the degree of resolution in our preparations, i.e. the presence of one form in the other. A careful examination of these spectra indicated that we had achieved good separation, the spectroscopic data indicating that any contamination of one form by the other amounted to less than 2-3%.

Table 2 gives a comparison of the most intense lines of cis- and trans-1,4-dimethylcyclohexane [7] with those of 1-ethyl-4-methylcyclohexane.

TABLE 1

No.	1-Ethyl-4-methylcyclohexane			
	cis isomer		trans isomer	
	Δν cm⁻¹	I_r	Δν cm⁻¹	I_r
1	—	—	345	38
2	368	15	—	—
3	—	—	454	27
4	—	—	477	23
5	631	31	—	—
6	738	15, sh	—	—
7	753	34	754	65
8	766	15	—	—
9	781	32	778	43
10	817	20	—	—
11	1059	31	1069	65
12	1163	19	1166	26
13	—	—	1175	23
14	1264	37	1251	41
15	1348	19	1345	24
16	—	—	1354	30

From these results it can be seen that, as we pointed out previously [7], replacement of methyl by ethyl in one stereoisomer does not result in substantial changes in frequencies. The most notable changes are in the intensities. For example, the intensity of the symmetrical vibration of the ring at 760 cm^{-1} is reduced for both forms by a factor of 3-4 when methyl is replaced by ethyl. It must be pointed out also that, both for the cis and for the trans form, we observe some fairly intense lines which can probably characterize one of these forms, irrespective of the number of carbon atoms in the side chain. For example, the frequency 630 cm^{-1} is present only in the cis forms and the frequency 454 cm^{-1} is present only in the trans forms. To such frequencies we must assign the frequency 1260 cm^{-1} for the characterization of the cis form and the frequency 1250 cm^{-1} for the characterization of the trans form.

It is characteristic that, when one methyl is replaced by ethyl, the frequency 760 cm^{-1} is lowered by about 6-7 cm^{-1} for both forms. These peculiarities can probably be applied in the solution of some analytical problems met in the investigation of higher-boiling hydrocarbons of the type under consideration.

Table 3 gives a comparison of the frequencies and intensities of the principal lines of the spectra of cis- and trans-1-butyl-2-methylcyclopentane. These isomers have spectra containing many lines, but the intensities are low. It is therefore difficult to establish the presence of one isomer in the other with adequate precision. As can be seen from Table 3, the spectra of the cis and trans forms contain lines which, although weak, are sufficiently intense for differentiation between the isomers. For the cis form such lines are 277 (8,b), 297 (8,b), 836 (8), 888 (29,b,db), 1018 (8), 1120 (9), and for the trans form: 895 (24,sh), 905 (10), 1001 (8), 1093 (11).

TABLE 2

No.	cis-1,4-Dimethylcyclohexane	cis-1-Ethyl-4-methylcyclohexane	trans-1,4-Dimethylcyclohexane	trans-1-Ethyl-4-methylcyclohexane
1	373(17, db)	368(15)	376(65)	345(38)
2	—	—	454(43)	454(27)
3	472(26, db)	468(5)	475(20)	477(23)
4	637(24)	631(31)	—	—
5	—	738(15,sh)	—	—
6	760(130)	753(34)	760(200)	754(65)
7	—	766(15)	—	—
8	788(23)	781(32)	786(8)	778(43)
9	—	817(20)	—	—
10	954(21)	951(5)	953(14)	967(5)
11	1055(31)	1059(31)	1062(95)	1069(65)
12	1263(31)	1264(37)	1250(48)	1251(41)

From these spectroscopic data we may conclude that, if one form is contaminated by the other, then the extent of contamination is probably not greater than 5%. The crudeness of this estimation is due to the low intensity of the analytical lines.

In Table 4 we give a comparison between the intense lines of 1,2-dimethylcyclopentane and 1-butyl-2-methylcyclopentane. It will be seen that the frequencies in the spectrum do not greatly change when methyl is replaced by butyl, but, as for the above-described hydrocarbons, the intensities fall appreciably. The data cited

indicate a fairly stable frequency of the symmetrical vibration of the ring at 888 cm^{-1} for the cis form and 898 cm^{-1} for the trans form. The stability of these lines can be traced also when the methyl group is replaced by ethyl or propyl [3].

With regard to the stability of lines characteristic for a definite class of compounds, hexylcyclohexane and hexylbenzene are not exceptions to this empirical rule. If, for example, we make comparisons between various monosubstituted benzenes, then here also we find that as the methyl of toluene is replaced by other radicals (ethyl, propyl, etc.) a series of extremely stable frequencies is to be observed (622, 1005, 1031 cm^{-1}, and others) with, on the other hand, considerable variations in intensity. For example, as we pass from toluene to hexylbenzene, the intensity of the line at 1005 cm^{-1} is reduced by about one-half.

All the data that we have cited appears to confirm the empirical law considered above. This law can be applied to the establishment of group criteria of value for the analysis of high-boiling hydrocarbons which, for one reason or another, are difficult to synthesize.

In conclusion we take the opportunity of expressing our sincere thanks to G. S. Landsberg and B. A. Kazansky for valuable advice and discussions.

SUMMARY

1. Raman spectra are given for five naphthene hydrocarbons and one aromatic hydrocarbon.

2. It is shown that the cis and trans isomers of dialkylcycloalkanes give lines that are sufficiently characteristic to enable the isomers to be distinguished from one another.

MECHANISM OF

THE CATALYTIC POLYMERIZATION OF PROPENE UNDER PRESSURE

L. I. Antsus and A. D. Petrov

The catalytic polymerization of propene began to be carried out on an industrial scale in 1936, and the catalyst, which had determined the success of the process, was phosphoric acid [1]. The reaction over this catalyst has been carried out under various conditions. In American literature temperatures of 200-220°, and sometimes higher, are referred to, the pressure being from 40-50 to 400 atm [2]. The German literature indicates a temperature of 200° and a pressure of 50 atm [3]. Until very recently there was very little information on the structure of the hydrocarbons in the polymerizate. One could only suppose that the olefins formed were of only slightly ramified structure, since the polymers of butenes have an octane rating of 80 both before and after hydrogenation, whereas the propene polymers have an octane rating of 80 before hydrogenation and of 56 after hydrogenation [4]. The structure of the propene polymers obtained over phosphoric acid and the mechanism of this polymerization were established by Terres as recently as 1953 [5]. It was shown that all the polymers gave only acids when oxidized: the dimer gave acetic and isobutyric acids, the trimer acetic and 2,4-dimethylvaleric acids, the tetramer acetic and 2,4,6-dimethylheptanoic acids, and the pentamer acetic and 2,4,6,8-tetramethylnonanoic acids.

In this case, therefore, the mechanism of the polymerization consists merely in the stepwise addition of propene without isomeric changes:

At first, propene polymers obtained over phosphoric acid were used as components of low-octane straight run motor fuels. Later, the main use for these polymers became basic organic synthesis, the most important polymer being the tetramer – the C_{12} fraction: this is used for the alkylation of phenols, the products being plasticizers for nylon, and as a raw material for the manufacture of non-ionic detergents, for which purpose it is condensed with 3-12 molecules of ethylene oxide [6]. The most important application is the preparation of a dodecylbenzenesulfonate from the C_{12} fraction and benzene: this was carried out in Germany during the war [7] and the product has recently received extensive application in the US as a base for detergents [8]. Some years

ago we undertook the study of the polymerization of propene over zinc chloride. This catalyst attracted our attention both because of its lower tendency to corrode, as compared with phosphoric acid, and because of the possibility that more highly branched structures might be obtained. Our hopes were fully justified. In 1950 we reported [9] the establishment of the structures of the nonene isomers in the main C_9 fraction, b.p. 132-136° (the whole of the C_9 fraction boiled over the range 122-142° and was twice the weight of the main fraction). The 133-136° fraction consisted mainly of 3-ethyl-4,4-dimethyl-2-pentene, 3,4,5-trimethyl-2-hexene, and 3,4-dimethyl-3-heptene. These results enable us to conclude that, in the process of condensation with propene, the dimer fraction (consisting of 2-methyl-1-pentene and 4-methyl-1-pentene) first undergoes isomerization into 3,3-dimethyl-1-butene to a considerable extent:

In the present paper we give some supplementary data on the structures of the hydrocarbons of the wide C_9 fraction, and also on the changes in the composition of the polymerizate and in the course of the process resulting from changes in polymerization conditions. The investigation of the wide C_9 fraction showed that it contained not only highly branched hydrocarbons, but also only slightly branched hydrocarbons, and it enabled us to characterize the polymerizate as a complex product arising as the result of a certain equilibrium between polymerization and depolymerization processes.

When the wide C_9 fraction, b.p. 122-142°, was oxidized, 1 kg gave 200 g of acids and 609 g of neutral oxidation products (ketones), b.p. 54-220°. Of the latter, only the fraction of b.p. 54-130° was investigated, and in this we identified acetone, ethyl methyl ketone, isopropyl methyl ketone, methyl propyl ketone, isobutyl methyl ketone, sec-butyl methyl ketone, and methyl neopentyl ketone. Acetic acid predominated among the acids, and propionic acid was second in order; the total amount of the higher acids did not exceed 20%, and among them acids containing 4, 6, 7, and 8 carbon atoms were detected; acids containing 5 carbon atoms were absent. We succeeded in identifying 4-methylvaleric acid and 3,5-dimethyl-2-hexenoic acid, clearly formed from 3,5-dimethylhexanoic acid:

A comparison of the oxidation products enables us to conclude that, apart from the compounds already found, the C_9 olefins include also trimethylhexenes, such as 2,3,5-trimethyl-2-hexene (acetone and isobutyl methyl ketone) and some only slightly branched alkenes: 4,6-dimethyl-1-heptene, 2,6-dimethyl-2-heptene, 7-methyl-3-octene, etc. The presence of 4,6-dimethyl-1-heptene

is supported by the formation of 3,5-dimethylhexanoic and formic acids in the oxidation treatment; and the presence of 2,6-dimethyl-1-heptene

is supported by the identification of 4-methylvaleric acid and acetone. The possibility of the same acid being associated not only with acetone, but also with propionic acid is suggestive of the probability that 7-methyl-3-octene is present.

Among the oxidation products formed without breakdown of the C_8 olefin molecule we found not only the previously identified [9] 3-ethyl-3-hydroxy-4,4-dimethyl-2-pentanone, but also 3-hydroxy-3,5-dimethyl-4-heptanone, b.p. 73-75° (10 mm). This hydroxy ketone was clearly formed by the oxidation of 3,5-dimethyl-3-heptene

It was identified by oxidation with periodic acid; ethyl methyl ketone was isolated together with an acid of b.p. 173-176°, f.p. below -70°, and silver content of silver salt 51.38%. From the boiling point, freezing point, and silver content of the silver salt we concluded that the acid was 2-methylbutyric acid. The view that it was this acid, and not isovaleric acid, is supported also by the fact that hydroxy ketones can be obtained in the oxidation of olefins only when there is a substituent in the α-position to the carbon at one end of the double bond.

Among the C_8 olefins, the identification of which is still far from complete, the above-mentioned only slightly branched alkenes are of particular interest. Their formation is mainly due to the reverse course of the isomerization, i.e. conversion of highly branched forms into less branched forms. The mechanism of these transformations, with formation, for example, of 7-methyl-3-octene and 2,6-dimethyl-2-heptene, can be represented as proceeding through carbonium ions. It was shown previously that the isomerization of the very important intermediate form 4,5,5-trimethyl-2-hexene leads to 3,4,5-trimethyl-2-hexene:

The carbonium ion formed by the addition of a proton to the first of these forms is converted into 4,6-dimethyl-3-heptene as a result of isomerization of the tert-butyl radical into isobutyl. The carbonium ion formed from 4,6-dimethyl-3-heptene is converted into 7-methyl-3-octene by isomerization of 1-methylbutyl into pentyl. The carbonium ion formed from the second converts to 2,6-dimethyl-2-heptene by isomerization of sec-butyl into isobutyl and 1,2-dimethylpropyl into isopentyl. (Apart from the above route for 4,6-dimethyl-3-heptene formation, the possibility of this olefin forming from 4,6-dimethyl-1-heptene, as in Terres's scheme [5], cannot be excluded). Analogously, representation of 3,5-dimethyl-3-heptene formation from the same highly branched form of 3,5,5-trimethyl-2-hexene is not difficult.

The occurrence of the reverse isomerization makes it possible to understand, in particular, the mechanism of the depolymerization of propene polymers and the formation from nonenes of propene, 4-methyl-1-pentene, and 2-methyl-1-pentene, which is observed in some experiments; these are probably formed according to the scheme:

Reverse isomerization of olefins is particularly notable when the raw material is in prolonged contact with the catalyst used when it is desired to raise the yield of macromolecular polymers. Analogous transformation of branched forms into normal forms was noted by Ciapetta and Hunter [10], who showed that 2-methylpentane, 3-methylpentane, and 2,3-dimethylbutane are converted into n-hexane over nickel supported by aluminosilicate. The n-hexane is formed by dehydrogenation of the C_6 paraffins into olefins, and the conversion of these through carbonium ions into n-hexane.

EXPERIMENTAL

Experiments on the polymerization of propene were carried out over zinc chloride supported by pumice (ratio 1:1) at a temperature of 200-240° and pressures of 440-400 and 140-100 atm. The reactor consisted of a tube, internal diameter 20 mm and length 470 mm, in which 140 ml of catalyst was placed. The reactor was heated with an electric block furnace fitted with automatic temperature control. Propene was pumped at the pressures indicated from an intermediate reservoir (a 2-liter autoclave) through a steel tube to the upper end of the reactor. The unchanged propene and polymers left at a valve at the exit of the reactor and passed through a condenser to a receiver fitted with a stabilizer which was connected with a flowmeter and gas meter, so that the velocity of gas could be registered at the outlet as well as at the inlet and the amount of gas converted into polymers could be calculated. The same rate of passage, 3-3.5 liters/hour, was used both at 400-440 atm and at 140-100 atm. In the first case the degree of conversion was about 100%, and in the second case about 70%.

In each case the efficiency of the catalyst remained constant over a period of 400 hours. The degree of ramification of the hydrocarbons (as judged by octane values) and the relative amounts of the fractions (about 50% of C_9, 20% C_{10} olefins) were the same in both cases. By increasing the duration of contact by a factor of 2.5-3, we succeeded in raising the yield of the C_{10} fraction to 55% under the normal conditions (100 atm, about 3 liters of propene per hour) the yield of the fraction of b.p. > 150° was 20% and the pressure fell by 40 atm in 5-8 minutes, but when the pressure fell by 40 atm in 20-30 minutes the yield of the fraction of b.p. > 150° was 53-55%.

Investigation of the structures of the C_9 olefins. Oxidation of 1 kg of C_9 olefins gave 200 g of acids. Half of this amount, in the form of a solution of the potassium salts, was subjected to further oxidation under Meyer's conditions [11] with the object of isolating acids containing tertiary carbon atoms. When oxidation was complete, the colorless solution was evaporated to dryness. Salts of organic acids were extracted from the dry residue with alcohol and, after removal of alcohol by distillation, were decomposed with sulfuric acid. The acids were extracted with ether, the ether was removed from the extracted with ether, the ether was removed from the extract, and volatile acids were distilled off with steam.

Investigation of the nonvolatile acids. In order to separate γ- and δ-hydroxy acids from α- and β-hydroxy acids in the mixture obtained by Meyer oxidation, the residue from the distillation of volatile acids was neutralized with sodium carbonate, and the surface layer of oil which then formed was extracted with ether. The product obtained began to boil at 200° and came over completely at 206°; it smelled of honey. In order to confirm that this product was a lactone, it was boiled with baryta water; the honey odor disappeared and the barium salt of the acid was precipitated. The barium salt was converted into the silver salt by double decomposition with silver nitrate; the silver content 45.31% corresponded to $C_6H_{11}O_2Ag$, the silver salt of a hydroxy acid.

From the above-described properties of the hydroxy acid we may conclude that 4-methylvaleric acid is present in the acid products of the oxidation of the wide fraction of C_9 olefins; it could be formed by the oxidation of two of these olefins; 2,6-dimethyl-2-heptene and 7-methyl-3-octene.

The residue of sodium salts of α- and β-hydroxy acids was decomposed with sulfuric acid, and the acids were extracted with ether. Ether was removed, and the acids were converted into their calcium salts. The water-insoluble calcium salts were filtered off and decomposed with sulfuric acid. The acids were extracted with ether and converted into ammonium salts, which were further converted into silver salts by reaction with silver nitrate solution.

Found %: Ag 43.13. $C_8H_{14}O_2Ag$. Calculated % Ag 42.9.

The silver content of the salt corresponded to a β-derivative of acrylic acid, which could be formed as the result of the decomposition of β-hydroxy acids containing eight carbon atoms. The structure of this acid was established by an examination of the products of its further oxidation, among which isobutyl methyl ketone and oxalic acid of m.p. 178-180° were isolated. Analysis of the acid of m.p. 178-180°:

Found %: C 23.30; H 4.25. $C_4O_4H_2$. Calculated % C 26.66; H 2.22.

The identification of 3,5-dimethyl-2-hexenoic acid

formed evidently from 3,5-dimethylhexanoic acid

indicates the presence of 4,6-dimethyl-1-heptene among the C_9 olefins.

Investigation of the volatile acids. The steam-distilled volatile acids were fractionated into 5° fractions. The fraction of b.p. 175-180° gave a white amorphous precipitate, which did not dissolve in the usual solvents and decomposed without melting at above 250°.

Found %: C 52.89; H 7.86; O 39.32. $C_3H_4O_2$. Calculated %: C 56.31; H 6.98; O 37.11.

The somewhat high values for hydrogen and oxygen indicate the presence of moisture. The presence of acrylic acid was proved by the reduction of silver nitrate and the preparation of a polymer of the acid, analysis of which gave the following results:

Found %: C 49.90; H 8.47. $C_3H_4O_2$. Calculated %: C 50 H 5.56.

Propionic acid was also identified (elementary analysis and silver salt).

Investigation of neutral oxidation products. The ketone fraction, b.p. 54-130°, was fractionated through a 40-plate column into 2° fractions. Semicarbazones were prepared from all these fractions. From the melting points and mixture melting points of the semicarbazones, the ketones shown in the table were identified.

Fraction (b.p. in °C)		Semicarbazone			
		N found (%)	N calculated (%)	M.p. (°C)	Data in literature
54-56	Acetone	—	—	188	188 [12]
78-80	Ethylmethyl ketone	—	—	145-146	146 [11]
92-94	Isopropyl methyl ketone	29.61	29.73	110-111	110 [12]
112-116	Mixture of isobutyl methyl ketone and	26.66	26.75	129-130	130 [12]
116-118	sec-butyl methyl ketone	—	—	110	—
122-128	Methyl neopenthyl ketone	24.35	24.56	176	176 [13]

The fractions of b.p. 112-116° and 116-118° were found to be mixtures of two ketones — isobutyl methyl and sec-butyl methyl ketones. For sec-butyl methyl ketone the 2,4-dinitrophenylhydrazone, m.p. 69-70° was prepared.

The formation of isobutyl methyl ketone and propionic acid indicate the presence of 4,6-dimethyl-3-heptene, the formation of ethyl methyl ketone — 3,4,5-trimethyl-3-hexene, the formation of ethyl methyl ketone and methyl propyl ketone — 3,4-dimethyl-3-heptene, etc. In addition, hydroxy ketones were isolated with the same number of carbon atoms as the original C_9 olefins; apart from the previously identified substance having a semicarbazone of m.p. 198°, an isomeric hydroxy ketone having a semicarbazone of m.p. 157° was isolated.

Found %: N 19.99. $C_{10}H_{21}O_2N_3$. Calculated %: 19.52.

When this hydroxy ketone was oxidized with periodic acid, the products were 2-methylbutyric acid and ethyl methyl ketone. The structure of the hydroxy ketone can therefore be considered to be:

$$CH_3-CH_2-\underset{\displaystyle CH_3}{\underset{|}{CH}}-CO-\underset{\displaystyle CH_3}{\underset{|}{C(OH)}}-C_2H_5$$

SUMMARY

1. It was established that, unlike the polymerization of propene over phosphoric acid (which proceeds by simple stepwise addition of propene), its polymerization over zinc chloride is accompanied by isomeric changes which result in the formation of hydrocarbons containing quaternary carbon atoms.

2. It was shown that, apart from trialkylalkenes containing quaternary carbons or three consecutive tertiary carbons, the propene trimers included also dialkylalkenes (3,4-dimethyl-3-heptene, 2,6-dimethyl-2-heptene, and 4,6-dimethyl-1-heptene) and the monoalkylalkene 7-methyl-3-octene.

3. The formation of only slightly branched olefins indicates that in the polymerization of propene isomeric changes occur, not only in the direction of the formation of highly branched forms, but also in the reverse direction, with conversion of highly branched forms into only slightly branched forms according to the mechanism of isomeric transformations in the corresponding carbonium ions.

BRIEF COMMUNICATIONS

PHYSICAL PROPERTIES OF cis-1,3,5-TRIMETHYLCYCLOHEXANE

A. L. Liberman, M. A. Pryanishnikova, and B. A. Kazansky

There are few data in the literature on the physical properties of cis-1,3,5-trimethylcyclohexane. The first preparations which, judging by their freezing points, may be identified with this stereoisomer were obtained by Eykman [1] in 1911, Eisenlohr [2] in 1925, and Leslie [3] in 1934. Later, in 1955, Chiurdoglu [4] made an attempt to separate a mixture of the stereoisomers of 1,3,5-trimethylcyclohexane by fractionation through a column. The physical properties of all these preparations of cis-1,3,5-trimethylcyclohexane – and also of the trans isomer [4], for comparison – are given in the table. Unfortunately, in none of the cited papers is there any indication of the degree of purity of the preparation. Although Chiurdoglu's preparation would appear to be the purest, our results show that even this was appreciably contaminated with the trans form, the boiling point of which is only 2° higher than that of the cis form. The constants published by this author therefore require some correction.

Fig. 1. Freezing curve of cis-1,3,5-trimethylcyclohexane

Fig. 2. Relation between freezing point of cis-1,3,5-trimethylcyclohexane and content of impurity.

Like all previous investigators, we prepared cis-1,3,5-trimethylcyclohexane by the hydrogenation of mesitylene, but we purified the mesitylene very carefully and we distilled the mixture of stereoisomers through a 100-plate column. The trans isomer, which was present in the mixture in small amount, was not isolated. The content of trans form in our preparation was established from the freezing curve (Fig. 1) and the cryoscopic constant, which, in its turn, was found from the depression of freezing point brought about by the addition of 1.7 moles % of methylcyclohexane.

Since refractive indices and specific volumes of hydrocarbons of a single class follow an additive law in mixtures, we were able to calculate the content of impurity (evidently trans isomer) in Chiurdoglu's preparation from these constants. For this calculation we used our data for the cis form and Chiurdoglu's data for the trans-

form. The same result was obtained both from refractive indices and from specific volumes: the preparation of cis-1,3,5-trimethylcyclohexane obtained by Chiurdoglu contained 12 moles % of impurity.

We prepared mixtures of our cis-1,3,5-trimethylcyclohexane with trans-1,3,5-trimethylcyclohexane, and one of these mixtures approximated to the above-mentioned mixture in content of impurity (12.4 moles %). The relation of the freezing point of cis-1,3,5-trimethylcyclohexane to the molar content of impurity is shown in Fig. 2. For Chiurdoglu's preparation, extrapolation gives a content of impurity of about 15%, which is fairly close to the value found from other constants.

TABLE

Constants of cis-1,3,5-Trimethylcyclohexane

Authors	B.p., °C	Freezing point (°C)	n_D^{20}	d_4^{20}
Eykman	136—137	—50	—	0.7744 (at 15.7°)
Eisenlohr	138—139	—	1.42710*	0.7720
Leslie	138.9	—50.7	1.4288 (at 25°)	—
Chiurdoglu	138.55	—50**	1.42680*	0.77050
Present authors	138.4	—43.2	1.4263	0.76942
Chiurdoglu for trans isomer	140.5	—107.5	1.43100*	0.77887

* For the yellow helium line.

** For the same preparation Timmermans [5] found freezing point −49.7°.

EXPERIMENTAL

Mesitylene. Mesitylene was prepared from acetone in the usual way [6]. In order to purify it, the crude mesitylene was chromatographed on silica gel and 300 g of the product was distilled through a 60-plate column. The mesitylene so obtained had the following constants: b.p. 103.0° (112 mm); n_D^{20} 1.4995; d_4^{20} 0.8652. According to the most reliable reported data [7], mesitylene has the properties: b.p. 164.716° (760 mm); n_D^{20} 1.49937; d_4^{20} 0.86518.

1,3,5-Trimethylcyclohexane. The purified mesitylene (160 g) was hydrogenated over platinized charcoal at 180–185° in a stream of hydrogen at atmospheric pressure. The catalyzate, which was freed from residual mesitylene by chromatography on silica gel, had the constants n_D^{20} 1.4271; and d_4^{20} 0.7724, i.e. according to its constants it contained a small amount of trans form.

cis-1,3,5-Trimethylcyclohexane. By the fractionation of 138 g of the preparation through a 100-plate column at a reflux number of about 150, it was found possible to isolate cis-1,3,5-trimethylcyclohexane giving a good freezing curve (Fig. 1). Judging from the freezing curve and the cryoscopic constant (0.0342 mole per mole per degree), the purity of our preparation was not less than 99.5 %. Its physical constants are given in table.

For the determination of the cryoscopic constant and the relation between the freezing point of 1,3,5-trimethylcyclohexane and the content of impurity, binary mixtures were prepared from this hydrocarbon and methylcyclohexane [b.p. 101.1° (760 mm); n_D^{20} 1.4230; d_4^{20} 0.7693] or trans-1,2-dimethylcyclohexane [b.p. 123.6° (760 mm); n_D^{20} 1.4270; d_4^{20} 0.7762]. The temperatures of incipient freezing of the mixtures are given in Fig. 2. The highest point (−43.05°) was found by calculation for zero content of impurity.

SUMMARY

1. cis-1,3,5-Trimethylcyclohexane was obtained in a higher state of purity than previously described preparations of this substance. Its physical constants are given.

ORGANOBORON COMPOUNDS

COMMUNICATION 12. SYNTHESIS OF ARYLDICHLOROBORINES

B. M. Mikhailov and T. V. Kostroma

All the known methods of preparing aryldihaloborines depend on exchange reactions between organometallic compounds and boron halides. Aryldichloroborines were prepared by Michaelis and coworkers [1-4] by the action of boron trichloride on diarylmercury compounds. Apart from the need to use organomercury compounds, this method has the further disadvantage that it is generally necessary to heat the reactants in sealed tubes at 200° for a long time. In no case do the authors indicate yield.

Aryldibromoborines were prepared similarly [4]. Of the fluoro compounds, only difluorophenylborine has been described [5]; it was prepared by the action of diphenylzinc or boron trifluoride. It was not found possible to obtain this compound from boron trifluoride and phenylmagnesium bromide, since the reaction was so vigorous that all three fluorine atoms were replaced by organic radicals [6].

For the preparation of aryldichloroborines we made use of the reaction between areneboronic esters and phosphorus pentachloride. As we have shown [7], reaction between equimolecular amounts of areneboronic esters and phosphorus pentachloride gives arenechlorobronic esters $ArB\begin{matrix}Cl\\OR\end{matrix}$, in accordance with the equation:

$$ArB(OR)_2 + PCl_5 \rightarrow ArB\begin{matrix}Cl\\OR\end{matrix} + RCl + POCl_3.$$

We have now shown that the use of two equivalents of phosphorus pentachloride instead of one results in the replacement of both alkoxy groups of he areneboronic ester with formation of an aryldichloroborine in good yield:

$$ArB(OR)_2 + 2PCl_5 \rightarrow ArBCl_2 + 2RCl + 2POCl_3.$$

The reaction proceeds in two stages. The first equivalent of PCl_5 reacts with the areneboronic ester with spontaneous evolution of heat. In this stage PCl_5 is added at such a rate that the temperature of the reaction mixture remains at about 70-80°. When reaction is complete, alkyl halide and phosphoryl chloride are distilled off under reduced pressure, and a second equivalent of PCl_5 is added to the residue of crude arenechloroboronic ester. The second stage of the reaction

$$ArB\begin{matrix}Cl\\OC_6H_5\end{matrix} + PCl_5 \rightarrow ArBCl_2 + C_6H_5Cl + POCl_3$$

Ar = C_6H_5, o-$CH_3C_6H_4$, p-ClC_6H_4

is much slower than the first, so that it is necessary to heat the reaction mixture at 105-110° for several hours with continuous removal of the phosphoryl chloride and alkyl halide formed by vacuum distillation. In this way, from isobutyl esters of the appropriate acids we prepared dichlorophenyl-, dichloro-o-tolyl-, and dichloro-p-chlorophenyl-borines in about 60% yield.

We have prepared more arenechloroboronic esters [7]: isobutyl esters of p-chlorobenzene- and 1-naphthalene-chloroboronic acids were obtained in 76-80% yield by the action of PCl_5 (one equivalent) on p-chlorobenzene- and 1-naphthalene-boronic esters.

EXPERIMENTAL

Isobutyl p-chlorobenzenechloroboronate. A Claisen flask containing 26.9 g (0.1 mole) of diisobutyl p-chlorobenzeneboronate was shaken vigorously by hand while 20.8 g (0.1 mole) of finely ground phosphorus pentachloride was added in portions. Reaction began spontaneously and was accompanied by evolution of heat. The temperature was maintained at 60-70° during the addition. When the whole of the phosphorus pentachloride had reacted, isobutyl chloride and phosphoryl chloride were distilled from the reaction mixture into a receiver cooled with solid carbon dioxide. The residue was fractionally distilled and gave 18.6 g (80.5%) of isobutyl p-chlorobenzenechloroboronate, b.p. 121-123° (8 mm) and d_4^{20} 1.125.

Found %: B 4.75; Cl 15.67*. $C_{10}H_{12}BOCl_2$. Calculated %: B 4.76; Cl 15.35.

The product was a colorless liquid which readily hydrolyzed in the air. In addition, 11.2 g of phosphoryl chloride and 9 g of isobutyl chloride were obtained.

Isobutyl 1-naphthalenechloroboronate. The procedure was as in the previous experiment. Reaction between 56.8 g (0.2 mole) of diisobutyl 1-naphthaleneboronate and 41.7 g (0.2 mole) of phosphorus pentachloride gave 37.3 g (76%) of isobutyl 1-naphthalenechloroboronate, b.p. 167.5-169° (9 mm) and d_4^{20} 1.091.

Found %: B 4.50; Cl 14.45. $C_{14}H_{16}BOCl$. Calculated %: B 4.46; Cl 14.40.

The chloroboronic ester was a colorless liquid, readily hydrolyzed in the air.

Dichlorophenylborine. Phosphorus pentachloride (83.4 g, i.e., 0.4 mole) was added in portions to 46.8 g (0.2 mole) of diisobutyl benzeneboronate contained in a Claisen flask. Addition of the first equivalent of PCl_5, which was accompanied by evolution of heat, was made at such a rate that the temperature of the reaction mixture remained at about 70-80°. About one hour was required for this operation, and isobutyl chloride and phosphoryl chloride were then distilled off under reduced pressure. The second half (0.2 mole) of the phosphorus pentachloride was then added to the residue over a period of 3.5 hours at a temperature of 105-110°, so that isobutyl chloride and phosphoryl chloride were continuously distilled off in a stream of nitrogen into a receiver cooled with solid carbon dioxide. After the whole of the phosphorus pentachloride had reacted, the reaction mixture was fractionally distilled and gave 18.9 g (60%) of dichlorophenylborine, b.p. 73-75° (28 mm) (the literature [1] gives b.p. 175°).

Found %: B 6.91; Cl 44.29. $C_6H_5BCl_2$. Calculated %: B 6.91; Cl 44.65.

In addition, 18 g (97%) of isobutyl chloride and 27 g (88.8%) of phosphoryl chloride were obtained.

Dichloro-o-tolylborine. The procedure was as in the preceding experiment. Reaction was between 49.6 g (0.2 mole) of diisobutyl o-toluneboronate and 83.4 g (0.4 mole) of phosphorus pentachloride, and the product, amounting to 21.5 g (60.3%), was dichloro-o-tolylborine, b.p. 96-97° (28 mm) (the literature [1] gives b.p. 193°).

Found %: B 6.24; Cl 40.93. $C_7H_7BCl_2$. Calculated %: B 6.35; Cl 41.04.

Dichloro-p-chlorophenylborine. The procedure was as in the preceding experiments. Reaction between 53.7 g (0.2 mole) of diisobutyl p-chlorobenzeneboronate and 83.4 g (0.4 mole) of phosphorus pentachloride gave 23.9 g (62%) of dichloro-p-chlorophenylborine, b.p. 106-107° (24 mm).

Found %: B 5.59; Cl 36.63**. $C_6H_4BCl_3$. Calculated %: B 5.68; Cl 36.69.

* Boron-attached halogen was estimated.

** Readily hydrolyzed boron-attached halogen was determined.

The substance is readily hydrolyzed by atmospheric moisture.

SUMMARY

Aryldichloroborines were prepared in good yield by the action of two equivalents of phosphorus pentachloride on areneboronic esters.

SYNTHESIS OF UNSATURATED ORGANOGERMANIUM COMPOUNDS

A. D. Petrov, V. F. Mironov, and I. E. Golgy

Like organosilicon compounds, organogermainum compounds can be prepared by direct synthesis, i.e. by direct reaction of an alkyl or aryl halide with elementary germanium at 300-350° in presence of a copper catalyst. In the direct synthesis use has been made of methyl chloride [1], ethyl chloride [2], propyl chloride [3], chlorobenzene [4], and methyl bromide [1].

In the case of ethyl and methyl chlorides, compounds of the type R_2GeCl_2 and $RGeCl_3$ are formed in a ratio of about 2:1. We repeated the direct synthesis of these compounds, but at much higher temperatures (about 550°). It was found that, under these conditions, the dialkyldichlorogermane content of the condensate was much lower. Dichlorodiethylgermane was not detected at all, and the yield of dichlorodimethylgermane was about the same as that of trichloromethylgermane. Also, for the first time, we made use of allyl and 2-methylallyl chlorides in the direct synthesis and so obtained good yields of the first representatives of unsaturated organogermainum compounds: allytrichlorogermane and trichloro (2-methylallyl)germane.

By reaction of Grignard reagents with alkyl- and alkenyl-chlorogermanes obtained in the direct synthesis, we synthesized some unsaturated tetrasubstituted germanes:

$$CH_2 = CHCH_2GeCl_3 + 3RMgX \rightarrow R_2GeCH_2CH = CH_2$$

$$CH_2 = \underset{\displaystyle CH_3}{\overset{|}{C}}CH_2GeCl_3 + 3CH_2MgCl \rightarrow (CH_2)_2GeCH_2\underset{\displaystyle CH_3}{\overset{|}{C}} = CH_2$$

$$(CH_2)_nGeCl_{4-n} + (4-n)CH_2 = CHCH_2MgBr \rightarrow (CH_2)_nGe(CH_2CH = CH_2)_{4-n}$$

in which R = CH_3 and C_2H_5; n = 1 and 2.

We did not succeed in preparing trichlorovinylgermane by the direct synthesis; this compound was prepared by the chlorination of trichloroethylgermane and subsequent dehydrochlorination. Chlorination of trichloroethylgermane with sulfuryl chloride (which is widely used for the chlorination of organosilicon compounds [4]) went satisfactorily, and we obtained a 1:9 mixture of trichloro (1-chloroethyl)- and trichloro (2-chloroethyl)-germanes:

$$Cl_3GeCH_2CH_3 \xrightarrow{Bz_2O_2+SO_2Cl_2} Cl_3GeCHClCH_3 + Cl_3GeCH_2CH_2Cl.$$

In this connection it is interesting to note that, in the chlorination of trichloroethylsilane with sulfuryl chloride [5], trichloro (1-chloroethyl)- and trichloro (2-chloroethyl)-silanes are formed in the proportions of 1:2,5 [5]. The Cl_3Ge group therefore possesses a much greater orienting effect than the Cl_3Si group [4]. This effect is shown also in the fact that we were unable to bring about the chlorination of trichloromethylgermane with sulfuryl chloride in spite of the use of a fairly high temperature. It is interesting that chloromethylsilanes are also not chlorinated by sulfuryl chloride at low temperatures; however, this reaction does go at higher temperatures, even in the case of trichloromethylsilane [4].

The dehydrochlorination of trichloro (2-chloroethyl)germane with quinoline went satisfactorily with formation of trichlorovinylgermane in 26% yield:

$$Cl_3GeCH_2CH_2Cl \xrightarrow{\text{quinoline}} Cl_3GeCH{=}CH_2$$

With the object of making a comparative investigation of the unsaturated compounds of silicon, germanium, and tin, allyltrimethylstannane was prepared by the usual procedure:

$$(CH_3)_3SnBr + CH_2{=}CHCH_2MgBr \rightarrow (CH_3)_3SnCH_2CH{=}CH_2.$$

EXPERIMENTAL

Allyltrichlorogermane $CH_2 = CHCH_2GeCl_3$

Allyl chloride was passed through a glass tube, diameter 20 mm, filled with amixture of 25 g of finely divided germanium and 10 g of copper turnings and heated in an electric tube furnace to 340 ± 10°. The allyl chloride (300 g) was passed in at the rate of 60 drops per minute, and 170 g of condensate was collected. Distillation through a column gave 85 g of allyltrichlorogermane, b.p. 153.8° (743.5 mm); n_D^{20} 1.4928; d_4^{20} 1.5274.

The synthesis was carried out under similar conditions with 2-methylallyl chloride. The yield of trichloro-(2-methylallyl)germane, b.p. 42° (7 mm), was 35 g (24% on the condensate). Methyl and ethyl chlorides were passed at 550° at the rate of 60 bubbles per minute. In the case of methyl chloride the composition of the condensate was about 35% of trichloromethylgermane, b.p. 110° (727 mm), n_D^{20} 1.4685; and d_4^{20} 1.7053 and about 26% of dichlorodimethylgermane, b.p. 122° (727 mm), n_D^{20} 1.4600, and d_4^{20} 1.5053. In the case of ethyl chloride the condensate contained about 65% of trichloroethylgermane, b.p. 141° (760 mm); n_D^{20} 1.4750; d_4^{20} 1.6041.

Allyltrimethylgermane $CH_2 = CHCH_2Ge(CH_3)_3$

Allyltrichlorogermane (61 g) was gradually added to methylmagnesium chloride prepared from 22 g of magnesium in 400 ml of ether. The mixture was boiled for ten hours and then decomposed with water. The ether layer was separated from the aqueous layer, the aqueous layer was extracted with ether, and the combined ether extracts were dried with calcium chloride. Ether was removed, and distillation of the liquid residue through a column gave 30 g (68.1%) of allyltrimethylgermane, b.p. 101° (764 mm); n_D^{20} 1.4333; d_4^{20} 0.9952.

Found %: C 45.62; 45.69; H 9.03; 9.08; Ge 45.55; 45.70. $C_6H_{14}Ge$. Calculated %: C 45.38; H 8.88; Ge 45.72.

Diallyldimethylgermane $(CH_2 = CHCH_2)_2Ge(CH_3)_2$

An ethereal solution of dichlorodimethylgermane (31 g) was added to allylmagnesium bromide prepared from 6 g of magnesium with 24 g of allyl bromide in 400 ml of ether. The mixture was boiled for ten hours, and the usual treatment gave 14 g (42%) of diallyldimethylgermane, b.p. 146° (737 mm); n_D^{20} 1.4645; d_4^{20} 1.0337.

Found %: Ge 39.00; 39.61. $C_8H_{16}Ge$. Calculated %: Ge 39.28.

Triallylmethylgermane $(CH_2 = CHCH_2)_3GeCH_3$

Trichloromethylgermane (35 g) was added to allylmagnesium bromide prepared from 25 g of magnesium and 95 g of allyl bromide. The usual treatment gave 17 g (45%) of triallylmethylgermane, b.p. 190.5° (747 mm); n_D^{20} 1.4867; d_4^{20} 1.0222.

Found %: Ge 34.50; 34.34. $C_{10}H_{18}Ge$. Calculated %: Ge 34.43.

Allyltriethylgermane $CH_2 = CHCH_2Ge(C_2H_5)_3$

Trichloroallylgermane (23 g) was added to ethylmagnesium bromide prepared from 9 g of magnesium and 36 g of ethyl bromide in 200 ml of ether. The usual treatment gave 11 g (52.3%) of allyltriethylgermane, b.p. 50° (6 mm); 180° (732 mm); n_D^{20} 1.4594; d^{20} 1.0004.

Found %: C 53.25; 53.37; H 9.96; 10.026; Ge 35.73; 35.92. $C_9H_{20}Ge$. Calculated %: C 53.81; H 10.03 Ge 36.14.

Trimethyl(2-methylallyl)germane $CH_2=C(CH_3)-CH_2Ge(CH_3)_3$

Trichloro(2-methylallyl)germane (35 g) was added to methylmagnesium chloride prepared from 18.5 g of magnesium in 300 ml of ether. The usual treatment gave 11 g (42.5%) of trimethyl(2-methylallyl)germane, b.p. 121° (733 mm); n_D^{20} 1.4416; d_4^{20} 0.9908.

Found %: C 49.17; 49.17; H 9.52; 9.57. $C_7H_{16}Ge$. Calculated %: C 48.65; H 9.33.

Trichloro(1-chloroethyl)germane $CH_3ClCHGeCl_3$ **and Trichloro(2-chloroethyl)germane** $ClCH_2CH_2GeCl_3$

Freshly precipitated benzoyl peroxide (0.7 g) was added to a mixture of 100 g of trichloroethylgermane and 80 g of sulfuryl chloride. When the mixture was heated there was a vigorous evolution of gas, which stopped after two hours. Addition of a further 0.3 g of benzoyl peroxide caused further evolution of gas for a period of one hour. Distillation through a column gave 5 g of unchanged trichloroethylgermane; 5 g (4%) of trichloro(1-chloroethyl)-germane, b.p. 167° (746.5 mm), n_D^{20} 1.4948; and d_4^{20} 1.6975; and 44 g (38%) of trichloro(2-chloroethyl)germane, b.p. 188°(746.5 mm); n_D^{20} 1.5094. and d_4^{20} 1.7587.

Trichlorovinylgermane $CH_2=CHGeCl_3$

A mixture of 49 g of trichloro(2-chloroethyl)germane and 31 g of quinoline was distilled from a flask up to a temperature of 200°. Distillation of 35 g of the distillate through a column gave 4 g of germanium tetra-chloride, b.p. 83°, and 11 g (26.6%) of trichlorovinylgermane, b.p. 127.5° (745.5 mm); n_D^{20} 1.4816; d_4^{20} 1.6520.

Found %: C 11.40; 11.46; H 1.32; 1.36; Ge 34.73; 34.90; Cl 51.46; 51.12. $C_2H_3GeCl_3$. Calculated %: C 11.65; H 1.46; Ge 35.24; Cl 51.63.

Allyltrimethylstannane $CH_2=CHCH_2Sn(CH_3)_3$

Bromotrimethylstannane [6] (20 g) was added to allylmagnesium bromide prepared from 4 g of magnesium and 12 g of allyl bromide in 100 ml of ether. The mixture was boiled for ten hours, and the usual treatment and distillation through a column gave 8 g (47.6%) of allyltrimethylstannane, b.p. 125.5° (642 mm); n_D^{20} 1.4734; d_4^{20} 1.2549.

Found %: Sn 57.69; 57.95. C_6H_4Sn. Calculated %: Sn 57.93.

SUMMARY

1. The following organogermanium compounds containing unsaturated radicals were prepared for the first time: $CH_2=CHCH_2GeCl_3$; $CH_2=C(CH_3)CH_2GeCl_3$; $CH_2=CHGeCl_3$; $CH_2=CHCH_2Ge(CH_3)_3$; $CH_2=CHCH_2Ge(C_2H_5)_3$; $CH_2=C(CH_3)CH_2Ge(CH_3)_3$; $(CH_2=CHCH_2)_2Ge(CH_3)_2$; $(CH_2=CHCH_2)_3GeCH_3$.

2. It was shown that, in presence of benzoyl peroxide, sulfuryl chloride chlorinates trichloroethylgermane with formation of a 1:9 mixture of trichloro(1-chloroethyl)- and trichloro(2-chloroethyl)-germanes.

3. It was found that quinoline readily eliminates HCl from trichloro(2-chloroethyl)germane with formation of trichlorovinylgermane.

PREPARATION OF CYCLOPENTENE FROM CYCLOPENTADIENE

A. F. Plate and V. I. Stanko

The usual laboratory method for the preparation of cyclopentene consists in the dehydration of cyclopentanol, which is prepared by the hydrogenation of cyclopentanone synthesized from adipic acid. The preparation of cyclopentene from cyclopentadiene by the action of calcium hexaammoniate was described by Kazansky and Glushnev [1]. David, Dupont, and Paquot [2] found an inflection on the curve for the hydrogenation of cyclopentadiene in alcoholic solution in presence of Raney nickel at room temperature and atmospheric pressure. When they interrupted the hydrogenation of cyclopentadiene after the adsorption of one molecular proportion of hydrogen, they were able to isolate a little cyclopentene. A patent [3] describes the formation of cyclopentene in 40% yield in the hydrogenation of cyclopentadiene at 430-470° in the presence of an $NiMoO_3$ catalyst at atmospheric pressure. Other investigators have also studied the hydrogenation of cyclopentadiene, but with the object of obtaining the ultimate hydrogenation product, cyclopentane [4-8].

TABLE

Experiments on the Hydrogenation of Cyclopentadiene (15 g of Raney nickel, initial pressure 70-80 atm, temperature about 20°).

Experiment	Amount of alcohol (ml)	Amount of cyclopentadiene (moles)	Hydrogen absorbed (moles)	Molar ratio of hydrogen absorbed to cyclopentadiene taken	Yield of cyclopentene (%)*
1	80	1.05	0.95	0.9 : 1	52
2	50	1.14	1.09	0.96 : 1	63
3	50	1.17	1.17	1 : 1	65
4	25	1.0	1.0	1 : 1	65
5	25	1.0	1.0	1 : 1	68
6	—	1.20	1.20	1 : 1	70
7	—	1.17	1.17	1 : 1	70

* Yield of cyclopentene isolated after fractionation through a 40-plate column.

With the object of establishing a preparative method, we carried out experiments on the hydrogenation of cyclopentadiene under pressure at room temperature in presence of Raney nickel, i.e. under the conditions for the preparation of cyclopentane [8], but with arrest of the process when one molecular proportion of hydrogen had been absorbed. In each experiment we took 66-88 g of cyclopentadiene and 15 g of catalyst. It was found that, under such conditions, the process went in a fairly selective fashion, and fractionation of the catalyzate through a column gave pure cyclopentene in yields of up to 70 % together with small amounts of unchanged cyclopentadiene (in the head fraction) and cyclopentane (in the residue from distillation). The results of some of the experiments are given in the table.

EXPERIMENTAL

Cyclopentadiene (b.p. 40-42°) was prepared by the depolymerization of technical dicyclopentadiene [fraction of b.p. 68-70° (19-20 mm)].

Catalyst was prepared from a 1:1 nickel-aluminum alloy, which was broken down into pieces of about 5 mm in size. One-half of the aluminum present in the alloy was leached out with alkali. All experiments were carried out over the same portion of catalyst; its activity was usually preserved until it broke down into a powder as a result of use.

Hydrogenation Experiments were carried out in a 250-ml stainless steel rotating autoclave. Catalyst (15 g), freshly distilled cyclopentadiene (66-80 g), and in some cases solvent were placed in the autoclave, hydrogen was blown through, and a pressure of 70-80 atm of hydrogen was then established in the autoclave. At first absorption of hydrogen was at the rate of 5-6 liters per hour, but owing to warming of the mixture by heat of reaction the rate of absorption increased after 20-25 minutes; after a second portion of hydrogen had been pumped in the rate of absorption attained 25-30 liters per hour. When the autoclave became hot, it was cooled to room temperature before the next charge of hydrogen. It was found that for an initial hydrogen pressure of below 50 atm there was no appreciable rise in temperature and hydrogen was absorbed at a rate of only 8-9 liters per hour.

After the absorption of 1 mole of hydrogen per mole of cyclopentadiene (it is convenient to use a manometer graduated in atmospheres), the autoclave was cooled with running water and excess of hydrogen was allowed to escape. The contents of the autoclave were removed, and the catalyst was washed with alcohol, the washings being added to the hydrogenation product. The catalyst was preserved under alcohol for use in the next experiment. The whole hydrogenation process generally occupied 1.75-2 hours. The reaction product was washed with water, dried with calcium chloride, and distilled through a 40-plate column filled with single turns of a nichrome spiral. The yield of cyclopentene are given in the table, its constants were b.p. 44.0° (760 mm), n_D^{20} 1.4222; d_4^{20} 0.7715. The literature [9] gives b.p. 44.2-44.4°, n_D^{20} 1.4228, and d_4^{20} 0.7713.

SUMMARY

A convenient laboratory method is proposed for the preparation of cyclopentene by the hydrogenation of cyclopentadiene. Yields of up to 70% are obtained.

SYNTHESIS AND REACTIONS OF VINYL COMPOUNDS OF SILICON

COMMUNICATION 2. CATALYTIC VINYLATION OF HALO- AND ALKYLDIHALO-SILANES CONTAINING SILICON-ATTACHED HYDROGEN

M. F. Shostakovsky and D. A. Kochkin

We have previously shown that it is possible to vinylate alkyldihalosilanes containing silicon-attached hydrogen according to the reaction $CH \equiv CH + HSiR_3 \rightarrow CH_2 = CHSiR_3$, in which R may be halogen, alkyl, aryl, alkoxy, etc. [1]. In this way we prepared dichloromethyl- and dichloroethyl-vinylsilanes $CH_3CH_2 = CH)SiCl_2$ and $C_2H_5(CH_2 = CH)SiCl_2$. These substances were synthesized in an autoclave at a pressure of 20-30 atm by reaction between the alkyldichlorosilane and acetylene at 170-200°. Trichlorovinylsilane can be prepared also by direct synthesis, vinyl chloride being passed over a copper-silicon alloy at 350-400° [2]. The present paper describes a catalytic method for the preparation of trichlorovinylsilane, dichloromethylvinylsilane, and dichloroethylvinylsilane from the corresponding halosilanes and acetylene. The reaction was carried out in an electrically heated catalysis tube, a mixture of acetylene and halosilane being passed over a catalyst of palladium supported by alumina at 260-300°. Other catalysts can be used: platinum on alumina, on calcium or barium carbonate, or on silica gel, and palladium on the same carriers.

This method appears to be a new one: it is not described in the literature. It has the advantage that the reaction is carried out without the application of pressure, so that the synthesis is safe and is easily carried out on an industrial scale. The yields are higher: for all three products the catalytic method gives yields of 45-50%, whereas vinylation in an autoclave gives yields of 30-40%. The formation of the products can be represented as follows:

$$HSiCl_3 + CH \equiv CH \rightarrow CH_2 = CHSiCl_3 \quad (1)$$

$$RSiHCl_2 + CH \equiv CH \rightarrow R(CH_2 = CH)SiCl_2 \quad (2)$$

By-products are formed in the reaction as follows:

$$Cl_3SiCH = CH_2 + HSiCl_3 \rightarrow ClSiCH_2CH_2SiCl_3 \quad (3)$$

$$(Cl)_2RSiCH = CH_2 + HSiRCl_2 \rightarrow Cl_2RSiCH_2CH_2SiRCl_2 \quad (4)$$

Other compounds can also be formed in the course of the reaction:

$$\begin{matrix} Cl & & & & Cl \\ | & & & & | \\ RSiCH = CH_2 + CH \equiv CH \rightarrow R - SiCH = CHCH = CH_2 \\ | & & & & | \\ Cl & & & & Cl \end{matrix} \quad (5)$$

or (6)

The apparatus used for the vinylation consisted of an electric muffle tube furnace, a stainless-steel catalysis tube, length 600-700 mm and diameter 18 mm, sulfuric acid and calcium chloride drying vessels, receiver, and reflux condenser attached to a trap cooled with solid carbon dioxide and acetone. Fractionation of the reaction products was carried out in a fractionation column 150 mm in height with a metal filling (20 theoretical plates).

EXPERIMENTAL*

1. Preparation of Catalyst (Palladium on Alumina). Alumina (13 g in the form of 3 mm × 3 mm cylinders) was impregnated with an aqueous solution of 0.18 g of palladium chloride. The palladium chloride solution was evaporated to dryness on the alumina with constant stirring in a porcelain dish. The material was then transferred to the reaction tube and heated in a stream of hydrogen at 260-300° for 3-4 hours. The palladium chloride was then reduced to metallic palladium. Before being passed into the tube, the hydrogen was dried with calcium chloride and sulfuric acid. Catalyst prepared in this way contained 0.8% of palladium.

2. Preparation of trichlorovinylsilane by the vinylation of trichlorosilane. A gaseous mixture of trichlorosilane [b.p. 31-33° (756 mm); Cl content 78.42%] and acetylene was passed at 260-300° through the reaction tube in which the catalyst was spread over the whole length of the tube. The acetylene was first dried by passage over calcium chloride. The mixing of acetylene and trichlorosilane was effected in a graduated Tishchenko vessel containing trichlorosilane. Acetylene passed through the vessel picked up the required amount of trichlorosilane, which was passed into the reaction tube at 20-25 ml/hour. The extent to which the acetylene reacted was determined by the rate at which it left the vinylation apparatus. In the course of three hours, 60 g of condensate was obtained. Fractionation and analysis showed that the reaction products included 1) 25.2 g (42% on weight of condensate) of unchanged trichlorosilane, b.p. 32-35° (756 mm); 2) 21.3 g (35.5% on weight of condensate and 51.3% yield on the amount of trichlorosilane that reacted) of trichlorovinylsilane, b.p. 92° (742 mm), n_D 1.4350; and d_4^{20} 1.2650; 3) 5.8 g (9.8% on weight of condensate) of 1,1,1,4,4,4-hexachloro-1,4-disilabutane $Cl_3SiCH_2CH_2SiCl_3$, b.p. 200.5° (748 mm); and 4) 6.9 g (11% on weight of condensate) of high-boiling products.

3. Preparation of dichloromethylvinylsilane by the vinylation of dichloromethylsilane. A mixture of dichloromethylsilane (b.p. 41.0-43.0°, d_4 1.1047) and acetylene was passed through a tube containing the same catalyst at 260-280° for three hours; 70 g of dichloromethylsilane was passed and 65.0 g of condensate was collected. Fractionation of the reaction products through a column gave 1) 24.0 g (40% on weight of condensate) of dichloromethylsilane; 2) 24.3 g (45% yield on the amount of dichloromethylsilane that reacted) of dichloromethylvinylsilane, b.p. 91° (742 mm), n_D^{20} 1.4270 and d_4^{20} 1.0868; 3) 6.3 g of 2,2,5,5-tetrachloro-2,5-disilahexane

, b.p. 72-73.0°, n_D^{20} 1.4760, and d_4^{20} 1.2628; 4) 9.3 g of high-boiling products.

4. Preparation of dichloroethylvinylsilane by the vinylation of dichloroethylsilane. Acetylene was passed into the tube containing alumina-supported palladium from a cylinder, and 84.5 g of dichloroethylsilane (b.p. 74.5-76.0° (756.0 mm), n_D^{20} 1.4129, and d_4^{20} 1.0849) was added from a graduated buret through a side tube; reaction was at 260-270° for 4.5 hours. Fractionation of the 75.0 g of condensate gave 1) 35.0 g (46.6% on the weight of condensate) of unchanged dichloroethylsilane; 2) 20.7 g (34.8%) of dichloroethylvinylsilane, b.p. 118.5-119.5° (756 mm), n_D^{20} 1.4385, and d_4^{20} 1.0664); 3) 3.5 g (4.7% on the weight of condensate) of 3,3,6,6-tetrachloro-3,6-disilaoctane, b.p. 100-102° (8 mm), n_D^{20} 1.4790; and d_4^{20} 1.187; 4) 13.0 g (17.2% on the weight of condensate) of high-boiling products.

* V. V. Vinogradova, a student of Irkutsk State University, took part in the experimental work.

We consider that this method will be applicable to the vinylation of aryldihalosilanes.

SUMMARY

1. It was shown that halo- and alkyldihalo-silanes containing silicon-attached hydrogen (trichlorosilanes, dichloromethylsilane, and dichloroethylsilane) can be vinylated by passing them together with acetylene through a catalysis tube at 260-300°.

2. This method does not require the application of pressure and is technically simple.

ROLE OF HYDROGEN DISULFIDE IN THE VULCANIZATION PROCESS

E. I. Tinyakova, E. K. Khrennikova, and B. A. Dolgoplosk

In a previous investigation [1] we have shown that many vulcanization accelerators, including ethylenediamine and its derivatives, ethanolamines, and hydroxy carbonyl compounds, react with sulfur at the vulcanization temperature with formation of hydrogen sulfide as main product. On anlogy with many oxidation-reduction systems in which oxygen takes part and reacts through the stage of hydrogen peroxide, the reaction of sulfur with vulcanization accelerators can be regarded as follows:

in which DH_2 is the vulcanization accelerator.

The species responsible for the initiation of the vulcanization process are ·SH radicals formed by the breakdown of hydrogen disulfide or hydrogen polysulfide. The breakdown of hydrogen disulfide in rubber solution at 50-70° results in the transformation of the rubber into a gel [1]. Its breakdown in paraffins and aromatic hydrocarbons leads to quantitative separation of hydrogen sulfide and sulfur [1,2]. We have shown that in the breakdown of hydrogen disulfide in α-olefins (styrene, α-methylstyrene, 1-pentene, and isoprene), which act as acceptors for free radicals, reaction proceeds at 50-70° without formation of hydrogen sulfide and sulfur, but with formation of addition products (mono-, di-, and tetra-sulfides).

The suppression of the reaction leading to evolution of hydrogen sulfide is associated with trapping of the intermediate breakdown product (the ·SH radical) by unsaturated compounds. Similar effects are observed when sulfur reacts with monoethanolamine in 1-pentene or α-methylstyrene solution at 130°. In ethylbenzene solution this reaction leads to the evolution of 80% of the theoretical amount of hydrogen sulfide. In the α-olefins, only addition occurs without formation of hydrogen sulfide. The table gives the compositions of products obtained by reaction of hydrogen disulfide with 1-pentene and of sulfur with monoethanolamine in presence of 1-pentene.

The formation of mono- and poly-sulfides is associated only with the formation of active intermediate products of the breakdown of hydrogen disulfide, for hydrogen sulfide does not add to the double bond in absence of free radicals. The formation of the products indicated can be explained on the assumption that HS· and HS_2· radicals take part in the initiation and development of the process.

EXPERIMENTAL

Hydrogen disulfide, b.p. 75°, was prepared by fractional distillation of hydrogen polysulfide [3]. 1-Pentene was prepared from ethyl bromide and allyl chloride [4]; it had b.p. 30°, n_D^{20} 1.3720; and d_4^{20} 0.6589. Isoprene, styrene, and α-methylstyrene were freed from stabilizer by shaking them with sodium hydroxide solution, after which they were washed with water, dried, and distilled.

The reactions were carried out in sealed tubes in a nitrogen atmosphere. At the end of the period of heating the tubes were cooled to −78° and H_2S was removed. The completeness of the decomposition of H_2S_2 was determined by shaking with $CdCl_2$ solution: absence of a precipitate of CdS_2 indicated complete decomposition of

TABLE

Compositions of the Products of the Reaction of 1-Pentene with Hydrogen Disulfide and with Sulfur and Monoethanolamine*

* Data from literature and calculated molecular weights and compositions are given in parentheses.

H_2S_2. In the solution, after treatment in this way, the mercaptan content and the total amount of elementary and polysulfide sulfur were determined [5]. 1-Pentene was distilled off, and the residue was vacuum-fractionated.

SUMMARY

It was shown that the breakdown of hydrogen disulfide in α-olefins results in the exclusive formation of addition products (mono-, di-, and tetra-sulfides) without formation of hydrogen sulfide and free sulfur. Similar results were obtained when sulfur reacted with monoethanolamine (vulcanization accelerator) in α-olefin solution.

The reaction products were isolated and characterized.

CURRENT EVENTS

SECOND JOINT SCIENTIFIC SESSION OF THE CHEMICAL INSTITUTES OF THE TRANSCAUCASIAN ACADEMIES OF SCIENCES

A little more than two years ago, the First Joint Scientific Session of the Chemical Institutes of the Georgian, Azerbaidzhanian, and Armenian Academies of Sciences was held in Tbilisi. This session resolved to hold sessions of this sort systematically and to hold the next session in Baku.

The Second Joint Session took place on April 23-27 in the capital of Soviet Azerbaidzhan, Baku. It was opened by the president of the Azerbaidzhanian Academy of Sciences M. M. Aliev, who praised the initiative of chemists in calling joint scientific sessions, which would help to establish closer scientific relations between chemical and industrial workers. He expressed the hope that the work of the session would be fruitful.

The nineteen papers read at the session were devoted to current chemical problems closely associated with the demands of the national economy. Most of the papers contained new and important data relating to the chemical characteristics and possible utilization of the natural resources of the three Transcaucasian republics.

Much attention was attracted by the paper of the delegate to the Twentieth Congress of Communist Party of the Soviet Union Yu. G. Mamedaliev, academician of the Azerbaizhdanian Academy of Sciences. He discussed immediate tasks in the development of the petrochemical industry in the light of the resolutions of the Twentieth Congress of the Communist Party. The speaker drew attention to promising future prospects in the development of the manufacture of such important products as fertilizers, toxic substances, synthetic alcohol, detergents, synthetic fibers, etc. on the basis of petroleum.

Several papers were devoted to adsorption and catalysis (Yu. G. Mamedaliev, M. A. Dalin, A. Z. Shikhmamedbekova, T. I. Mamedov, Z. G. Zulfugarov, G. V. Krmoyan, G. I. Mikaelyan, Kh. I. Areshidze, and G. V. Tsitsishvili); new data were presented on the characteristics of various catalysts and adsorbents for several adsorption and catalytic processes of great practical importance. The papers by A. T. Babayan, B. K. Zeinalov, R. M. Lagidze, Sh. M. Mamedov, and L. D. Melikadze discussed the splitting of quaternary ammonium compounds, the complex utilization of the products in the paraffinous distillate, the alkylation of benzene with acetic esters, the synthesis and reactions of α-halo esters, and the nature of the petroleum aromatics of high molecular weight. Papers on the structure-mechanical properties and utilization of clay suspensions in oil-drilling were given by A. K. Miskarli, A. M. Gasparyan and A. P. Zaminyan, M. M. Gurvich, and L. A. Abduragimova. Papers by I. L. Bagbanly and E. M. Nanobashvili were concerned with various questions of chemical analysis and the geochemistry of copper, gallium, and germanium. The papers by M. V. Darbinyan and M. Nalchadzhanyan concerned the utilization of magnesia raw material and the mechanism of the corroding of electrodes in the electro-melting of glass.

The papers prompted lively discussions, in which the chemists of Azerbaidzhan took an active part. Hopes were expressed for the further development of various theoretical investigations and the application of the results of some of the investigations in industry. The speakers were unanimous in their praise of the excellent organization of the session under the guidance of the Azerbaidzhanian Academy of Sciences and the Institute of Chemistry of the Azerbaidzhanian Academy of Sciences.

The results of the session were summarized by the director of the Institute of Chemistry of the Azerbaidzhan Academy of Sciences, G. Kh. Efendiev. He pointed out that the session had made possible an exchange of experience and the further strengthening of the creative bond between Transcaucasian chemists. At the same time the lines along which joint work should proceed in future were laid down. The session approved of the papers

presented and took note of the fact that the Institutes of Chemistry of the Academies of Sciences of the three Transcaucasian republics are carrying out work in fields of immediate importance in chemistry associated with the demands of the national economy. It was resolved that the questions for joint work should be recorded and the transactions of the session should be published. The next session is to be in Erevan in 1957.

The participants in the session made themselves acquainted with the work of various scientific establishments and industrial concerns and with the noteworthy sights of the city of Baku.

Salutation to Semen Isaakovich Volfkovich

The Division of Chemical Sciences of the Academy of Sciences of the USSR and the Editorial Board of the Bulletin of the Academy of Sciences of the USSR, Division of Chemical Sciences congratulate you on the attainment of the age of sixty years and the completion of thirty-five years of varied activities in science, teaching, and the organization of scientific work.

Your investigations on the chemistry and technology of phosphorus, phosphoric acid and its salts, and nitrogen, potassium, and fluorine compounds are widely known among chemists.

We wish you good health, continued creative activity, and further successes in all the fields in which you work.

GENERAL AND INORGANIC CHEMISTRY

"COMPLEX" REDUCTION OF MULTIMETAL IRON AND NICKEL ORES AS A BASIS FOR NEW METHODS FOR THEIR CHEMICAL TREATMENT

G. G. Urazov and D. P. Bogatsky

In order to provide industry with a broader basis of ores and other raw materials and to effect "complex" utilization of raw materials (i.e., rational, simultaneous utilization of all useful components)– as required by the directives of the Twentieth Congress of the Communist Party of the Soviet Union– Soviet chemistry must solve some very important problems, the solution of which will contribute to the progress of chemical technology. Among these problems, the study of new sources of raw material and the development of new methods for their rational utilization are of primary importance. Accordingly, for some years we have been investigating the problem of the efficient utilization of low-grade complex multimetal iron and nickel ores by methods in which chemical treatments follow "complex" direct reduction. The problem of developing new chemical treatments must be solved in such a way that it is possible to extract not only iron, but also nickel, cobalt, chromium, vanadium, etc., in the form of finished products from these ores. As we have shown, such "complex" methods are provided by hydrometallurgical and chlorine-gas treatments, by means of which all the above-mentioned metals can be extracted from the reduced ores.

Processes of selective reduction of iron from its oxides and ores have been investigated in fair detail. Considerably less study has been devoted to the reduction of the other metals that can be extracted from complex iron ores. We have made a detailed study of the behavior of nickel in the direct reduction of low-grade and waste complex iron and nickel ores under various conditions.

The complex iron-nickel ores of the Urals contain nickel in the form of oxide, oxide-silicate, and sulfide minerals. The nickel oxide minerals (bunsenite, texasite, etc.), which are various non-siliceous nickelous compounds, exist in the complex ores mainly in the "impregnation" state and contain a rather small part of the total amount of nickel present. In complex iron ores most of the nickel is present as oxide-silicate minerals, which are magnesium-nickel and magnesium-iron-nickel hydrosilicates and hydroaluminosilicates of variable composition and having a metacolloidal character; they are mineral gels, i.e., ultimate products of all normal weathering of peridotites and serpentinites that have not undergone previous transformations and have not been subjected to a thermal treatment. They include garnierite (Ni, Mg)O·SiO_2·H_2O, which contains up to 45% of nickelous oxide; nepouite-revdinskite-3 (Ni, Mg)O·$2SiO_2$·$2H_2O$, which contains about the same amount of nickelous oxide; nickel cerolite (Mg, Ni)O·SiO_2·H_2O which contains up to 1% of nickelous oxide; nickel deweylite-4 (Mg, Ni)O·$3SiO_2$·$3H_2O$, which contains up to 5% of nickelous oxide; nickel aluminosilicate; and aidyrlite, the chemical formula of which has not yet been determined – it contains up to 32% of nickelous oxide. Nickel is found in complex iron ores not only in these silicate minerals, but also, in the impregnation state, in nontronite $0.5RO(Al, Fe)_2O_3 \cdot 8SiO_2 \cdot 3H_2O$, in which RO = MgO, CaO, and NiO, the nickelous oxide content being 3–5%, and in serpentine $3MgO \cdot 2SiO_2 \cdot 2H_2O$, which contains up to 1% of adsorbed nickelous oxide. Nickel frequently occurs also in asbolan $MnO \cdot MnO_2 \cdot nH_2O + CoO + NiO$, which may contain up to 10-12% of nickelous oxide in the impregnation state.

Magnesium nickel hydrosilicates and aluminosilicates of variable composition, and also hydrated nickelous oxide and other non-siliceous nickel compounds are by no means invariably present in complex iron ores in a clearly individualized form. Most frequently, they are finely dispersed through the whole mass of these ores and very frequently permeate the various mineral ingredients of the gangue, which contains, in particular, quartz, chalcedony, opal, and other mineralogical modifications of silica. In accordance with the form in which nickel occurs (mainly in the oxide state in all ores which contain iron and cobalt), D. P. Bogatsky classifies complex iron-nickel ores as follows: 1) oxide ores, in which nickel is present mainly as hydrated nickelous oxide, sulfate,

and other mainly nonsiliceous oxide minerals, and in which iron and cobalt are present as oxides; 2) oxide-silicate ores, in which nickel is present mainly as magnesium nickel hydrosilicates and hydroaluminosilicates of variable composition but partly as nonsiliceous oxide minerals, and in which iron and cobalt are present mainly as oxides; 3) oxide-sulfide-silicate minerals, which contain iron and nickel as silicate and oxide compounds, and also as sulfides.

EXPERIMENTAL

Physicochemical investigations that we carried out on ten different complex iron ores showed that iron, nickel, and cobalt were present as oxides and silicates and that it is desirable and, in principle, possible to employ the process of complex direct reduction as a general technological basis for the extraction of all iron–group metals from these ores. In order to determine the optimum conditions for carrying out this process in practice, experimental and theoretical studies were made of largely uninvestigated processes of calcination and direct reduction of oxide and silicate nickel compounds and minerals, and also of the reduction of iron-nickel ores with hydrogen, carbon monoxide, a mixture of carbon monoxide and dioxide, and carbon.

Fig. 1. Phase diagram of the nickel-oxygen system (Bogatsky).

An investigation of the phase diagram of the nickel-oxygen system (Fig. 1), carried out with the object of identifying the forms in which nonsiliceous nickel compounds may be present in complex iron ores, showed that nickelous oxide, nickelic oxide, and nickel dioxide occur together with continuous series of solid solutions between these. An experimental and theoretical study of the dissociation of these oxides and their solid solutions at high temperatures provided an explanation for the results of a study of the rational chemicometallurgical composition of the nonsiliceous nickel compounds in complex iron ores. It was established that, at the very beginning of the process of calcination in the course of direct reduction under practical conditions, together with removal of adsorbed and constitutional water of crystallization, dehydration of nonsiliceous nickel oxide minerals occurs. These processes together with the inevitable dissociation processes occurring in oxides other than nickelous oxide and in nonsiliceous nickel compounds, if they are present in the ore, finally result in the formation of only nickelous oxide, or its solid solutions with nickelic oxide. Hence, at the temperatures required for rapid direct reduction, of the various nickel minerals in complex oxide-silicate iron ores the following partially or wholly dehydrated minerals react: nickelous oxide and its solid solutions with nickelic oxide, and also magnesium-nickel and magnesium-iron-nickel silicates and aluminosilicates, the reduction of which was submitted to investigation.

The main results of our experimental and theoretical investigations of direct-reduction processes on these nickel-containing components of complex iron ores are given briefly below. Experimental investigations of the equilibrium in the reaction of reduction of nickelous oxide with hydrogen showed that the equilibrium constant for this reaction $K_p = P_{H_2O} : P_{H_2}$ varies from 15.2 at 450° to 75.9 at 1000° in accordance with the equation $\log K_p = -\frac{1169}{T} + 2.803$ (Fig. 2). Experimental investigation of the equilibrium in the reduction of nickelous oxide with carbon monoxide showed that the equilibrium constant for this reaction $K'_p = P_{CO_2} : P_{CO}$ varies from 554.6 at 500° to 57.2 at 1100° in accordance with the equation $\log K'_p = \frac{1735.1}{T} + 0.49935$ (Figures 3 and 4), which has been confirmed by other authors.

The temperature at which reduction of nickelous oxide by hydrogen begins to become appreciable is about 229-230°, and for reduction with carbon monoxide it is about 344-346°. Complete reduction of nickelous oxide with hydrogen is attained at 700° in three hours and at 800° in one hour (Fig. 5). At 900°, complete reduction of nickelous oxide is attained in one hour (Fig. 6). Solid solutions of nickel oxides begin to be reduced

at lower temperatures - depending on their compositions. For the solid solution of nickel oxides obtained by calcination of the nitrate to constant weight in air at 600°, reduction by hydrogen begins at about 111-112°, complete reduction being complete in two hours at 700°. The temperature at which the same solid solution begins to be reduced by carbon monoxide is about 120-122°, and complete reduction is attained in one hour at 900°.

Fig. 2. Temperature-dependence of equilibrium in the reaction $NiO + H_2 = Ni + H_2O$ (Bogatsky).

Fig. 3. Temperature-dependence of equilibrium in the reaction $NiO + CO = Ni + CO_2$; 1) Bogatsky, 1935; 2) Smirnov, 1941; 3) Fricke and Weitbrecht, 1942.

On the basis of the experimental equilibrium data, thermodynamic investigations were carried out. These yielded the following: equations for the temperature-dependence of enthalpy and free energy changes for the reversible reactions of reduction of nickelous oxide by carbon monoxide:

$$\Delta H = -46\,000T^{-1} - 9.21T + 0.0_2492T^2 - 0.0_6627^3 + 12\,293:$$

$$\Delta F = 12\,293 - 23\,000T^{-1} + 21.21T\log T - 61.29T - 0.0_2492\,T^2 + 0.0_6317T^3:$$

and of reduction of nickelous oxide by hydrogen:

$$\Delta F = \frac{23\,000}{T} + 60.75T - 25.38T\log T + 0.0_2937T^2 - 0.0_699T^3 - 2193:$$

the heats of reaction and free energy changes for these reactions under standard conditions; the equation for the temperature-dependence of the free energy of the dissociation reaction (formation of nickelous oxide):

$$\Delta F = 23000T^{-1} - 27.54T\log T + 56.83T + 0.0_3772T^2 - 0.0_6627^3 + 55217:$$

the temperature-dependence of the dissociation pressure of nickelous oxide (Fig. 7); the heat of reaction ($\Delta H^\circ_{298.1} = -58285$ cal) and free energy change ($\Delta F^\circ_{298.1} = -52,591$ cal)for the formation of nickelous oxide, and its entropy under standard conditions ($S^\circ_{298.1} = 8.01$ cal/degree).

These experimental and theoretical investigations showed that nickelous oxide and its solid solutions are very readily reduced, so that previously dehydrated and calcined non-siliceous oxide minerals in complex iron ores are reduced considerably more readily than ferrous and ferrous-ferric oxides, but somewhat less readily than ferric oxide. The heat of the reduction of nickelous oxide with hydrogen is negative, but is extremely small. The heat of the reduction of nickelous oxide with carbon monoxide has a high positive value, i.e., this reaction is exothermic, like the reduction of ferric oxide with hydrogen or carbon monoxide at high temperatures. This fact is of great technological importance for the simplification of the comple direct reduction of iron ores under practical conditions.

Investigation of the reduction of nickelous oxide with carbon showed that the process is highly endothermic and can be detected thermographically from temperatures of about 585-600° and upwards. Almost complete reduction

of nickelous oxide is effected by carbon at about 950-1000°. The reduction of nickelous oxide to nickel in complex iron ores is, from the practical point of view, much less rational when carried out with carbon, rather than with gaseous reducing agents:

1) the process is completed in the temperature region in which iron undergoes rapid carburization with formation of austenite, so that spongy formations greatly contaminated with carbon are formed together with other undesirable impurities; 2) under these conditions, the reduction of nickelous oxide, like that of iron oxides, is highly endothermic, so that its practical realization is greatly complicated; 3) the reduced nickel (and also ferronickel) is considerably less active chemically than the more finely dispersed pyrophoric and extremely active nickel (ferronickel) obtained with appreciable cementation by gaseous reduction in the temperature region for the existence of iron in the α-modification. This was confirmed very clearly by the results of an investigation of the reduction processes of oxide-silicate minerals and complex iron ores.

Under given conditions, the reduction of oxide-silicate minerals with hydrogen and also with CO proceeds considerably more slowly than that of nickelous oxide. All the oxide-silicate minerals investigated are reduced by hydrogen and by carbon monoxide at below the temperature at which appreciable sintering occurs. Under given conditions, the extent to which the various silicate minerals of nickel are reduced varies. In one hour at 600,° the extent to which these minerals are reduced by hydrogen is already considerable, attaining 25-45% for garnierite, 61% for nepouite-garnierite, 32% for nickel cerolite, 42% for nickel deweylite, 37% for aidyrlite, and 55% for nickel aluminosilicate. With rise in temperature in the reduction process from 600° to 800° and with increase of the duration of the process to four hours, all these minerals are reduced to a considerably greater extent. On the other hand, a substantially different behavior is shown by these minerals in reduction processes at 900°, the effect being greatly dependent on the physiochemical nature of the mineral. For garnierite, nepouite-garnierite, and aidyrlite at 900°, the extent of reduction increases with increase in the duration of the reduction process, but the extent of reduction of nickel deweylite and cerolite at 900° diminishes appreciably as the duration of the reduction process is increased. This is to be explained by the effect of crystallization or recalescence (established thermographically), which occurs when these and similar magnesial silicates are heated at 800-900° In this temperature region the thermograms of deweylite, cerolite, and associated minerals of this class show considerable exothermic effects (Figures 8 and 9) which, according to x-ray investigation, is due to the crystallization or recalescence of a mineralogical component of the olivine type. The evolution of heat is due to appreciable increase in the grain size of the mineral, i.e., to the conversion of the substance from the amorphous or finely crystalline state into a more coarsely crystalline state, a change that is associated with a corresponding reduction in free energy and increase in entropy of the system.

In order to avoid the undesirable effects of this process on the extraction of the reduced metal, it is necessary and sufficient first to calcine the mineral at temperatures above the temperature established thermographically for the beginning of the exothermic crystallization effect; grinding and reduction may then follow. Hence, differential thermographic investigation of the physicochemical nature of silicate minerals indicates practical methods for improving the extraction of reduced metal from them. For those oxide-silicate minerals which give a crystallization effect in the differential thermographic investigation, almost complete extraction of nickel should be attained either a) by reduction of the minerals below the temperature of the crystallization effect, the other conditions of the reduction process being made as favorable as possible, or b) by reduction of these minerals after prior calcination at a temperature of not lower than the characteristic temperature for the beginning of the crystallization effect in the particular mineral. Complete reduction of oxide-silicate minerals is attained under the following conditions:

	Reduced with Hydrogen	Reduced with Carbon Monoxide
a) Garnierite	at 900° for 4 hr	
b) Nepouite-garnierite	at 800° for 3 hr	at 800° for 3 hr
c) Cerolite *	at 900° for 1 hr	at 900° for 2 hr
d) Deweylite *	at 900° for 0.5 hr	at 900° for 0.5 hr
e) Aidyrlite	at 900° for 0.5 hr	at 900° for 2 hr
f) Aluminosilicate	at 800° for 3 hr	at 900° for 0.5 hr

* Thermally treated.

Fig. 8. Thermogram of Akkerman nickel cerolite.

Fig. 9. Thermogram of Akkerman nickel dewylite.

All the investigated oxide-silicate minerals were reduced almost completely by hydrogen and by carbon monoxide in the temperature range 800-900°. Hence, in the process of direct gaseous reduction of complex iron ores, nickel can be almost completely reduced from all oxide and silicate minerals containing it at temperatures of about 900°, i.e., before sintering sets in the minerals that are to be reduced.

Investigation of the reduction of silicate minerals of nickel with carbon showed that this process becomes appreciable only at temperatures of about 770-800°, and becomes rapid only at temperatures at which crystallization effects occur in these minerals, so that the process tends to be inhibited. Under the conditions studied the maximum extents of reduction by carbon were as follows: a) for nepouite-garnierite – 83% at 1000° for 3 hours; b) for nickel dewylite – 69.0% at 1000° for 1 hour; c) for nickel cerolite – 47.8% at 1000° for 1 hour; and d) for nickel alumino-silicate – 73.7% at 1000° for 2 hours. Complete reduction of oxide-silicate minerals by carbon is not attained below the sintering temperature, and therefore the process of direct reduction with solid carbon is considerably inferior to the process of gaseous reduction in practicability and efficiency.

Investigation of the reduction process for eight different low-grade complex ores of iron-group metals from important worked deposits in the USSR showed that these ores can be reduced efficiently with gaseous reducers. At the beginning of the process of direct reduction, not only ferric oxide is reduced, but also non-siliceous oxide compounds of nickel, which are present in various amounts in these ores. The reduction of nickel from complex iron ores by means of hydrogen can therefore be detected to an appreciable extent already at 300°. Complete reduction of nickel from these oxide ores by means of hydrogen is attained at temperatures ranging from 400-500° to 800-900°, and the temperature for complete reduction bears an inverse relationship to the nickel content of the ore. Almost complete reduction of oxide-silicate ores with hydrogen is attained in the temperature range 900-1100°. Reduction of nickel from oxide complex ores with carbon monoxide becomes appreciable at 400°, and is almost complete at 600-700°, the temperature being dependent on the chemical and mineralogical compositions of the ore. Almost complete reduction of nickel from oxide-silicate ores by means of carbon monoxide is attained in the temperature range 900-1000°.

It was not found possible to reduce nickel with carbon from complex iron ores below the sintering temperature. The process of reducing complex iron ores with carbon before chemical-metallurgical treatment cannot therefore be recommended, for it is desirable to carry out this process without the sintering or melting of the ore to be reduced. Ferronickel reduced from complex iron ores with hydrogen has enhanced reactivity in various chemical-metallurgical processes, whereas ferronickel reduced from the ores with carbon monoxide or carbon is of low reactivity in such processes. Hence, when reduced ores are intended for subsequent chemical-metallurgical treatment with the object of the removal of gangue, it is undesirable to reduce them with carbon monoxide or carbon. The direct reduction of complex iron ores before chemical-metallurgical treatment should therefore be carried out with hydrogen, water gas enriched as much as possible in hydrogen, or natural and technical methane-containing gases after high-temperature conversion or cracking.

Apart from the proposed method of obtaining technical hydrogen from water gas, the following industrial methods of preparing hydrogen may be used: 1) conversion, i.e., reduction of steam with methane and other hydrocarbons (or carbon monoxide) at high temperatures; 2) cracking, i.e., thermal dissociation of methane at high temperatures; 3) the iron-steam method, i.e., thermal decomposition of steam under the action of iron at

high temperatures; 4) deep-freeze method; 5) electrolysis of water. Conversion and cracking are used for industrial and natural gases rich in methane and other hydrocarbons (and also carbon monoxide), but poor in nitrogen. The carbon dioxide obtained in the conversion process can be removed by washing with water at high pressure or by chemical absorption by ammonia and its compounds. The iron-steam method is associated with the necessity for periodic regeneration of the iron and is applicable to gases poor in methane, carbon monoxide, and hydrogen. The deep-freeze method is applicable to gases containing more than 50% of hydrogen (e.g., coke-oven gas). Electrolysis of water can be used in places where electrical energy is cheap.

Apart from purely gaseous reduction, combined processes may be of practical importance. Thus, according to the results of our investigations, the presence of steam and carbon dioxide in the reducing gas phase appreciably lowers the intensity of the reduction process, so that the introduction of some carbon (desirably peat coke) into the charge may be found to have a favorable effect. Such an addition will reduce the unfavorable effect of carbon dioxide and steam, which are always present in the sphere of reaction; these will react with carbon at high temperature with formation of carbon monoxide and hydrogen. This appears to be desirable also as a means for the removal of the deleterious effect of the air that is always present in the ore, and it is also desirable from the point of view of reducing any possible tendency for the ore to sinter at the temperatures required for the completion of the reduction of ores difficult to reduce. The drawing of air into the sphere of the reduction reaction, as may occur in practice, is by no means so harmful. Ground peat coke, and also reduced ferronickel, introduced into the ore to be reduced, has a catalytic accelerating effect at the appropriate high temperature on the conversion of methane and other hydrocarbons of industrial reducing gases, which are of low activity under the usual conditions. The hydrogen and carbon monoxide obtained in this way have an intensifying effect on the reduction processes.

Satisfactory plans for the complex direct reductions of iron ores may consist of specially designed multihearth roasters or rotary furnaces that ensure the attainment of the optimum conditions that we have established for the carrying out of this process on the large scale. A mechanical multihearth furnace has some advantages over a rotary furnace owing to the principle by which it operates; a more precise control can be kept over its functioning and it therefore gives more satisfactory trouble-free running under works conditions.

SUMMARY

1. Experimental and theoretical investigations were carried out on various processes for the complex direct reduction of multimetal iron and nickel ores, these processes being examined as a technological basis for the chemical treatment of the ores by methods that we have proposed.

2. This work established the theoretical and technological principles underlying the process of reducing these ores in such a way that the metals to be extracted show high reactivity in the subsequent chemical treatment.

3. The optimum conditions were found for carrying out the process efficiently under industrial conditions, and suggestions are made with regard to the plant required for the process.

ELECTRON-MICROSCOPE INVESTIGATION OF POLISH SANDOMIR SILICAS

E. A. Leontyev, V. M. Lukyanovich, and Z. Ya. Sokalsky

The extensive literature on problems relating to carriers bears witness to the great importance of this question for heterogenous catalysis. There are some catalytic processes in which carriers are of special importance, in particular the Fischer-Tropsch process for the synthesis of hydrocarbons. There is an extensive patent literature on the preparation of carriers from silicas [1]. Teichner [2] showed that treatment of a filtration silica with acid resulted in a 50% increase in specific surface.

The results of Teichner's investigations have been confirmed by work at the Institute of Chemical Synthesis in Oswencim. In the work of Sokalsky, Szota [3], and others on silicas, acid treatments were used, and the effect of the method of treatment on the catalytic properties of the catalyst was confirmed.

It follows from Teichner's work that increase in specific surface occurs on account of the formation of small amounts of gel by the action of acid on silica. Confirmation of Teichner's views can be found in the electron-microscope results of Perroux [4]. Catalyst activity has been ascribed also to the formation of small amounts of hydroxyl compounds of cobalt, and increase in specific surface has been ascribed to the separation of chemically bound water in the process of reducing the catalyst.

Apart from the problem of the action of acids on silica, the effect of alkaline treatment on the carrier during the wet formation of the catalyst is also a very important problem for the elucidation of the catalytic process. No electron-microscope studies have yet appeared in the literature which could give information on the changes undergone by the carrier in alkaline media. It was this circumstance that prompted the present work.

EXPERIMENTAL

Polish silica of the following average composition was used for the investigations:

SiO_2	90.10 wt.%
Al_2O_3	4.02 wt.%
Fe_2O_3	2.31 wt.%
CaO	0.94 wt.%
MgO	0.24 wt.%
Ignition loss	2.07 wt.%
	99.68 wt.%

A more complete characterization of the silica is to be found in the literature cited [5].

Two methods of investigation were used in the study of silica under the electron microscope: the direct transmission method, and the indirect, replica method. In the first case, the pieces of silica were shaken in distilled water giving a partially colloidal suspension, and this was allowed to settle for about 20 minutes. Several drops were then taken by pipet from the upper layer of the suspension and transferred to a supporting film fixed to the grid of the object carrier. After being dried, the objects were examined in a UEM-100 electron microscope.

We used also the replica method, which has the advantage that information can be obtained about the surface relief of undamaged particles of the preparation. The preparation of replicas from a silica surface is associated with considerable difficulties owing to the low mechanical strength of the silica and its high porosity. We therefore rejected the usual method of two-stage replicas and developed a method of one-stage carbon replicas that is applicable to samples of this sort [6].

Plates (~ 5 × 10 × 10 mm) were split from a piece of silica and placed under a bell jar, which was evacuated. The fresh surface formed by splitting was sputtered with carbon. The distance from the sample to the carbons was

10 cm, the current was 30-50 amp, and the duration of sputtering was 1.5-2 minutes. The film so formed on the silica surface was cut into 3 x 3 mm squares by means of a lancet, and the plate was placed in hydrofluoric acid. After dissolution of the silica, a carbon film remained on the surface of the acid, and this was transferred, for washing, to another vessel of pure hydrofluoric acid with the aid of a loop of gold wire. The replica was then washed in hydrochloric acid and in water, removed on a copper grid, and shadowed with chromium.

Alkaline tratment was carried out by attaching a piece of the silica to a nylon thread and immersing it in 1% aqueous potassium hydroxide solution. After one minute, the sample was removed from the alkaline solution, carefully washed in distilled water, and dried at 105°. A carbon replica was then prepared from it by the method described above.

Let us consider the results obtained. As will be seen from Fig. 1, transmission photographs show the silica particles in the form of thin plates that are semitransparent to the electron rays. The edges of the plates are not sharp, and the plates themselves show in the photographs in varying contrast. It is probable that these plates have a layered structure and consist of still thinner leaves, so that the silica particles under examination are reminiscent of a pack of playing cards displaced with respect to the vertical axis. The preparation has a hydrophilic character and is fairly readily peptized by the simple action of water.

A different picture is observed in the case of the replicas (Fig. 2). Stereoscopic examination is very useful here, for flat representations cannot give an adequate idea of the character of the surface. An examination of stereoscopic photographs (Fig. 2a) shows that the cleavage surface of the silica has a very rough relief. Many protruberances of the order of one micron in size can be seen, and these are broken up by crevices varying in width and depth. In some cases the surface of these protruberances appears to be smooth; it is probable that the protruberances are formed of layers of the fine plates shown in Fig. 1, into which the preparation is broken down when dispersed in an aqueous medium. The highly developed crevice formation that can be readily seen in the photographs may explain the high porosity of the silica and its low mechanical strength.

After alkaline treatment, a sharp change occurs in the structure of the silica surface (Fig. 3). The characteristic protruberances and crevices disappear, the surface becomes much smoother, and many fine, almost spherical particles appear on the surface (in Fig. 3 they can be seen in the form of bright spots). The particles are fairly constant in size, the linear dimensions lying in the range 200-300 A for the great majority of them.

The sharp change that is observed to occur in the surface relief of the silica can be explained as follows. As a result of the alkaline treatment, a layer of alkali silicate is formed on the silica surface, and simultaneous smoothing of the surface occurs as a result of the dissolution of protruberances. During subsequent washing in water, potassium silicate is hydrolyzed with separation of silicic acid:

$$K_2SiO_3 + 2H_2O \rightleftharpoons H_2SiO_3 + 2KOH$$

The free silicic acid forms a colloidal solution, the particles of which cover the pieces of silica, filling the crevices and still further increasing the smoothness of the surface. In the drying of the preparation we obtain a surface layer formed from silicic acid gel, i.e., we are concerned essentially with the same process of hydrolysis of alkali silicate as is used for the preparation of silica gel. It may therefore be expected that the particles observed on the replicas taken from alkali-treated silica will be similar to the particles that form the usual silica gels. This supposition was confirmed by recently published work by two authors of the present paper, in which it was shown that silica gel has a corpuscular structure [7]. By way of example we show a photograph of a replica taken from coarsely porous silica gel, on which the particles forming the silica gel are visible in the form of bright spots (Fig. 4). The undoubted resemblance between Figures 3 and 4 is evidence in favor of the concepts we have described.

It may therefore be considered that alkaline treatment of silica results in covering of its surface with round particles of silicic acid gel and conversion of the surface silica layers into silica gel. This phenomenon may have a considerable effect on the characteristics of the catalysts obtained, which will be dependent on the degree of hydrolysis of the silicate and the structural peculiarities of the silica gel formed. The described method of investigation opens up new possibilities for the study of carriers and the appraisal of their suitability for the preparation of catalysts.

SUMMARY

Silica was examined under the electron microscope – directly by transmission and indirectly in the form of carbon replicas – and the change in structure resulting from alkaline treatment was examined. It was found that the original silica has a lamellar structure with marked surface relief. After treatment with alkali and washing with water, its surface becomes covered with round particles about 100-200 A in size, a phenomenon which results from the hydrolysis of alkali silicate and separation of colloidal silicon dioxide.

STAGEWISE CHARACTER OF THE HYDROGENATION OF THE DOUBLE BONDS OF CYCLOPENTADIENE OVER RANEY NICKEL

L. Kh. Freidlin and B. D. Polkovnikov

The addition of hydrogen to the conjugated bonds of cyclopentadiene has been studied by various investigators. When cyclopentadiene is hydrogenated in alcoholic solution with "hydrogen at the moment of its separation" obtained by the action of hydrochloric acid on zinc, a mixture containing small amounts of cyclopentene and cyclopentane is formed [1]. When reduced with active hydrogen formed by the action of calcium hexamoniate, cyclopentadiene is hydrogenated only as far as cyclopentene. However, the yield of cyclopentene is low: most of the cyclopentadiene is polymerized [2]. Considerable dimerization occurs also when cyclopentadiene is reduced with sodium and alcohol [3]. Over a nickel catalyst at 180-200° [4] and over platinized charcoal at 100° and higher [5,6], cyclopentadiene is hydrogenated to cyclopentane. Over Raney nickel [7] at a hydrogen pressure of 60-70 atm, cyclopentadiene is hydrogenated to cyclopentane even at room temperature. Hence, under these various conditions cyclopentadiene has been hydrogenated to a mixture of cyclopentene and cyclopentane and also exhaustively to cyclopentane.

In a short communication [3] it is indicated that with a deficiency of hydrogen, cyclopentadiene in absolute ethanol at room temperature in presence of Raney nickel is hydrogenated to cyclopentene, which was determined by the Raman spectrum method. It was noted also that the reaction rate changed sharply after the absorption of one molecular proportion of hydrogen. However, the experimental procedure and conditions are not described in detail.

In preliminary experiments on the hydrogenation of cyclopentadiene under similar conditions, no sharp change in the course of the hydrogen-absorption curve was observed by us. The addition of the second molecular proportion of hydrogen also proceeded at a high rate. In the present investigation we have studied the stagewise character of the hydrogenation of the conjugated double bonds of cyclopentadiene and the effect of the solvent on the reaction kinetics. Alcohols and hydrocarbons were used as solvents. Our kinetic investigation and our analytical results show that, in presence of Raney nickel at room temperature, the hydrogenation of cyclopentadiene does indeed proceed in two stages. At first the whole of the cyclopentadiene is hydrogenated to cyclopentene, which then begins to combine with hydrogen with formation of cyclopentane. In an alcoholic medium both stages are very rapid. In hydrocarbon solvents the second stage is slow and the kinetic curve for the overall process has a marked point of inflection corresponding to addition of 50% of the hydrogen. The steeply falling branch of the curve corresponds to hydrogenation of cyclopentadiene to cyclopentene, and the horizontal branch to hydrogenation of cyclopentene to cyclopentane.

EXPERIMENTAL

Procedure and Experimental Conditions

The cyclopentadiene was hydrogenated at 25° in a glass hydrogenation flask fitted with a water jacket and inlet and outlet tubes, in one of which a No.3 filter was sealed. The flask was 180 mm in length and 30 mm in diameter. Hydrogenation was considered to begin from the time when the shaker motor was switched on. When the reaction was very slow, it was not always carried to completion. Agitation was at 900 shakes per minute with a shaker amplitude of 12.7 cm. It was established by special experiments on the hydrogenation of cyclopentadiene in cyclohexane that such agitation is quite sufficient to ensure that reaction proceeds in the kinetic region.

The cyclopentadiene used (b.p. 41-42°; n_D^{20} 1.442—1.4446), was prepared by the depolymerization of the dimer. The catalyst was Raney nickel prepared by leaching a nickel-aluminum alloy (50%) with 20% sodium

hydroxide solution for two hours at 100°. A new 0.42 g portion of catalyst was used in each experiment. The hydrogen used was electrolytic and was freed from traces of oxygen. Before the reaction the catalyst was saturated with hydrogen under the conditions (same temperature, solvent, and rate of agitation) used for the hydrogenation. In the experiments carried out in hydrocarbon solvents the catalyst was washed from the spoon into the flask with the aid of 10 ml of alcohol, alcohol was poured off, the catalyst was washed twice with 10 ml portions of the relevant hydrocarbon, and a weighted amount of the substance to be hydrogenated in 10 ml of hydrocarbon solvent was introduced. All such operations (introduction and washing of catalyst, decanting and filtering, introduction of the substance to be hydrogenated, etc.) were carried out in a current of hydrogen. Reaction rate and catalyst activity were estimated from the rate of absorption of hydrogen.

Hydrogenation of Cyclopentadiene in Methanol

The alcohol used had b.p. 64.5° and n_D^{20} 1.3290. The results show that hydrogenation of cyclopentadiene in methanol at 25° proceeds rapidly and is complete in 8-9 minutes (Table 1, Experiments 1 and 2). The amount of hydrogen used corresponds to complete hydrogenation of both double bonds with formation of cyclopentane. The half-period of hydrogenation of cyclopentadiene sample (0.0019 mole) was 1.2-1.3 minutes, and 43 ml of hydrogen was absorbed in the first minute. About 6-8 minutes was required for the absorption of the second molecular proportion of hydrogen (47-49 ml). In methanol, therefore, both double bonds of cyclopentadiene are comparatively rapidly hydrogenated.

Figures 1-5 give the kinetic curves for the hydrogenation of cyclopentadiene. As will be seen from Fig. 1a, from the kinetic curve for the hydrogenation of cyclopentadiene in an alcoholic medium it is impossible to form an opinion about stagewise addition of hydrogen to the conjugated double bonds of cyclopentadiene. Hence, in order to establish the stagewise character of the hydrogenation of cyclopentadiene, experiments were carried out in which reaction was arrested after the addition of about 50% of the hydrogen; solution was separated from catalyst and was tested for the presence of cyclopentadiene by the hydroquinone reaction [8]. The reagent was prepared by dissolving 0.3 g of hydroquinone in 50 ml of methanol. In the test for cyclopentadiene 1-4 ml of reagent was generally taken, and 1-2 drops of 10% NaOH was added; in presence of cyclopentadiene the solution acquired an intense green color, and in its absence the methanolic hydroquinone gave an orange coloration.

Special experiments showed that the hydroquinone reaction is very sensitive and permits the detection of cyclopentadiene in mixtures containing less than 1%. One drop of a cyclopentadiene solution (0.12 g in 10 ml of methanol) gives a dark-green, almost black coloration. Even at a concentration of 0.6 mg in 10 ml of cyclohexane (i.e., 0.5%), the result is an orange solution that rapidly becomes brownish green. The color of the solution gradually changes into brown with formation of flocs. Cyclopentene and other olefins do not affect the color of hydroquinone in presence of alkali and do not interfere in the test for cyclopentadiene.

It was shown by the hydroquinone test that cyclopentadiene was absent form the solution after the consumption of about 50% of the amount of hydrogen required for the conversion of cyclopentadiene into cyclopentane (45-47 ml instead of 94-95 ml) (Table 1, Experiments 3 and 4). Hence, in methanol at 25° in presence of Raney nickel, the hydrogenation of cyclopentadiene proceeds in two stages. All the cyclopentadiene is first hydrogenated to cyclopentene, which then begins to combine with hydrogen with formation of cyclopentane.

In order to confirm that in alcoholic solution the second stage also proceeds rapidly, special experiments were carried out. The results showed that in methanolic and ethanolic media cyclopentene is indeed hydrogenated at a high rate (Experiments 15-18).

Hydrogenation of Cyclopentadiene in Ethanol

The kinetic curve for the hydrogenation of cyclopentadiene in 96% ethanol is given in Fig. 1c. Comparison with the kinetic curves for Experiment 1 (Fig. 1a) and Experiment 5 (Fig. 1b) shows that in absolute ethanol the hydrogenation of cyclopentadiene proceeds at about the same rate as in methanol. The consumption of hydrogen corresponds to complete hydrogenation of cyclopentadiene to cyclopentane. The half-period of reaction (hydrogenation to cyclopentene) is 1.5 minutes with an initial rate of hydrogen absorption of 35.2 ml/minute. In character the kinetic curve for the hydrogenation of cyclopentadiene in absolute ethanol is similar to the curve for hydrogenation in methanol; there is no point of inflection.

Fig. 1. Hydrogenation of cyclopentadiene: a) in methanol; b) in absolute ethanol; c) in 96% ethanol; d) in 75% ethanol; e) in isobutyl alcohol; f) in hexyl alcohol

In an aqueous-alcoholic medium the reaction rate is greatly reduced. Thus, comparison of the kinetic curve for Experiment 5 in absolute ethanol (Fig. 1b) with the curves obtained in Experiments 7 and 8 (Figures 1c and 1d) in an aqueous-alcoholic medium shows that in 96% alcohol the rate of reaction is about 35% lower, and in 75% alcohol it is about 65% lower, than in absolute alcohol. In the case of 75% alcohol, the kinetic curve (Fig. 1d) shows a distinct inflection at the point corresponding to the absorption of 38.4 ml of hydrogen – which corresponds to about 50% of the hydrogen necessary to saturate the given sample of cyclopentadiene. The half-period of hydrogenation is 5 minutes. From this point the rate of hydrogen absorption falls: the second section of the curve is less steep than in the case of 96% ethanol. It may be supposed that the steeply falling part of the kinetic curve corresponds to hydrogenation of cyclopentadiene to cyclopentene, whereas the gently falling part represents the slower hydrogenation of the cyclopentene formed into cyclopentane. It was confirmed by the qualitative test that at the moment corresponding to the point of inflection on the kinetic curve cyclopentadiene was absent from the solution (Experiment 9).

Hydrogenation of Cyclopentadiene in Isobutyl, tert-Butyl, and Hexyl Alcohols.

The alcohols used had the following constants: isobutyl alcohol, b.p. 108°, n_D^{20} 1.3952; tert-butyl alcohol, b.p. 83°, n_D^{20} 1.3880; hexyl alcohol (fraction of b.p. 152-155° (743 mm) and n_D^{20} 1.4188).

In isobutyl alcohol (Table 1, Experiment 14) reaction proceeds at almost the same rate as in 96% ethanol (Fig. 1e). In tert-butyl and hexyl alcohols (Experiments 10 and 12) the rates of hydrogenation of cyclopentadiene are identical and are appreciably lower than in ethyl and isobutyl alcohols. The theoretically necessary amount of hydrogen adds in 30 minutes. The half-period of hydrogenation is 5 minutes. There is no inflection on the curve at the point for 50% addition of hydrogen (Fig. 1f). The qualitative reaction with hydroquinone showed that, in these solvents also, hydrogenation of cyclopentadiene proceeds in stages (Experiments 11-13).

Hydrogenation of Cyclopentadiene in Aromatic Hydrocarbons

The solvents used had the constants: benzene (thiophene-free), b. p. 79.6-80.6°, n_D^{20} 1.5008; toluene, b. p. 110.5°, n_D^{20} 1.4954; ethylbenzene, b. p. 136°, n_D^{20} 1.4960; isopropylbenzene (fraction of b. p. 150-151° treated with sulfuric acid; n_D^{20} 1.4910); m-xylene, b. p. 139°, n_D^{20} 1.4974; p-xylene, b. p. 138°, n_D^{20} 1.4960.

The kinetic curve for the hydrogenation of cyclopentadiene in benzene is given in Fig. 2a. The character of the kinetic curve for the hydrogenation of cyclopentadiene is benzene differs greatly from that for reaction in methyl and ethyl alcohols. The curve has a marked inflection at the point for the absorption of 47-50 ml of hydrogen, which is about 50% of the amount required to saturate the cyclopentadiene taken. After the point of inflection the rate of hydrogenation falls sharply.

As shown by the data in Table 2 (Experiments 4, 5, and 6), the half-period for hydrogenation of cyclopentadiene in benzene is 4 minutes. For the absorption of the remaining 50% of the hydrogen, 30-32 minutes is required. Such a reduction of the rate of hydrogenation of cyclopentadiene in benzene cannot be explained by poisoning of the catalyst owing to the polymerization of cyclopentadiene. A new sample of cyclopentadiene is rapidly hydrogenated on the used catalyst. Moreover, in the further hydrogenation of the solution over a $Pt/BaSO_4$ catalyst, the remaining 47-50 ml of hydrogen is absorbed very rapidly. Hence, the presence of an inflection on the kinetic curve and its position are due to the fact that the process proceeds in stages. The steeply falling section of the kinetic curve represents the hydrogenation of cyclopentadiene to cyclopentene and the gently sloping section represents addition of hydrogen to cyclopentene. With the aid of the qualitative hydroquinone reaction and Afanasyev's reaction [10] it was shown that cyclopentadiene is absent from the reaction mixture at the point for 50% hydrogen addition. This indicates the selectivity of the process and confirms the correctness of our interpretation of the character of the kinetic curve for the hydrogenation of cyclopentadiene in benzene.

In toluene (Experiments 7 and 8), ethylbenzene (Experiment 9), p- and m-xylenes (Experiments 10 and 11), and isopropylbenzene (Experiment 12), the character of the kinetics are in general the same as in benzene (Figures 2b, 2c, 2d, 2e, and 2f).

Hydrogenation of Cyclopentadiene in Naphthene Hydrocarbons

The cyclohexane used as solvent had b.p. 81° and n_D^{20} 1.4266. In cyclohexane, as also in benzene, hydrogenation of cyclopentadiene is considerably slower than in methanol. The kinetic curve for the hydrogenation of cyclopentadiene in cyclohexane is similar to the curve for its hydrogenation in benzene, but in the first case the inflection corresponding to addition of one molecular proportion of hydrogen is more sharply marked.

Fig. 2. Hydrogenation of cyclopentadiene: a) in benzene; b) in toluene; c) in ethylbenzene; d) in p-xylene; e) in m-xylene; f) in isopropylbenzene.

It was shown by Shuikin's [9] and Afanasyev's [10] qualitative reactions, and also by the hydroquinone method, that at the point at which about 50% hydrogen addition occurred in Experiments 18 and 19 (Table 2) cyclopentadiene was indeed absent from the solution. At 46-47% hydrogenation the reaction for cyclopentadiene was positive. Hence, again in cyclohexane stepwise saturation of the conjugated double bonds of cyclopentadiene occurs.

The sharp reduction in reaction rate after the absorption of 50% of the total amount of hydrogen required is due to the low rate at which cyclopentene is hydrogenated in cyclohexane. It was shown by special experiments

that, unlike the addition of hydrogen to cyclopentene in an alcoholic medium, addition of hydrogen in a cyclohexane medium is indeed very slow (Table 2, Experiment 24), and the character of the kinetic curve for the hydrogenation of cyclopentene is found to correspond to the horizontal section of the kinetic curve for the hydrogenation of cyclopentadiene to cyclopentane (Fig. 4). The half-period of hydrogenation of a sample of cyclopentene (0.0019 mole) in cyclohexane is 18 minutes, but in ethanol – 2 minutes (Table 2, Experiments 17 and 18). The character of the kinetic curve for the hydrogenation of cyclopentadiene in methylcyclohexane (Experiments 20 and 21) is the same as that for cyclohexane.

In an experiment with decahydronaphthalene (Experiment 22), after addition of about 50% of the total amount of hydrogen required, a qualitative test with hydroquinone showed only traces of cyclopentadiene in the solution, i.e., hydrogenation proceeded in stages. The rate of hydrogenation is lower in decahydronaphthalene than in cyclohexane. Thus, the half-period for the hydrogenation of an 0.08 g sample of cyclopentadiene was 11 minutes.

Hydrogenation of Cyclopentadiene in Heptane

The heptane had b. p. 98.4° and n_D^{20} 1.3880. The kinetic curve for the hydrogenation of cyclopentadiene in heptane is given in Fig. 5. It will be seen from Fig. 5 that the kinetic curve is similar to that obtained for reaction in cyclohexane. The process proceeds in stages. The first stage – hydrogenation to cyclopentene – proceeds at about the same rate as in absolute ethanol. The second stage – the hydrogenation of the cyclopentene formed into cyclopentane – proceeds very slowly in heptane solution.

Fig. 6. Fractionation curve.

Possibility of the Practical Preparation of Cyclopentene by the Partial Hydrogenation of Cyclopentadiene

As shown above, with small samples of cyclopentadiene it is easy to bring about hydrogenation in stages. It was of interest to determine whether it is possible to apply this method to the preparation of cyclopentene, which is generally prepared by a multistage synthesis from adipic acid. With this object, cyclopentadiene was hydrogenated in several portions, and in all 7.6284 g was hydrogenated with agitation in presence of 1.7 g of catalyst. After 50% of the theoretically necessary hydrogen (3450 ml) had been consumed, reaction slowed down considerably, and the reaction was interrupted. A test for cyclopentadiene was negative. The hydrogenation product was fractionated through a 30-plate column. The fractionation curve is given in Fig. 6. A fraction (5.4718 g) of b.p. 43.4-44.9° and n_D^{20} 1.4202 was isolated. The content of unsaturated hydrocarbons was 94%, and in the hydrogenation of 0.2596 g in presence of Raney nickel and ethanol at 20°, 88.1 ml of hydrogen was consumed instead of the 96.4 ml theoretically required. These properties of the hydrogenation product are close to those of cyclopentene. In this exploratory experiment, therefore, stagewise hydrogenation of the bonds of cyclopentadiene is found to be preserved when a large sample of the diene is hydrogenated.

SUMMARY

1. An investigation was made into the kinetics of the hydrogenation of cyclopentadiene in presence of Raney nickel at 25° and normal pressure in alcoholic and hydrocarbon solutions.

2. It was shown that cyclopentadiene is rapidly hydrogenated to cyclopentane in methyl, ethyl, and isobutyl alcohols.

3. In aromatic, hydroaromatic, aliphatic hydrocarbon solutions, cyclopentadiene is rapidly hydrogenated only as far as cyclopentene, and the second molecular proportion of hydrogen adds very slowly.

4. In all solvents examined, the conjugated double bonds of cyclopentadiene are hydrogenated successively. In hydrocarbon solvents the two-stage character of the process can be demonstrated also by kinetic methods.

5. Both in alcohol and in hydrocarbon solvents cyclopentene can be obtained from cyclopentadiene if the hydrogenation is arrested after the addition of one molecular proportion of hydrogen.

CATALYTIC ACTIVITY AND ACIDITY OF SILICA GEL TREATED WITH SOLUTIONS OF ALUMINUM SALTS

K. G. Miesserov

Acidic aluminosilicates are able to catalyze cracking reactions, polymerizations, redistribution of hydrogen, and various other reactions [1-5]. We have shown that the catalytic activity of aluminosilicates in the reaction of redistribution (disproportionation) of hydrogen is determined only by ions having exchange and hydrolytic acidity. It was established that a linear relationship exists between the amount of sodium ions absorbed from sodium chloride and sodium acetate solutions and the degree of conversion of cyclohexene (the extent of formation of saturated hydrocarbons), and this enabled us to determine, by extrapolation, the acidity characterizing the activity of the aluminosilicate catalyst [6].

However, the catalytic effects of various samples of aluminosilicates may not be proportional to the acidity determined in this way inasmuch as the activity of an aluminosilicate is determined not only by the chemical properties of its surface, but also by other, purely physical factors, such as its surface area and the character of its porosity. Silica gel is not a catalyst for the reactions mentioned above, but it becomes catalytically active after activation with aluminum ions*.

Frost and coworkers [8] showed that, in the activation of silica gel with alumina, the surface area and porosity characteristics of the gel were not affected. Hence, the varying activities of samples having various aluminum contents must be due entirely to different degrees of acidity.

EXPERIMENTAL

Samples of silica gel containing various amounts of alumina were prepared by treating finely porous KSM silica gel, which had been roasted at 450° for three hours, with aluminum salts by the following methods: 1) treatment with aluminum nitrate solutions of various concentrations and subsequent washing with water until the washings ceased to give a reaction for nitrate; 2) impregnation with a definite amount of concentrated aluminum nitrate solution; 3) treatment with $NAlCl_3$ neutralized to the extent of 25% with N NaOH** and subsequent washing with water until the the washings ceased to give a reaction for chloride; 4) treatment with a suspension of barium carbonate in N NaCl with subsequent displacement of absorbed sodium ions by aluminum ions by treatment with aluminum nitrate solution and washing with water to remove excess of salt. The duration of treatment and the volumes of the solutions of aluminum salts were also varied. The samples were dried at 100° and roasted for three hours at 450°. Some samples were prepared by treating coarsely porous silica gel with aluminum salts.

* The active complex formed in the activation of silica gel with aluminum ions is of the following form [7]

** When the sodium hydroxide solution is added to the aluminum chloride solution, a precipitate of aluminum hydroxide is formed, but this ultimately vanishes owing to the conversion of aluminum hydroxide into soluble basic aluminum compounds.

The aluminum contents and the exchange and hydrolytic acidities of the samples were determined by the methods described in previous papers [9,10]. The degree of conversion of cyclohexene (amount of saturated hydrocarbons formed) was taken as a measure of catalytic activity. The experiments were carried out in the usual apparatus employed for the study of catalytic processes during continuous flow.

Figure. Relation between the degree of conversion of cyclohexene and the exchange acidity of the samples of aluminosilica gel.

Table 1 gives the values of the exchange and hydrolytic acidities of the aluminosilica gel samples and the degree of conversion of cyclohexene in their presence.

It will be seen from the results that the activities of the samples are not characterized by the values of their hydrolytic acidity: the hydrolytic activities of samples treated with aluminum nitrate solutions did not differ from the hydrolytic acidity of the original silica gel. We therefore attempted to establish the character of the relationship between activity and exchange acidity.

A graph was constructed from the data in Table 1, the abscissae representing exchange acidity and the ordinates percent of saturated hydrocarbons formed. We see that catalytic activity is at first approximately proportional to exchange activity, but the slope of the curve then diminishes and it becomes almost parallel to the axis of abscissae.

TABLE 1

Acidity and Activity of Silica Gel Treated with Aluminum Salts

(Hydrolytic activity of original silica gel 27.6 mg-equiv/100 g. Experimental conditions in catalytic conversion: temperature 316°; volume of catalyst 30 ml; space velocity 2 hour $^{-1}$)

Method of activation		Exchange acidity (mg-equiv/100 g	Hydrolytic acidity mg-equiv/100 g	Yield of saturated hydrocarbons (%)
Treated with $Al(NO_3)_3$ solution	0,1 *N*	1.8	27.6	13.8
	0,2 *N*	3.0	27.6	20.9
	1,0 *N*	3.5	27.6	21.2
Impregnated with $Al(NO_3)_3$, solution so as to apply	1%	4.6	29.4	29.9
	3%	9.6	33.6	44.4
Treated with N $AlCl_3$ 25% neutralized with N NaOh for	1	9.6	34.2	42.8
	3 "	13.0	35.9	42.5
	7 "	18.0	39.6	47.2

We have attempted to explain the results of our experiments as follows. We have previously suggested [11], that silica gel surfaces contain hydroxyls as isolated groups and as pairs*. The two hydroxyls of each pair are equivalent, but if the hydrogen of one of the hydroxyls is replaced by a metal ion, the activity of the second hydroxyl falls, for the part of the silica gel structure in which the two hydroxyls occur attached to a silicon atom may be regarded as a dibasic acid for which the constant of the first stage of dissociation is much greater than that of the second.

Hence, only one of the hydroxyls of a paired group is active, and the second hydroxyls and isolated hydroxyls are inactive. The number of active hydroxyls is taken into account in the value of the hydrolytic acidity. When silica gel is treated with aluminum nitrate solutions, only a part of the active (hydrolytic) hydroxyls reacts. The hydrolytic acidity does not change, for the number of active aluminum ions displaced into the sodium acetate solution is equal to the number of hydrogen ions replaced by them. In this case, the hydrolytic acidity is the sum of the displaced hydrogen and aluminum ions, and catalytic activity increases as the proportion of aluminum ions in this sum increases. Maximum activity should be found in the sample in which hydrogen ions are replaced by aluminum ions in all hydrolytic hydroxy groups. It will in fact be seen from Table 2 that the sample obtained by treating silica gel with a suspension of barium carbonate in N NaCl and then with aluminum nitrate solution** and containing only active aluminum ions in amount closely equivalent to the hydrolytic acidity of the original silica gel had an activity close to the maximum obtained.

TABLE 2

Degree of Conversion of Cyclohexene over Aluminosilica Gel Having Various Aluminum Contents (Experimental conditions: temperature 320°; volume of catalyst 20 ml; space velocity 2 hour^{-1})

Method of activation		Aluminum content mg-equiv/100 g	Yield of saturated hydrocarbons (%)
Treated with $Al(NO_3)_3$ solution	0.1 N	6.5	16.8
	0.1 N	8.9	20.8
	1.0 N	12.4	28.2
Treated with suspension of $BaCO_3$ in N NaCl and then with N $Al(NO_3)_3$ for	2 days	17.2	37.6
	5 "	27.2	48.3
Impregnated with $Al(NO_3)_3$, solution so as to apply	1%	58.8	39.1
	3%	176.4	47.9
Treated with N $AlCl_3$ 25% neutralized with N NaOh for	1 day	64.2	48.7
	7 "	84.5	55.7

* We consider paired and isolated hydroxyls to correspond to the structures $>Si\langle^{OH}_{OH}$ and $-\overset{|}{Si}-OH$ respectively.

** By treatment of silica gel with a suspension of barium carbonate in sodium chloride solution, complete replacement of the active hydrogen ions with sodium ions can be attained because the acid liberated is neutralized by barium carbonate and reaction proceeds to completion [12]. By treatment with aluminum nitrate solution, the absorbed sodium ions are then replaced by aluminum ions.

All the active aluminum ions in a given sample of catalyst are equivalent: this is proved by experiments on the poisoning of aluminosilicate catalysts with sodium ions and pyridine [6,13]. This equivalence shows itself only at high temperatures under catalysis conditions. In an aqueous medium the active aluminum ions show variation in mobility: for example, not all of them can be replaced by sodium ions of NaCl solutions.

Increase in the amount of aluminum absorbed by silica gel may result in increase in exchange acidity not only because of increase in the number of active aluminum ions, but also because of increase in the mobility* of the already existing active aluminum ions in an aqueous medium: an aluminum ion, in taking up its place in the vicinity of an active aluminum ion, increases the mobility of the latter [11]. Hence, increase in exchange acidity does not necessarily result in a proportionate increase in catalytic activity.

The absorption of aluminum by silica gel during treatment with a solution of an aluminum salt proceeds as a result of interaction between hydroxyls of the silica gel and basic aluminum compounds [11,14]. In the sample prepared by impregnation with aluminum nitrate solution, not all of the aluminum is chemically bound to the silica gel: part of it is in the form of alumina and does not contribute to an increase in catalytic activity. Treatment with aluminum chloride solution that is partially neutralized with sodium hydroxide ensures that the whole of the aluminum absorbed becomes chemically bound to the silica gel. This is found to be the most efficient treatment. For example, a sample of coarsely porous silica gel (Table 3) obtained by impregnation with aluminum nitrate solution was almost inactive,, but the activity, calculated per unit weight, of a sample prepared by treatment of coarsely porous silica gel with aluminum chloride solution partially neutralized with sodium hydroxide was found to be even more active than finely porous silica gel activated by the same method. A sample treated in this solution should have maximum activity because all hydrogen ions in its active hydroxy groups are replaced by aluminum ions in such a treatment, i.e., the sample contains the maximum possible number of active aluminum ions. However, the data in Tables 1 and 2 show that with increase of the duration of treatment with fresh portions of the solution, the activity continues to increase somewhat. This is probably due to the fact that increase in the ability of active aluminum ions to undergo exchange partially affects catalytic activity, this being determined not only by the value of the acidity, but also by the dissociation constant of the acid.

TABLE 3

Degree of Conversion of Cyclohexene over Coarsely Porous and Finely Porous Aluminosilica Gels (Experimental conditions: temperature 316°; volume of catalyst 30 ml; space velocity 2 hour^{-1})

Method of activation	Silica gel sample	Weight of sample taken for experiment	Exchange acidity (mg-equiv/100 g	Yield of saturated hydrocarbons (%)	Yield of saturated hydrocarbons per 100 g of sample (%)
Impregnated with $Al(NO_3)_3$ solution so as to apply 3% Al_2O_3	Finely porous	25.0	9.6	44.4	17.7
	Coarsely porous	13.3	9.6	2.4	1.8
Treated with N $AlCl_3$ 25% neutralized with N NaOH for 3 days	Finely porous	24.2	9.6	42.8	17.7
	Coarsely porous	14.2	12.7	20.7	14.6
		23.8			
Treated with N $AlCl_3$ 25% neutralized with N NaOH for 7 days	Finely porous	14.8	18.0	47.2	19.8
	Coarsely porous		18.0	31.9	21.5

* Mobility is here understood to mean the ability of cations attached to a silica gel surface to undergo exchange with cations of a neutral salt.

SUMMARY

1. Increase in the catalytic activity of preparations obtained by treatment of silica gel with solutions of aluminum salts is not proportional to the increase in their exchange acidity, for the ability of active aluminum ions to undergo exchange increases more rapidly than the number of these ions.

2. Silica gel acquires catalytic activity as a result of replacement of hydrogen ions by aluminum ions in hydrolytic hydroxy groups only.

3. Activation of silica gel by treatment with solutions containing basic aluminum salts is considerably more effective than activation by application of alumina.

INVESTIGATION WITH THE AID OF LABELED ATOMS OF THE CONDITIONS REQUIRED FOR THE SEPARATION OF ZINC AND COBALT FROM ALUMINUM AND IRON

Yu. V. Morachevsky and Z. S. Bashun

The separation of tervalent ions from bivalent ions is frequently carried out in the complete analysis of minerals, rocks, and many industrial products. Many of the methods of separation are based on the precipitation under various pH conditions, of hydroxides and basic salts of the elements to be separated. This principle lies at the basis of the precipitation of hydroxides and basic salts of ter-and quadri-valent ions from the buffer solutions ammonia + ammonium salt (the widely practiced precipitation with ammonia) and ammonium acetate + acetic acid (the so-called "acetate hydrolysis" method), and it lies also at the basis of precipitation with weak organic bases, etc.

The conditions required for maximum completeness of separation have frequently attracted the attention of investigators. However, the detailed elucidation of the effect of individual factors on completeness of separation and the complicating phenomenon of coprecipitation was rendered difficult by the complexity and insufficient sensitivity of methods of determining the distribution of the particular ion between precipitate and solution.

There are wide possibilities for the application of radioactive isotopes to the accurate determination of the behavior of an ion in various analytical separations. In our opinion, one of the urgent tasks of modern analytical chemistry is the detailed study, with the aid of labeled atoms, of the methods of ion separation used in analytical practice with the object of revealing sources of error and methods of avoiding error. Work in this direction has already begun [1,2].

In the present paper we give the results of an investigation of three methods of separating aluminum and iron from zinc and cobalt: 1) precipitation of hydroxides of tervalent metals with ammonia; 2) so-called "acetate hydrolysis"; and 3) precipitation of aluminum and iron with pyridine. These particular bivalent ions were selected because conditions for their separation have received very little investigation.

The precipitation of the hydroxides of aluminum, iron, and titanium with ammonia in order to separate these elements from manganese, calcium, and magnesium is extensively used in the analysis of silicates. The conditions for separation were studied very fully by Blum [3], who recommended precipitation from hot solutions containing a sufficient amount of ammonium salts, the pH of the solution being maintained at 6-6.5 with the aid of Methyl red. The conditions recommended by Blum for the precipitation of aluminum and iron hydroxides have been accepted by most authors of later publications. Hillebrand and Lundell [4] also recommend the precipitation conditions proposed by Blum, though they point out that complete separation of aluminum and iron from zinc, cobalt, and copper is not attained even when the precipitate of hydroxides is reprecipitated; they cite the results of Lundell and Knowles [5], which characterize the degree of entrainment of various bivalent ions by precipitates of aluminum hydroxide formed under Blum's conditions.

The method of so-called "acetate hydrolysis" consists in boiling a very dilute ammonium acetate + acetic acid buffer solution containing tervalent iron, aluminum, and titanium, which are precipitated as sparingly soluble basic acetates. As precipitation occurs at relatively low pH (5.2-5.6) [6], it may be expected that, after reprecipitation, the precipitate will not contain bivalent ions, including those in which we are interested,

zinc and cobalt. This method is often recommended for the separation of iron and aluminum from bivalent ions; its main defect is incomplete precipitation of aluminum, it being generally recommended that its precipitation be completed in the filtrates after the separation of the main precipitate, for which purpose the filtrates are evaporated down to small bulk and their pH is increased somewhat by addition of ammonia [7]. Lassieur [8] considers that complete precipitation of aluminum as basic acetate is attained at pH not less than 5.3.

The use of pyridine for the separation of tervalent ions from bivalent is considered in a series of papers by Ostroumov and coworkers [9-12]. Being a weak base, pyridine precipitates aluminum and ferric hydroxides, whereas it forms soluble complex compounds with several bivalent ions. In order to maintain zinc in solution it has been proposed that a large amount of ammonium chloride be added.

EXPERIMENTAL

1. Behavior of Zinc and Cobalt in the Precipitation of Aluminum and Ferric Hydroxides with Ammonia

A definite amount of the radioactive isotope of zinc or cobalt (Zn^{65} or Co^{60}) was introduced into a solution containing known amounts of aluminum or iron and zinc or cobalt in the form of chlorides. The original solution, prepared in this way, was always 100 ml in volume. The solution was heated to the boil, and aluminum or ferric hydroxide was precipitated with ammonia. After ten minutes the hot solution was filtered and the residue was washed with 2% ammonium nitrate solution; the main filtrate and washings were collected separately. The volume of the washings, like that of the original solution, was 100 ml. Activity measurements were made on the filtrate and washings, and the pH of the main filtrate was determined - generally with a quinhydrone electrode, and in control experiments with a hydrogen electrode. The precipitate of hydroxide was dissolved in dilute hydrochloric acid, and aluminum (or ferric) hydroxide was reprecipitated under the same conditions as in the first precipitation. The filtrate and washings were collected separately, each was made up to 100 ml, and their activities were measured. The reprecipitated material was redissolved and its activity was measured.

Thus, activity measurements were taken only on solutions. For this purpose the solutions were placed in glass vessels having two walls of thin glass; 20 ml of solution was always taken. The counter tube was fixed vertically, and the vessel was placed on it. Before each measurement the background of the apparatus and vessel (filled with water) was checked: it was fairly great, but stable, varying between 38 and 41 impulses per minute. In the measurement of the activity of the solutions under investigation, counts were taken over 5-15 minutes, depending on the activity; in the case of very low activity, the count was continued until the total number of impulses registered reached 500. A correction for background was always made to the results of the count. The procedure is outlined schematically on the following page.

Separation of Zinc from Aluminum. The first series of experiments had the object of determining the effect of the pH of the solution on the coprecipitation of zinc with aluminum hydroxide. The contents of aluminum and zinc were not varied. The results are given in Table 1.

It will be seen from Table 1 that complete separation of aluminum and zinc under the selected conditions (identical with those recommended by Blum) is attained only at pH values lying within very narrow limits, 5.5-5.8. With rise in pH to about 7, the zinc content of the reprecipitated precipitate increases; with further rise in pH the amount of zinc carried down with the precipitate begins to diminish owing to partial formation of a zinc ammine; at pH 9.4 (considerable excess of ammonia) the precipitate contains only 1.6% of the whole of the zinc. Further rise in pH is made difficult by the buffering action of the ammonium salt, but it is of no practical interest since the precipitation of aluminum was found to be incomplete under these conditions.

Ammonium chloride, apart from having a buffer action and improving conditions for coagulation of the hydroxide, reduces coprecipitation of zinc due to exchange adsorption. Special experiments showed that reduction of the concentration of ammonium salt without change in other conditions results in increase in the entrainment of zinc by the precipitate; on the other hand, increase in the concentration of ammonium chloride beyond 5% had no effect on the results of the experiments.

The data in Table 1 refer to a zinc content of 13.5 mg/100 ml and a weight ratio of Al : Zn of 2 : 1. Experiments were carried out under similar conditions with lower and higher Zn concentrations, 2.7-27 mg/100 ml, and the same aluminum content (i.e., 27 mg). The results were quite analogous: within a narrow pH range (5.5-5.8) and with 5 g of ammonium chloride per 100 ml, the reprecipitated precipitate of aluminum hydroxide was free from zinc. Increase in the aluminum concentration to 80 mg of Al^{3+} per 100 ml and simultaneous increase in the zinc concentration to 40 mg/100 ml gave a reprecipitated precipitate of aluminum hydroxide that contained 1-1.25% of the whole of the zinc, even though precipitation was carried out under optimum conditions (pH 5.5-5.8). Entrainment of zinc by the precipitate is so small that one is assured of complete separation in a double reprecipitation.

The adjustment of pH to within the necessary limits was carried out as follows: the solution was neutralized with ammonia until the indicator showed a faint pink coloration, and 1% ammonia solution was then added dropwise until one drop caused the pink tinge to disappear. Under these conditions, at a definite ammonium chloride concentration (5 g/100 ml), the pH was found to be within the range 5.5-5.8; it was always checked electrometrically.

Separation of Zinc from Iron. Experiments on the separation of zinc from iron were carried out under precisely analogous conditions. As ferric hydroxide is completely precipitated at lower pH values, the pH was varied from 4 to 7.5 in the experiments. The results of some of the experiments are given in Table 2.

TABLE 2

Results of Experiments on the Separation of Zinc from Iron Precipitated with Ammonia

Amount taken				Amount of zinc found (% on amount taken					
				First precipitation		Reprecipitation			
Fe^{3+} (mg)	Zn^{2+} (mg)	NH_4Cl (g)	pH	Filtrate	Washings	Filtrate	Washings	In reprecipitated precipitate	Total
35.6	3.5	5.0	4.0	96.6	2.3	1.1	Nil	Nil	100.0
35.6	3.5	5.0	5.0	88.3	6.5	7.0	»	»	100.0
35.6	3.5	5.0	5.3	96.3	3.3	1.3	»	»	100.9
35.6	3.5	5.0	5.5	93.1	5.4	0.7	»	»	99.2
35.6	3.5	5.0	5.6	86.0	13.5	0.9	»	»	100.4
35.6	3.5	5.0	6.5	52.2	15.2	30.3	0.4	1.6	99.7
35.6	3.5	5.0	7.5	51.6	16.1	24.5	1.7	5.0	89.9

These results are closely in accord with the corresponding results for aluminum. In the precipitation of ferric hydroxide in solutions of pH below 6, complete separation could be obtained. Experiments with an increased amount of zinc for a given iron content gave analogous results.

Separation of Cobalt from Aluminum. Similar experiments were carried out with the object of obtaining more precise information about the conditions for the quantitative separation of cobalt and aluminum. Results of experiments on the effect of the pH of the solution on the entrainment of cobalt by an aluminum hydroxide precipitate for constant concentrations of aluminum, cobalt, and ammonium are given in Table 3.

27.0	3.0	5.05	9.2	31.0	10.7	38.7	8.0	11.7	100.1

In general character the dependence on pH is the same as in the case of zinc (Table 1). Complete separation is attained when the precipitation of aluminum hydroxide is carried out from a solution containing 5% of ammonium chloride in the pH range 5.5-6.0. With rise in pH the amount of cobalt coprecipitated with aluminum hydroxide increases still more sharply than in the case of zinc under like conditions. When the excess of ammonia is considerable, the amount of coprecipitated cobalt begins to fall owing to the formation of its ammine.

The essential point is that complete separation of aluminum and cobalt can be attained even when the relative amounts of the ions are unfavorable, cobalt predominating over aluminum. The results are given in Table 4.

Separation of Cobalt from Iron and Aluminum. The above-cited data on the separation of aluminum and cobalt and the analogy with previously cited data on the separation of zinc and iron enabled us to foresee that ferric hydroxide may be separated from cobalt just as completely so long as the pH of the solution during precipitation does not exceed 6.0 and the solution contains not less than 5 g of ammonium chloride per 100 ml. As ferric hydroxide is completely precipitated even at lower pH, it is evident that the pH range in which iron can be quantitatively separated from cobalt can be extended in the direction of more acidic solutions. This is confirmed by experiment.

When iron and aluminum are present simultaneously, the extent to which the pH at which precipitation is carried out can be lowered is limited because of the danger of incomplete precipitation of the aluminum. It may be expected, however, that ferric hydroxide will be a "collector" for aluminum hydroxide and will enable us to lower the pH without any risk of incomplete precipitation of aluminum. This was confirmed by experiment.

The solution contained 13.3 mg of Al^{3+}, 18.7 mg of Fe^{3+}, 4.27 mg of Co^{2+}, and 5.26 g ammonium chloride. Not only was the cobalt entrained by the precipitate determined, but also the completeness of the precipitation of aluminum and iron. The results of the experiments are given in Table 5.

As can be seen from Table 5, aluminum was completely precipitated with ferric hydroxide in spite of the relatively low pH of the solution during precipitation: the ferric hydroxide played the part of a "collector".

2. Behavior of Zinc and Cobalt in the Precipitation of Aluminum and Iron by the so-called "Acetate-Hydrolysis" Method

First of all we made a more precise examination of the relationship between the completeness of precipitation of basic aluminum acetate and the pH of the solution. For this purpose we took 100 ml of solution containing not only aluminum chloride but also hydrochloric acid, and added ammonia solution until a turbidity appeared, which was removed by addition of 1-2 drops of dilute hydrochloric acid. The solution was heated to the boil and diluted with boiling water to about 300 ml, after which 10 ml of N acetic acid and 1-6 g of solid ammonium acetate were added. The hot solution was allowed to stand for 10-15 minutes, and the precipitate was then filtered off and washed with 1% ammonium acetate solution. The precipitate was dried, calcined, and weighed. The pH of the main filtrate was determined electrometrically. The results are given in Table 6.

As will be seen from Table 6, complete precipitation of aluminum occurs only in the pH range 7.5-7.8, i.e., only when basic aluminum acetate is already being transformed into aluminum hydroxide [13, 14].

In order to find the behavior of zinc in the separation of aluminum by the above-described method, experiments were carried out in the following manner. A solution of the radioactive isotope of zinc was introduced into a solution containing definite amounts of aluminum and zinc chlorides; the solution was made up to 100 ml, and the activity of this original solution was measured. Precipitation of basic aluminum acetate was then carried out as described above. The washed precipitate was dissolved in dilute hydrochloric acid, and basic aluminum acetate was reprecipitated from the resulting solution in the same way. In both precipitations the filtrates and washings were combined. As we were interested not only in the completeness of separation of zinc, but also in the completeness of the separation of aluminum, each of the solutions, after precipitation and after reprecipitation was evaporated to low bulk and was treated with ammonia to precipitate any residual aluminum. These supplementary precipitates of aluminum hydroxide were filtered off, washed, calcined, weighed.

* The aluminum contents of the filtrates were determined by means of aluminum, either gravimetrically (for high contents) or colorimetrically.

The alumina precipitates were dissolved, and the activities of the resulting solutions were measured. The activities of both filtrates from the precipitation of aluminum were measured, as also was that of the solution obtained by dissolving the main precipitate of basic aluminum acetate in dilute hydrochloric acid. The following scheme will make the procedure clear.

By adding activities (2+3 and 4+5), we are able to determine the behavior of zinc in the first and second precipitations of basic acetate. Measurement of activity (6) enables us to calculate the amount of zinc entrained by the reprecipitated basic aluminum acetate. Measurements (2) and (4) enable us to determine the amount of zinc entrained in the supplementary precipitation of aluminum hydroxide. Finally, the weights of the precipitates (3) and (4) characterize the incompleteness of the precipitation of aluminum under the given experimental conditions. Tables 7 and 8 give the results of experiments on the separation of aluminum and zinc in accordance with the scheme described.

8	—	—	3.48	2.94

As will be seen from Tables 7 and 8, zinc remains completely in solution when the precipitation of the basic aluminum acetate is carried out at pH below 6. Under these conditions, however, some aluminum also remains in solution, and in its complete precipitation there is a considerable loss of zinc, up to 5-6% of its total content. Experiments with different proportions of aluminum and zinc (increase of the amount of aluminum to 57 mg and variation of the weight ratio of Al^{3+} to Zn^{2+} from 10:1 to 1:2) gave completely analogous results.

Above, we pointed out the increase in the completeness of precipitation of aluminum by ammonia observed by us even at low pH when iron was present simultaneously. It was of interest to determine whether basic ferric acetate could act as a "collector" in the same way and whether completeness of separation of aluminum and zinc could be achieved by the introduction of iron. The procedure for the precipitation and reprecipitation of basic acetates was as described above. The results are given in Table 9.

TABLE 9

The data in Table 9, which have been confirmed by many experiments, showed that basic ferric acetate, and probably also ferric hydroxide formed at pH below 5.8, is a "collector" for aluminum, and the presence of iron in an amount exceeding that of aluminum ensures complete precipitation of aluminum and its complete separation from zinc.

Completely analogous results were obtained for the separation of aluminum from cobalt. When the precipitation of basic aluminum acetates by the above-described method was carried out at pH not above 6, cobalt remained completely in solution irrespective of the proportions of aluminum to cobalt, but in the supplementary precipitation of aluminum from the filtrates with ammonia up to 5% of the total amount of cobalt was entrained in the aluminum hydroxide precipitates. It is interesting that, in this case also, iron acted as a "collector" for aluminum, and when iron predominated over aluminum it was possible to separate the latter from cobalt quantitatively. Thus, in experiments in which the amounts of Al^{3+}, Fe^{3+}, and Co^{2+} were 28.58, 18.88, and 38.4 mg respectively, part of the aluminum remained unprecipitated, but when the amounts of these ions were 14.29, 37.76, and 38.40 mg respectively, aluminum passed completely into the precipitate and cobalt passed completely into the solution.

3. Behavior of Zinc and Cobalt in the Precipitation of Aluminum and Iron with Pyridine

The following procedure was adopted: 100 ml of solution containing the required amounts of the various salts was neutralized with ammonia until a turbidity appeared, and this was removed by addition of a few drops of dilute hydrochloric acid. Ammonium chloride (10 g) was added, the solution was heated, and the hydroxide was precipitated by slow addition of 20% pyridine solution until a faint odor of pyridine remained. The solution was stirred, 20 ml of pyridine solution was added, and the precipitate was allowed to settle and was then filtered off and washed with a 3% solution of ammonium chloride containing a little pyridine. The precipitate was dissolved in hydrochloric acid and was reprecipitated in accordance with the same procedure. In both cases the washings were collected separately. The distribution of zinc between precipitate and solutions was determined by introducing the radioactive isotope into the original solution and measuring the activities of the solutions and redissolved precipitates. The results of the experiments on the separation of aluminum and zinc are given in Table 10.

As will be seen from Table 10, the best separation is attained at pH 6-6.5; on the other hand, in the pH range that is favorable for separation by means of ammonia or hydrolysis (5.5-5.9), separation is incomplete. It was not possible to raise the pH above 6.5 by means of pyridine. Reduction of the ammonium chloride concentration below 8g/100 ml resulted in considerable coprecipitation of zinc with aluminum hydroxide. Aluminum and iron are completely precipitated when the above-described conditions are observed.

TABLE 10

Results of Experiments on the Separation of Aluminum and Zinc by Pyridine

Amount taken				Amount of zinc found (% on amount taken					
				First precipitation		Reprecipitation			
Al^{3+} (mg)	Zn^{2+} (mg)	NH_4Cl (g)	pH	Filtrate	Washings	Filtrate	Washings	In reprecipitated precipitate	Total
28.58	28.33	10	5.5	85.02	2.13	5.87	2.42	4.52	99.96
28.58	28.33	10	5.6	85.79	2.89	5.95	1.87	3.37	99.87
28.58	28.33	10	5.8	89.13	2.63	4.32	1.18	3.14	100.40
28.58	28.33	10	5.9	90.20	2.75	4.18	1.28	1.62	100.03
28.58	28.33	10	6.0	92.15	2.35	3.81	1.66	Nil	100.00
28.58	28.33	10	6.2	92.91	2.78	4.68	Nil	»	100.37
28.58	28.33	10	6.3	92.80	3.13	3.67	»	»	99.60
28.58	28.33	10	6.4	93.11	3.37	3.47	»	»	99.65
28.58	28.33	10	6.5	93.10	2.75	4.15	»	»	100.00

Similar results were obtained for the separation of aluminum and also of aluminum and iron, from cobalt. In this case also, complete separation is attained when the pH of the solution is above 6. The ammonium chloride concentration is not of particular importance and can be considerably reduced (to 2 g/100 ml). When the cobalt content is low, it is not necessary to reprecipitate the precipitate.

SUMMARY

1. A study was made of the conditions ensuring complete separation of zinc and cobalt from aluminum and iron, the latter being precipitated with ammonia, in the form of basic acetates, or with pyridine.

2. It was shown that, for the first of these methods, complete separation of both zinc and cobalt from aluminum and iron is attained only within a narrow pH range, 5.5-5.9, and it is necessary that not less than 8% of ammonium salt should be present. Under these conditions separation is attained irrespective of the relative amounts of the ions to be separated. It was shown that ferric hydroxide is a "collector" for aluminum hydroxide and presence of iron in the solution permits complete precipitation of aluminum at relatively low pH.

3. The "acetate-hydrolysis" method is unsuitable when zinc or cobalt is accompanied only by aluminum, for the latter very incompletely precipitated. However, the presence of iron in amounts exceeding the amount of aluminum removes this defect of the method. Precipitation of ferric and aluminum hydroxides with excess of pyridine gives excellent separation of zinc and cobalt from aluminum and iron.

ORGANIC AND BIOLOGICAL CHEMISTRY

CONDENSATION OF 2-CHLOROVINYL KETONES WITH BENZENE AND ITS HOMOLOGS

A. N. Nesmeyanov, M. I. Rybinskaya, and N. K. Kochetkov

We have shown previously that 2-chlorovinyl ketones react readily with phenols [1, 2] and their ethers [3] with formation of the corresponding styryl ketones. The present paper is concerned with the study of the condensation of 2-chlorovinyl ketones with benzene and its homologs. It was found that the condensation of 2-chlorovinyl ketones even with active benzene homologs does not go in presence of stannic chloride, which is an active catalyst, as shown for the case of phenol ethers [3]. Even in presence of aluminum chloride in complete absence of moisture, the desired results were not obtained. However, by the use of moist m-xylene in reaction with 4-chloro-3-buten-2-one in presence of aluminum chloride, 4-(2, 4-xylyl)-3-buten-2-one was obtained in 43% yield.

In the course of the investigation it was found that the condensation of 2-chlorovinyl ketones with benzene and its homologs proceeds more satisfactorily in presence of aluminum chloride in a strong current of moist hydrogen chloride. The necessity for moisture is worthy of attention; almost no reaction occurs in a stream of dry hydrogen chloride.

$$ArH + ClCH = CHCOR \xrightarrow[HCl]{AlCl_3} ArCH = CHCOR$$

I) $R = CH_3-$; $Ar = m\text{-}(CH_3)_2C_6H_3-$; $p\text{-}(CH_3)_2C_6H_3-$; $symm\text{-}(CH_3)_3C_6H_2-$

II) $R = C_6H_5-$; $Ar = m\text{-}(CH_3)_2C_6H_3-$; $symm\text{-}(CH_3)_3C_6H_2-$

III) $R = CH_2Cl-$; $Ar = C_6H_5-$, $CH_3C_6H_4-$, $m\text{-}(CH_3)_2C_6H_3-$, $p\text{-}(CH_3)_2C_6H_3$; ClC_6H_4-

It should be noted that not all 2-chlorovinyl ketones react equally readily. It was found that 4-chloro-3-buten-2-one reacts readily with comparatively active benzene homologs such as mesitylene and m-xylene. With p-xylene it reacts feebly, 4-(2, 5-xylyl)-2-buten-2-one being formed in only 20% yield, and with toluene and benzene it does not react at all under these conditions. 3-Chloroacrylophenone also reacts readily with mesitylene and with m-xylene, but with toluene it gives a negligible yield. The most reactive vinyl ketone was found to be 1,4-dichloro-3-buten-2-one, which reacts readily not only with m- and p-xylenes, but also with toluene and with benzene, giving the previously inaccessible 4-aryl-1-chloro-3-buten-2-ones in high yield (50-79%). Reaction proceeds even with chlorobenzene, which by condensation with 1, 4-dichloro-3-buten-2-one gives a mixture of o- and p-isomers.

$X = CH_3-$, Cl—.

When the mixture is oxidized with potassium permanganate, phthalic and terephthalic acids can be iso-

lated and identified in the first case, and o- and p-chlorobenzoic acids in the second.

The styryl ketones that we synthesized from 2-chlorovinyl ketones corresponded in properties and constants with known styryl ketones obtained by the condensation of the corresponding aromatic aldehydes with acetone and acetophenone. Treatment of 4-(2,4-xylyl)-3-buten-2-one with iodine in alkaline medium gave the already known 2, 4-dimethylcinnamic acid. The same 2, 4-dimethylcinnamic acid was isolated also in the oxidation with stannic chloride of 1-chloro-4-(2, 4-xylyl)-3-buten-2-one, obtained by reaction between 1, 4-dichloro-3-buten-2-one and m-xylene.

EXPERIMENTAL

4-(2, 4-Xylyl)-3-buten-2-one. a) A powerful current of moist hydrogen chloride was passed through an ice-cooled solution of 15 g of 4-chloro-3-buten-2-one in 30.5 g of m-xylene for ten minutes. Aluminum chloride (19.5 g) was then added in portions with vigorous agitation and continued passage of the powerful current of hydrogen chloride. When the whole of the aluminum chloride had been added, cooling was discontinued. The reaction mixture was stirred in the stream of hydrogen chloride until a dark-red complex was precipitated (3-4 hours). After 20-30 minutes the reaction mixture was decomposed with a mixture of ice and concentrated hydrochloric acid. The mixture was extracted with ether, and the ether extracts were washed several times with water and dried over calcium chloride. Distillation gave 16 g (64.2%) of 4-(2, 4-xylyl)-3-buten-2-one, b.p. 145-146° (8 mm). The literature [4] gives b.p. 145-148° (10 mm). The semicarbazone, prepared in the usual way, had m.p. 226-228° (from alcohol); the literature [4] gives m.p. 227°.

4-(2, 4-Xylyl)-3-buten-2-one is a colorless viscous liquid of pleasant odor. It crystallizes when cooled upon scratching of the sides of the flask with a glass rod; m.p. 32°. It is readily soluble in the usual organic solvents.

b) Aluminum chloride (19.5 g) was added in portions to a cooled stirred solution of 15 g of 4-chloro-3-buten-2-one in 30.5 g of moist m-xylene. Stirring was continued at room temperature for four hours. Decomposition and treatment as given in Experiment (a) gave 11 g (43.6%) of 4-(2, 4-xylyl)-3-buten-2-one, b.p. 139-142° (5-6 mm). Semicarbazone: m.p. 227°, undepressed by admixture with sample obtained in the previous experiment.

The iodoform reaction was carried out with 4-(2, 4-xylyl)-3-buten-2-one in the usual way; it gave 2, 4-dimethylcinnamic acid, m.p. 180° (from benzene) (the literature [4] gives 181°).

Found %: C 75.29; H 7.01. $C_{11}H_{12}O_2$. Calculated %: C 75.01; H 6.86.

4-(2, 5-Xylyl)-3-buten-2-one. The procedure was as in Experiment (a), the reactants being 4-chloro-3-buten-2-one (6 g), p-xylene (13 g), and aluminum chloride (7.7 g). The mixture was stirred in a vigorous stream of hydrogen chloride for five hours. After the dark-red complex had been precipitated, the reaction mixture was heated for 30 minutes at 35-37°. The product was 2 g (20%) of 4-(2, 5-xylyl)-3-buten-2-one, b.p. 130° (4-4.5 mm); the literature [5] gives 154-156° (15 mm). The semicarbazone was prepared in the usual way; m.p. 201-202° (the literature [5] gives 204°).

4-(2, 5-Xylyl)-3-buten-2-one is a colorless viscous liquid of pleasant odor, readily soluble in the usual organic solvents.

4-Mesityl-3-buten-2-one. This was prepared in a similar way from 14 g of 4-chloro-3-buten-2-one, 30.6 g of mesitylene, and 18.1 g of aluminum chloride. The mixture was stirred in a stream of moist hydrogen chloride for three hours. After decomposition, the mixture was extracted with ether and the ether extracts were washed several times with water. After removal of ether, needles of 4-mesityl-3-buten-2-one came down from the residue, and these were filtered off. The filtrate was steam-distilled, distillation being interrupted as soon as crystals appeared in the condenser. The residue crystallized in the flask and was pressed off on a porous plate. The total yield of 4-mesityl-3-buten-2-one was 10.4 g (61%). It melted at 65-66° (from aqueous alcohol); the literature [6] gives m.p. 67°.

Found %: C 83.18; H 8.65. $C_{13}H_{16}O$. Calculated %: C 82.98; H 8.55. The semicarbazone was prepared in the usual way; m.p. 190-191° (from alcohol). Found %: N 16.87; 16.82. $C_{14}H_{19}ON_3$. Calculated %: N 17.13.

2,4,6-Trimethylchalcone. This was prepared similarly from 10 g of 3-chloroacrylophenone [7], 15 g of mesitylene, and 8.1 g of aluminum chloride. The mixture was stirred in a stream of hydrogen chloride until the complex was precipitated (4 hours). The mixture was decomposed and then extracted with benzene. The benzene extracts were washed several times with water and then steam-distilled. After the removal of benzene and mesitylene, distillation was discontinued. The residue crystallized and was filtered, the crystals being well pressed off on the filter. The yield was 8.5 g (56.6%); m.p. 95° (from diluted alcohol) (the literature [6] gives 96°).

Found %: C 86.20; H 7.20. $C_{18}H_{18}O$. Calculated %: C 86.40; H 7.25.

2,4,6-Trimethylchalcone forms needles, readily soluble in ether and benzene and moderately soluble in alcohol. Its semicarbazone melts at 188° (from alcohol).

Found %: C 74.10, 73.93; H 6.83, 6.81; N 13.70, 13.72. $C_{19}H_{21}ON_3$. Calculated %: C 74.23; H 6.88; N 13.67.

1-Chloro-4-phenyl-3-buten-2-one. This was prepared similarly from 10 g of 1,4-dichloro-3-buten-2-one, 50 ml of benzene, and 10 g of aluminum chloride, the mixture being vigorously agitated in a strong current of hydrogen chloride for 4.5-5 hours. After precipitation of the dark-red complex, the mixture was heated for 30 minutes at 40-45°. The mixture was decomposed and extracted with ether. Vacuum distillation gave 10.25 g (79%) of 1-chloro-4-phenyl-3-buten-2-one, b.p. 138-139° (5 mm), m.p. 62° (from aqueous alcohol).

Found %: C 66.10; H 5.09. $C_{10}H_9OCl$. Calculated %: C 66.49; H 5.23.

1-Chloro-4-phenyl-3-buten-2-one forms colorless needles, readily soluble in ether, chloroform, and acetone and moderately soluble in cold benzene and petroleum ether.

Boiling of 1-chloro-4-phenyl-3-buten-2-one in m-xylene solution with excess of stannic chloride for many hours gave 2,4-dimethylcinnamic acid, m.p. 179°; the literature [4] gives 181°. In admixture with the sample obtained previously there was no depression of melting point.

1-Chloro-4-o-tolyl- and 1-Chloro-4-p-tolyl-3-buten-2-ones. These were prepared similarly from 15 g of 1,4-dichloro-3-buten-2-one, 30 g of toluene, and 15 g of aluminum chloride, the mixture being vigorously agitated in a strong current of hydrogen chloride for two hours. The reaction mixture was decomposed with ice and concentrated hydrochloric acid. The precipitate formed was rapidly filtered off, washed with ice water, and well pressed off. A mixture of o- and p-isomers was obtained; yield 17.5 g (83.7%); m.p. of mixture 49-52°.

Found %: C 67.90; 67.62; H 5.63; 5.69; Cl 18.67. $C_{11}H_{11}OCl$. Calculated %: C 67.89; H 5.75; Cl 18.22.

Oxidation of the mixture with potassium permanganate in 5% sodium carbonate solution gave a mixture of phthalic and terephthalic acids, which we succeeded in separating by fractional crystallization from alcohol. Terephthalic acid does not melt; its dimethyl ester, prepared by boiling the acid in methanol in presence of concentrated sulfuric acid, melted at 137° (the literature [8] gives 140°); a mixture test with a known sample showed no depression. Phthalic acid melted at 189° (rapid heating), and its anhydride at 126° (the literature [9] gives 128°); a mixture test with a known sample showed no depression.

1-Chloro-4-(2,5-xylyl)-3-buten-2-one. This was prepared from 10 g of 1,4-dichloro-3-buten-2-one, 22.8 g of p-xylene, and 10 g of aluminum chloride, the mixture being stirred in a powerful current of hydrogen chloride for three hours. The reaction mixture was decomposed with ice and concentrated hydrochloric acid; the precipitate formed was rapidly filtered off and washed with cooled methanol. Yield 10.8 g (74.8%); m.p. 98-100° (from alcohol).

Found %: C 68.76; 68.75; H 6.22, 6.36; Cl 16.76; 17.10. $C_{12}H_{13}OCl$. Calculated %: C 69.04; H 6.28; Cl 16.97.

1-Chloro-4-(2,5-xylyl)-3-buten-2-one forms colorless needles which can be readily crystallized from aqueous alcohol.

1-Chloro-4-o-chlorophenyl- and 1-Chloro-4-p-chlorophenyl-3-buten-2-ones. These were prepared similarly from 10 g of 1,4-dichloro-3-buten-2-one, 20 g of chlorobenzene, and 10 g of aluminum chloride, the mixture being stirred at room temperature in a powerful current of hydrogen chloride for ten hours. The reaction mixture was decomposed with ice and hydrochloric acid and extracted with ether. Unchanged chlorobenzene and ketone were distilled off with steam, and the residue was distilled off with superheated steam. The product was 1.65 g (10.7%) of a mixture of o- and p-isomers; m.p. of mixture 70-80°.

Found: %: C 55.84; 56.02; H 3.60; 3.38; Cl 33.48; 32.95. $C_{10}H_8OCl_2$. Calculated %: C 55.84; H 3.75; Cl 32.96.

Oxidation of the mixture with potassium permanganate in 5% sodium carbonate solution gave a mixture of o- and p-chlorobenzoic acids, which were separated by fractional crystallization from water. p-Chlorobenzoic acid melted at 238°; the literature [10] gives m.p. 236-237°. o-Chlorobenzoic acid melted at 136°; the literature [11] gives m.p. 137°. Mixture tests with known samples showed no depression.

SUMMARY

1. A new method was developed for the synthesis of styryl ketones. It consists in the condensation of 2-chlorovinyl ketones with aromatic hydrocarbons in presence of aluminum chloride and moist hydrogen chloride.

2. It was shown that 1,4-dichloro-3-buten-2-one is extremely reactive in this reaction.

ACTION OF CHLORINE ON UNSATURATED POLYCHLORO COMPOUNDS IN AN ACID MEDIUM

R. Kh. Freidlina, V. N. Kost, and A. N. Nesmeyanov

As we have shown previously [1], compounds of structure

$CCl_2=CH-CH_2X$ in which X=OCH_3, $N(C_2H_5)_2$, NO_2, etc.,

combine smoothly with chlorine when the substituent X is an electron acceptor, whereas in cases in which this substituent is an electron donor, not only addition occurs, but also replacement of hydrogen by chlorine.

It was considered that replacement of allyl hydrogen occurred, but it has now been found that treatment of 1, 1-dichloro-3-methoxypropene with chlorine gives mainly a product in which the methoxy group is chlorinated:

$$CCl_2=CHCH_2OCH_3+Cl_2\rightarrow CCl_2CHClCH_2OCH_2Cl.$$

The structure of this product was proved by its conversion into 2, 3, 3, 3-tetrachloro-1-propanol by the action of methanol in presence of hydrochloric acid. We also synthesized 1, 1, 1, 2-tetrachloro-3-(chloromethoxy) propane by the chloromethylation of 2, 3, 3, 3-tetrachloro-1-propanol. When compounds of the above structure containing an electron-donating substituent (OCH_3, $N(C_2H_5)_2$) are treated with chlorine in presence of hydrogen chloride, the substitution reaction predominates [1].

It was further shown [2] that compounds containing the $CCl_2=CH$ group react with chlorine in a H_2SO_4 medium by "conjugated addition" with formation of α-chloro carboxylic acids in accordance with the scheme:

$$RCH=CCl_2+Cl_2\xrightarrow{H_2SO_4}[RCHCl-CCl_2OSO_3H]\xrightarrow{H_2O}RCHClCOOH.$$

In this way good yields were obtained of α-chloro carboxylic, α,ω-dichloro carboxylic, and α-chloro dicarboxylic acids from compounds of the type $CH_3(CH_2)_nCH=CCl_2$, $Cl(CH_2)_nCH=CCl_2$ and $HOOC(CH_2)_nCH=CCl_2$, respectively.

In the present investigation we have shown that the suppression of substitution on saturated carbon atoms of compounds of structure $CCl_2=CH(CH_2)_nX$ in chlorine treatments in presence of hydrogen chloride is of great general significance. For example, when 1, 1, 5-trichloro-1-pentene, 6, 6-dichloro-5-hexenenitrile, and 8, 8-dichloro-7-octenoic acid were treated with chlorine in chloroform at 0-15°, reaction went with brisk evolution of hydrogen chloride and formation of a mixture of chlorination products. In presence of hydrogen chloride these unsaturated compounds smoothly combined with chlorine at the double bond with formation in good yield of 1, 1, 1, 2, 5-pentachloropentane, 5, 6, 6, 6-tetrachlorohexanoic acid, and 7, 8, 8, 8-tetrachlorooctanoic acid, respectively.

In order to determine the relationship between the strength of an acid and the effect of the acid on the reaction between chlorine and compounds containing the $CCl_2=CH$ group, a study was made of the reaction of 1, 1, 5-trichloro-1-pentene and chlorine in media of glacial acetic acid, 90% phosphoric acid, concentrated sulfuric acid, and 70% perchloric acid at 0-15° without irradiation. It was found that conjugated addition of

chlorine with formation (after treatment with water) of 2,5-dichlorovaleric acid occurred only in media of sulfuric (concentrated) and perchloric acids. In 70% sulfuric acid, as in presence of hydrogen chloride, addition of chlorine at the double bond occurred without appreciable substitution at saturated carbon atoms. In this respect there is a definite difference in behavior between dichlorovinyl compounds and olefins in these reactions. As is well known, olefins react with chlorine by "conjugated addition" not only in media of strong mineral acids, but also in other media (see, for example, [3,4]).

The preparation of α-chloro carboxylic acids by the action of chlorine on dichlorovinyl compounds in concentrated sulfuric acid is carried out under mild conditions, so that it is possible to prepare α-chloro carboxylic acids containing various substituents. In particular, in this paper we describe the action of chlorine on 1,1,5,5,5-pentachloro-1-pentene in concentrated sulfuric acid, in which a trichloromethyl group is preserved and 2,5,5,5-tetrachlorovaleric acid is obtained.

There are as yet no experimental data on the orienting effect of the trichloromethyl group on electrophilic addition at the double bond of a compound containing the grouping $CCl_3C{=}C$. Attempts to investigate the reaction between hydrogen bromide and 3,3,3-trichloropropene with this object were not successful, since reaction occurred only in presence of aluminum chloride, which isomerized the original compound into 1,1,3-trichloropropene [5] (compare [13]), or in presence of benzoyl peroxide, in which case reaction occurred with isomerization into an intermediate radical [6]. It was therefore of interest to study the electrophilic conjugated addition of chlorine to 3,3,3-trichloropropene.

According to Titov and Maklyaev [3], addition of chlorine to propene in a medium of acetic, formic, or benzenesulfonic acid results in the formation of a compound of the formula:

$$CH_3-\underset{\displaystyle OX}{\underset{|}{CH}}-CH_2Cl,$$ in which $X = CH_3CO-$, $HCO-$, $C_6H_5SO_2-$,

so that the reaction is subject to the usual rules of electrophilic addition. When chlorine reacted with 3,3,3-trichloropropene in concentrated sulfuric acid or glacial acetic acid, in addition to 1,1,1,2,3-pentachloropropane, 2,3,3,3-tetrachloro-1-propanol was obtained in form of its sulfate or acetate, respectively. Hydrolysis of these esters gave 2,3,3,3-tetrachloro-1-propanol, which was found to be identical with the substance obtained as follows:

$$CCl_3CH=CH_2 + CH_3COONa \xrightarrow{CH_3COOH} CCl_2=CH-CH_2OCOCH_3 \xrightarrow[HCl]{CH_3OH}$$
$$\rightarrow CCl_2=CH-CH_2OH \xrightarrow[HCl]{Cl_2} CCl_3CHClCH_2OH.$$

It was thus shown that the trichloromethyl group in 3,3,3-trichloropropene has an orienting effect in the direction opposite to that of the methyl group in propene. This result confirms the view of the electron-accepting character of the trichloromethyl group formed by two of the authors of this paper and Zakharkin [7] on the basis of a study of the dissociation constants of a series of acids of structure: $CCl_3(CH_2)_nCOOH$.

EXPERIMENTAL

Action of Chlorine on 1,1,5-Trichloro-1-pentene in Hydrochloric Acid. Chlorine and hydrogen chloride were passed through a solution of 26 g of 1,1,5-trichloro-1-pentene in 15 ml of ether and 15 ml of saturated aqueous hydrogen chloride until no further reaction occurred. The mixture was diluted with water, and the organic layer was separated, washed with water, and dried over calcium chloride. Distillation gave 29 g (81%) of 1,1,1,2,5-pentachloropentane, b.p. 92-93° (2.5 mm); n_D^{20} 1.5104; d_4^{20} 1.4815; found MR 49.37; calculated MR 49.62.

For 1,1,1,2,5-pentachloropentane the literature [8] gives b.p. 121-122° (12 mm); n_D^{20} 1.5135; d_4^{20} 1.4807. The structure of 1,1,1,2,5-pentachloropentane was proved by its hydrolysis with nitric acid to 2,5-dichlo-

rovaleric acid [9].

Action of Chlorine on 6,6-Dichloro-5-hexenenitrile. The chlorine treatment was carried out as in the preceding experiment. When reaction was complete, one volume of the reaction mixture was diluted with one volume of water and two volumes of acetic acid, and the mixture was boiled for six hours in order to hydrolyze the reaction product. A high yield (about 80%) of 5,6,6,6-tetrachlorohexanoic acid, m.p. 47-48° (from petroleum ether), was obtained.

Found %: C 28.51; 28.37; H 3.23; 3.14. $C_6H_8Cl_4O_2$. Calculated %: C 28.38; H 3.17.

Action of Chlorine on 8,8-Dichloro-7-octenoic Acid. A mixture of 6 g of 8,8-dichloro-7-octenoic acid, 6 ml of ether, and 6 ml of hydrochloric acid was saturated with hydrogen chloride and chlorine. The usual treatment gave 8 g (99%) of 7,8,8,8-tetrachlorooctanoic acid, b.p. 158-160° (1 mm) and n_D^{20} 1.5018.

Found %: C 34.28; 34.20; H 4.25; 4.08 $C_8H_{12}Cl_4O_2$. Calculated %: C 34.07; H 4.29.

Hydrolysis of this acid with concentrated nitric acid gave 2-chlorooctanedioic acid, m.p. 98-99° (from chloroform). A mixture of this acid and the substance obtained as follows:

$$CCl_2=CH(CH_2)_5COOH + Cl_2 \xrightarrow{H_2SO_4} HOOCCH(Cl)(CH_2)_5COOH$$

shows no depression of melting point [2].

Action of Chlorine on 1,1,5-Trichloro-1-pentene in Phosphoric Acid. Chlorine was passed at 0-10° through a vigorously stirred mixture of 18 g of 1,1,5-trichloro-1-pentene and 20 g of 90% phosphoric acid until evolution of hydrogen chloride ceased. Treatment of the reaction mixture gave only polychloro hydrocarbons.

Action of Chlorine on 1,1,5-Trichloro-1-pentene in Perchloric Acid. Chlorine was passed at 30° through a mixture of 18 g of 1,1,5-trichloro-1-pentene and 25 g of 70% perchloric acid until evolution of hydrogen chloride ceased. The mixture was then heated in a water bath for two hours. The mixture was diluted with water, the organic layer was separated, and the acid products were removed by washing with a solution of sodium hydroxide. Acidification of the alkaline extract gave 6.5 g (36%) of 2,5-dichlorovaleric acid, b.p. 105-108° (1 mm); n_D^{20} 1.4859; d_4^{20} 1.3440. The literature [9] gives b.p. 129-131° (5 mm); n_D^{20} 1.3421.

The neutral products were not investigated because of the risk of explosion.

Action of Chlorine on 1,1,5,5,5-Pentachloro-1-pentene in Sulfuric Acid. The pentachloropentene was prepared, as previously described [10], by the condensation of 3,3,3-trichloropropene with 1,1-dichloroethylene. It was found that a mixture of products is formed in this reaction. Fractionation through a column gave pure 1,1,5,5,5-pentachloro-1-pentene, b.p. 71° (1.5 mm); n_D^{20} 1.5108; d_4^{20} 1.4771; found MR 49.14; calculated for $C_5H_5Cl_5$ F MR 49.16 and 1,1,5,5-tetrachloro-1,4-pentadiene, b.p. 57° (1.5 mm); n_D^{20} 1.5197; d_4^{20} 1.4307; found MR 43.73; calculated for $C_5H_4Cl_4$ 2F, MR 43.82.

Found %: C 28.74; 28.78; H 1.90; 2.00. $C_5H_4Cl_4$. Calculated %: C 29.16; H 1.96.

The total yield of these two products was 60-70%, and the relative amounts depended on the condensation conditions, in particular the temperature and quality of aluminum chloride. Glutaric acid was prepared from 1,1,5,5-tetrachloro-1,4-pentadiene by hydrolysis with sulfuric acid.

Chlorine was passed at 20-25° through a mixture of 62 g of 1,1,5,5,5-pentachloro-1-pentene and 75 g of 93% sulfuric acid until hydrogen chloride ceased to be evolved. The mixture was diluted with water and extracted with chloroform. Acidic products were removed from the chloroform layer by washing with 10% sodium hydroxide solution. Acidification of the alkaline extract gave 2,5,5,5-tetrachlorovaleric acid, m.p. 82-83° (from benzene + petroleum ether).

Found %: C 24.80; 24.90; H 2.47; 2.49; Cl 59.43; 58.75 $C_5H_6Cl_4O_2$. Calculated %: C 25.02; H 2.52; Cl 59.12.

Yield 32 g (52%).

Action of Chlorine on 3,3,3-Trichloropropene in Sulfuric Acid. 3,3,3-Trichloropropene (21 g) and concentrated sulfuric acid (20 g) were mixed with cooling to about −30°. Chlorine was passed through the mixture at 0–10° until saturation was attained. After dilution with water, the organic layer was separated, washed with water, and dried with sodium sulfate. Distillation gave 14 g of 1,1,1,2,3-pentachloropropane, b.p. 54–56° (4 mm); n_D^{20} 1.5100 the literature [7] gives b.p. 64–65° (8 mm) and n_D^{20} 1,5105 and 11 g of bis-2,3,3,3-tetrachloropropyl sulfate, b.p. 189–190° (2 mm), m.p. 46–47° (from petroleum ether).

Found %: C 15,35; 15,58; H 1,26; 1,26; Cl 60,78; 61,06. $C_6Cl_8H_6SO_4$. Calculated %: C 15,73; Cl 61.30.

Hydrolysis of this sulfuric ester in acid medium gave 2,3,3,3-tetrachloro-1-propanol, m.p. 39–40°. In admixture with tetrachloropropanol obtained by the action of chlorine on 3,3-dichloro-2-propen-1-ol it melted at 39–40°.

Action of Chlorine on 3,3,3-Trichloropropene in Acetic Acid. Chlorine was passed at 50° through a solution of 28 g of 3,3,3-trichloropropene in 50 g of glacial acetic acid until no further reaction occurred. Acetic acid was distilled off, and the residue was vacuum-distilled. The products isolated were 23 g of 1,1,1,2,3-pentachloropropane, b.p. 65–66° (8 mm) and n_D^{20} 1,5102 and 9 g of 2,3,3,3-tetrachloropropyl acetate, b.p. 81–82° (2 mm); n_D^{20} 1.4858; d_4^{20} 1,4905; found MR 46.20; calculated for $C_5H_6Cl_4O_2$ MR 46.41.

Found %: C 24,78; 24,70; H 2,45; 2,45; Cl 59,77; 60,05. $C_5H_6Cl_4O_2$; Calculated %: C 25,02; H 2,52; Cl 59,12.

Treatment of this acetic ester with methanol in presence of hydrochloric acid gave 2,3,3,3-tetrachloro-1-propanol, identical with the tetrachloropropanol obtained by the action of chlorine on 3,3-dichloro-2-propen-1-ol.

Preparation of 3,3-Dichloro-2-propenyl Acetate. A mixture of 58 g of 3,3,3-trichloropropene, 40 g of calcined sodium acetate, and 75 ml of glacial acetic acid was boiled for 12 hours. The mixture was diluted with water, and the organic layer was separated, washed with water, and dried over calcium chloride. Distillation gave 43 g (71%) of 3,3-dichloro-2-propenyl acetate, b.p. 71–72° (14 mm); n_D^{20} 1,4650; d_4^{20} 1,2846; found MR 36,36; calculated for $C_5H_6O_2Cl_2$ F MR 36.21.

The literature [11] gives b.p. 116 − 117° (103 mm); n_D^{20} 1.4652.

Found %: Cl 41,34; 41,06. $C_5H_6O_2Cl_2$. Calculated %: Cl 41,95.

Preparation of 3,3-Dichloro-2-propen-1-ol. This was prepared by the action of methanol in presence of hydrochloric acid on 3,3-dichloro-2-propenyl acetate, prepared as described above. The alcohol had b.p. 56–57° (4 mm); n_D^{20} 1.4945; d_4^{20} 1.3763; found MR 26.88; calculated for $C_3H_4OCl_2$ F MR 26.85.

Found %: C 27,96; 28,04; H 3,25; 3,19. $C_3H_4OCl_2$. Calculated %: C 28,37; H 3,17.

Action of Chlorine on 3,3-Dichloro-2-propen-1-ol. Chlorine and hydrogen chloride were passed through a solution of 25 g of 3,3-dichloro-2-propen-1-ol in 25 ml of hydrochloric acid and 25 ml of ether saturated with hydrogen chloride at a temperature of −5° to 0° until no further reaction occurred (increase in weight 13 g). The mixture was diluted with water, and the organic layer was separated, washed with sodium carbonate solution and with water, and dried over sodium sulfate. Distillation gave 25 g (65%) of 2,3,3,3-tetrachloro-1-propanol, b.p. 78° (5 mm) and m.p. 39–40° (from petroleum ether) (the literature [12] gives m.p. 38–39°), and 5 g of a residue boiling up to 170° (5 mm).

Found %: C 19,60; 19,57; H 2,11; 2,01 $C_3H_4Cl_4O$. Calculated %: C 19,50; H 2,04.

When 3,3-dichloro-2-propen-1-ol was treated with chlorine in chloroform solution, reaction was accompanied by vigorous evolution of hydrogen chloride. Only 21% of the chlorine-addition product (2,3,3,3-tetrachloro-

propanol) was obtained, but a large amount of a mixture of high-boiling compounds was obtained.

Action of Chlorine on 1,1-Dichloro-3-methoxypropene. The reaction was carried out as described previously [1]. Fractionation of the products through an efficient column gave a pentachloro compound in 62% yield: b.p. 97-98° (5.5 mm); 81-82° (1.5 mm); n_D^{20} 1.5070; d_4^{20} 1.5713.

Boiling of 36 g of this pentachloro compound with 200 ml of methanol in presence of 1 ml of hydrochloric acid gave 26 g (90%) of 2,3,3,3-tetrachloro-1-propanol, m.p. 38-39° (from petroleum ether). A mixture of this with the tetrachloropropanol obtained by the action of chlorine on 3,3-dichloro-3-propen-1-ol melted at 38-39°.

The pentachloro compound therefore has the structure $CCl_3CHClCH_2OCH_2Cl$.

This pentachloro compound was obtained in 50% yield also by the action of paraform and hydrogen chloride in chloroform on 2,3,3,3-tetrachloro-1-propanol: b.p. 91-92° (2 mm); n_D^{20} 1.5065; d_4^{20} 1.5711; found MR 46.63; calculated for $C_4H_5Cl_5O$ MR 46.55.

Found %: C 19.60; 19.57; H 2.11; 2.01. $C_4H_5Cl_5O$. Calculated %: C 19.50; H 2.04.

SUMMARY

1. It was shown that compounds of the type $CCl_2 = CH(CH_2)nX$ react with chlorine in a neutral medium with formation of a mixture of saturated polychloro hydrocarbons and hydrogen chloride. When this reaction is carried out in presence of concentrated sulfuric acid at 0-15° without irradiation, smooth addition of chlorine at the double bond occurs.

2. It was found that reaction of compounds of structure $CCl_2 = CH(CH_2)n\,X = H, Cl, COOH, CCl_3$) with chlorine proceeds by "conjugated addition" only when the medium is a concentrated strong mineral acid (sulfuric or perchloric) with formation (after hydrolysis) of a α- chloro carboxylic acids. In phosphoric acid, and also in carboxylic acids, neutral chlorination products are obtained.

3. When chlorine reacts with 3,3,3-trichloropropene in glacial acetic or concentrated sulfuric acid, 2,3,3,3-tetrachloropropyl acetate or sulfate is obtained, respectively. This confirms that the trichloromethyl group shows the orienting effect characteristic of an electron-accepting group.

ACTION OF WATER ON 3,4-BISCHLOROMETHYL-2,5-DIMETHYLTHIOPHENE

Ya. L. Goldfarb and M. S. Kondakova

In the course of a study of the properties of 3,4-bischloromethyl-2,5-dimethylthiophene (I) it became necessary to study its behavior toward water at a moderate-temperature (70-80°).

(I)

It might be supposed that, as an analog of 2-thenyl chloride, which is readily affected by nucelophilic reagents [1], the compound (I) would readily undergo hydrolysis, even under such mild conditions, with formation of a compound or compounds containing an intra- or inter-molecular oxygen bridge and also compounds containing an alcohol grouping. In this connection it must be mentioned that Steinkopf [2] heated 3,4,5-tribromo-2-thenyl bromide with water in presence of sodium carbonate and obtained the corresponding bromine-substituted dithenyl ether. Another relevant observation is that of Cairns and McKusick on the formation of ethyl 2-thenyl ether by reaction of 2-thenyl chloride with aqueous alcohol.

Our first experiments already showed that the bischloromethyl compound (I) does indeed undergo change in even a very short treatment with hot water. Outwardly this is clear from the fact that, after it has melted, the compound (I) slowly begins to solidify. By repeated recrystallization of the mass so obtained we succeeded in isolating crystals of m.p. 154-155° in a yield that varied from one experiment to another. Further study of this substance showed that, as had been supposed, it contained ether oxygen, but it corresponded in composition to the formula $C_{18}H_{18}OS_2$, with an odd number of carbon atoms. This result can be explained only by the view that the formation of a compound $C_{18}H_{18}OS_2$ in the course of the reaction of (I) with water is associated with the elimination of one carbon atom in the form of formaldehyde. Formaldehyde is indeed found in the filtrate obtained in separation of the product of the reaction of (I) with water.

It is pertinent to mention here that this kind of scission of a C—C bond under conditions close to those described in this paper has been observed previously, for example in the hydrolysis of bromomethyl and hydroxymethyl derivatives of pyrrole, by Fischer and coworkers [3] and later by Corwin and coworkers [4]; as a result of this reaction, the corresponding methylenedipyrroles are obtained with elimination of formaldehyde. However, our case of carbon—carbon scission differs from those cited in that it occurs at a β-carbon not directly attached to the hetero atom of the ring.

Consideration of the data obtained on the composition and properties of the substance of m.p. 154-155° together with the nature of the original compound (I) enables us to assign the structure (II) to this compound.

(II)

This formula indicates that the compound contains a condensed ring system built up from an eight-membered oxygen-containing ring and two thiophene rings, i.e. 1,3,7,9-tetramethyl-4H,6H,10H-dithieno [3,4-c,3', 4'-f] oxocin. The readiness with which the substance of m.p. 154-155° is formed may give rise to doubt about the correctness of this view of its structure, particularly since there is the possibility of the intramolecular ring-closure of (I) with formation of (III), which contains a hydrogenated furan ring:

(III)

However, further experiments, designed for the verification of the view that we have advanced, confirmed the correctness of the formula (II). Thus, when the compound (II) was submitted to the reaction described by one of us and Smorgonsky [5] - which consists in the splitting of ethers with thionyl chloride in presence of stannic chloride - it was converted into a dichloro compound, which was found to be identical with 3,3'-methylenebis [4-(chloromethyl)-2,5-dimethylthiophene] (IV), which we have prepared by the chloromethylation of 3,3'-methylenebis[2,5-dimethylthiophene] (V) [6]. When treated with water, the bischloromethyl compound (IV) again gives the cyclic ether (II). These reactions, particularly the last, give poor yields, for other, parallel reactions occur. However, they make it possible to establish a relationship between the various compounds.

(II)

(IV)

(V)

The structure (II) for the compound of m.p. 154-155° is supported also by its dipole moment. This property was measured in E. N. Guryanova's laboratory at the L. Ya. Karpov Institute. The authors take this opportunity to express their thanks to E.N. Guryanova for her readiness to undertake this work and for carrying it out.

The value found for the dipole moment (1.42 D) is identical with the value calculated on the assumptions that the molecule is built up of two flat systems attached through the common carbon atom (I)

(I)

and that the oxygen completing the eight-membered ring is in the syn-position, as shown diagrammatically in (Ia) and not in the anti-position (Ib) For the latter structure (Ib), the calculated dipole moment is 2.4-2.5 D.

The compound (II) can be obtained directly in low yield from 2,5-dimethylthiophene by chloromethylation under conditions somewhat different from those described previously [6], namely, by replacement of concentrated hydrochloric acid by dilute (1:1) acid. When the experiment is carried out under such conditions, apart from the compound (II), a small amount of another compound of composition $C_9H_{12}O_2S$, m.p. 75-75.5°, can be isolated.

This compound does not contain active hydrogen and appears to be the product (VI) of the condensation of 3,4-bischloromethyl-2,5-dimethylthiophene:

However, this view on the structure of the compound (VI) is in need of experimental confirmation.

In view of these results, it was of interest to study the behavior of other 2,5-dialkyl-3,4-bischloromethylthiophenes toward water. The investigation that we have undertaken in this direction, in which the behaviors of 2,5-di-tert-butyl-3,4-bischloromethylthiophene (VII) and 3,4-bischloromethyl-2,5-diethylthiophene (VIII) were examined, cannot be regarded as complete, mainly because we succeeded in isolating the reaction products in only insignificant amounts. With water, the first of these two chloromethyl derivatives forms a cyclic ether, probably of structure (III) (R = $C(CH_3)_3$), m.p. 220°; with thionyl chloride (see above) this gives the original 2,5-di-tert-butyl-3,4-bischloromethylthiophene, which indicates that the structure (III) is correct for the compound of m.p. 220°. Together with this ether, 2,5-di-tert-butyl-3-4-thiophenedimethanol (IX) is formed:

This was found to be identical with the product of the hydrolysis of the corresponding diacetic ester obtained by action of sodium acetate on (VII). From the product obtained by reaction of 3,4-bischloromethyl-2,5-diethylthiophene with water we succeeded in isolating only an insignificant amount of compound of m.p. 119°, which corresponded in composition to formula (III) (R=C_2H_5). We could not detect the presence of condensed systems of the type (II) among the products of the reaction of (VII) and (VIII) with water.

At present it does not appear to be possible to give a satisfactory explanation of the surprising difference in behavior between the analogous systems (I), (VII), and (VIII) in reaction with water. However, we hope to return to this question later.

EXPERIMENTAL

1. Action of Water on 3,4-Bischloromethyl-2,5-dimethylthiophene. A stirred mixture of 6 g of 3,4-bischloromethyl-2,5-dimethylthiophene, m.p. 68-68.5°, and 120 ml of water was heated at 70-80° in a water bath for 1 hour 15 minutes. After one hour at room temperature, the solid reaction product was filtered off, ground, and washed with small amounts of acetone. The colorless product (2 g) melted at 153-155° (it showed a preliminary fusion effect). Recrystallization from acetone gave long colorless needles, m.p. 154-155.5°.

Further recrystallization from acetone and heptane did not affect the melting point.

Found %: C 64.55; 64.44; H 6.41; 6.47; S 22.87; 22.98. $C_{15}H_{18}OS_3$. Calculated %: C 64.74; H 6.47 S 23.02.

Found: M 263 Calculated: M 278.

The substance does not contain active hydrogen. It is insoluble in water, soluble in alcohol and benzene, difficulty soluble in cold heptane. The dipole moment of the substance of m.p. 154-155° was measured in benzene solution at 25° by the pulse method on the apparatus of the Karpov Institute. The results of the measurements are given in the table.

TABLE

c	E	d

0.023	2.2726	0.87293
0.051	2.2738	0.87322
0.093	2.2753	0.87369
0.117	2.2762	0.87387
0.149	2.2774	0.87428

P_{∞} = 124.1

μ = 1.42

Note: c — mole percentage of solution; E — dielectric constant of solution; d — density of solution; P_{∞} — polarization of substance at infinite dilution.

Extrapolation to infinite dilution was carried out by the Hedestrand method. The dipole moment was calculated from the formula:

$$\mu = 0.22 \sqrt{P_{\infty} - P_E}.$$

P_E was calculated additively on the basis of the experimentally determined refraction of tetramethylthiophene.

Formaldehyde was detected in the aqueous filtrate with the aid of the reaction of Rimini et al. [7]. The formaldehyde was isolated as its 2,4-dinitrophenylhydrazone, which melted at 163.5° after recrystallization from alcohol. In admixture with a known sample of formaldehyde 2,4-dinitrophenylhydrazone, it melted without depression.

Found % N 26.54. $C_7H_6N_4O_4$. Calculated % N 26.66.

2. Action of Thionyl Chloride on the Compound of M.p. 154-155°. Thionyl chloride (0.3 g) and stannic chloride (two drops) were added to a solution of 2.3 g of the hydrolysis product in 30 ml of dry benzene, and the mixture was heated in a water bath for five hours, after which it was left at room temperature overnight. The reaction product was decomposed with water. The benzene solution was separated and washed with water and with 5% sodium bicarbonate solution (ether was added to promote better separation of the layers). Benzene was distilled off under reduced pressure, and the solid residue (1.9 g) was washed with heptane and then crystallized twice from hot heptane.

The crystals so obtained melted at 171-172°. In a mixture test with the substance obtained by the chloromethylation of 3,3'-methylenebis [2,5-dimethylthiophene] there was no depression.

Found % C 54.32; 54.34; H 5.73; 5.15. $C_{15}H_{18}Cl_2S_3$. Calculated % C 54.05; H 5.40.

3. Action of Water on 3,3'-Methylenebis [4-(chloromethyl)-2,5-dimethylthiophene]. A stirred mixture of 2.6 g of 3,3'-methylenebis[4-(chloromethyl)-2,5-dimethylthiophene] and 120 ml of water was heated at 60-80° in a water bath for four hours. The mixture was cooled, and the solid product was filtered off and dissolved in hot heptane. After several days in a refrigerator, the heptane solution gave 0.9 g of crystals, m.p. 138-148°. After recrystallization from acetone the melting point range was unchanged. The substance was again heated with water at 90-95° for eight hours, after which the product was filtered off and crystallized from acetone; m.p. 155°, undepressed by admixture of the substance obtained by the action of water on 3,4-bischloromethyl-2,5-dimethylthiophene.

Found % C 65.01; 65.21; H 6.48; 6.44; S 22.60; 22.50. $C_{15}H_{18}OS_3$. Calculated % C 64.71; H 6.47; S 23.02.

4. Action of Water on 2,5-Di-tert-butyl-3,4-bischloromethylthiophene. A stirred mixture of 5 g of 2,5-di-tert-butyl-3,4-bischloromethylthiophene and 70 ml of water was heated at 80-90° in a water bath for six hours. The solid reaction product was dissolved in benzene, the solution was washed with water, and benzene was distilled off under reduced pressure. The residue (4.4 g of oil) was dissolved in hot heptane. After standing in a refrigerator, the solution yield a small amount (0.2 g) of crystals, m.p. 141-143°, which melted at 162.5° after compound, see below). Heptane was distilled from the heptane filtrate. The residue was heated with 80 ml of water and a little acetone at 90° for four hours. The mixture was cooled, and the solid was separated from the water and dissolved in a mixture of acetone and water. When this solution was kept in the refrigerator for several days, some crystals (0.5 g) separated after recrystallization from heptane they melted at 220-221°.

Found %: C 70.41; 70.35; H 9.23; 9.39; S 13.12; 13.20. $C_{14}H_{22}OS$. Calculated %: C 70.58; H 9.24; S 13.44.

Water was added to the acetone-water filtrate, and the mixture was again stirred in the water bath (90°) for 6 hours 30 minutes. The resulting semisolid mass was dissolved in hot heptane. On cooling, 0.4 g of crystals, m.p. 167-169°, separated. After recrystallization from heptane they melted at 166-167°.

Found %: C 65.29; 65.34; H 9.22; 9.15; S 12.68; 12.95. $C_{14}H_{24}O_2S$. Calculated %: C 65.62; H 9.37; S 12.50.

The substance was found to be identical with the dihydroxy compound obtained by the hydrolysis of the diacetic ester of 2,5-di-tert-butyl-3,4-thiophenedimethanol.

5. Diacetic Ester of 2,5-Di-tert-butyl-3,4-thiophenedimethanol. Anhydrous sodium acetate (1.8 g) was added to a solution of 3 g of 2,5-di-tert-butyl-3,4-bischloromethylthiophene in 10 ml of glacial acetic acid. The mixture was heated at 60-70° in a water bath for 4 hours 30 minutes. The mixture was cooled, and the precipitate was filtered off. On standing, the filtrate yielded 1.2 g of crystals, m.p. 134-135°. Evaporation of the filtrate gave a further 1.2 g of m.p. 135° (preliminary fusion occurred at a lower temperature). After recrystallization from heptane it melted at 135-135.5°.

Found %: C 63.50; 63.50; H 8.25; 8.04; S 9.43; 9.60. $C_{18}H_{28}O_4S$. Calculated %: C 63.52; H 8.22; S 9.41.

6. Hydrolysis of the Diacetic Ester of 2,5-Di-tert-butyl-3,4-thiophenedimethanol. The diacetic ester of 2,5-di-tert-butyl-3,4-thiophenedimethanol (2.3 g) was added to an alcoholic solution of sodium ethoxide prepared from 0.04 g of sodium and 10 ml of absolute ethanol. The mixture was stirred at room temperature for seven hours and then set aside for two days. The precipitate that formed was filtered off and washed with alcohol. Alcohol was distilled from the filtrate, and the residue (1.4 g) was crystallized from heptane. The product, amounting to 0.5 g, melted at 166-167°. Recrystallization from heptane did not affect the melting point.

Found %: C 66.05; 66.13; H 9.42; 9.29; S 12.14; 11.96. $C_{14}C_{24}O_2S$. Calculated %: C65.62; H 9.37; S 12.50.

7. Action of Thionyl Chloride on the Substance of M.p. 219-220° obtained by the Action of Water on 2,5-Di-tert-butyl-3,4-bischloromethylthiophene. A mixture of 0.6 g of the substance of m.p. 219-220°, 10 ml of dry benzene, 0.3 g of thionyl chloride, and one drop of stannic chloride was heated in a water bath for three hours. The mixture was cooled and poured into water, and the benzene layer was separated and washed with 5% sodium carbonate solution and with water. The residue remaining after removal of benzene was dissolved in acetic acid. The crystals that separated when the solution was kept in a refrigerator were filtered off and washed with heptane and alcohol. After recrystallization from acetic acid they melted at 85.5-86.5°. In admixture with 2,5-di-tert-butyl-3,4-bischloromethylthiophene [6] they melted at the same temperature.

8. Action of Water on 3,4-Bischloromethyl-2,5-diethylthiophene. A stirred mixture of 6 g of 3,4-bischloromethyl-2,5-diethylthiophene and 140 ml of water was heated at 90-95° in a water bath for 1 hour 20 minutes. The substance was gradually converted into reddish oil. The aqueous layer was poured off, and the oil was dissolved in hot acetone. The crystals that separated when the solution was kept in a refrigerator (0.3 g) melted at 119°, and the melting point was not affected by recrystallization from heptane.

Found %: C 66.08; 66.33; H 7.70; 7.94; S 17.21; 17.45. $C_{10}H_{14}OS$. Calculated %: C 66.00; H 7.70; S 17.60.

9. Action of Formaldehyde on 2,5-Dimethylthiophene in presence of Dilute Hydrochloric Acid. A mixture of 5.6 g of 2,5-dimethylthiophene, 10 ml of concentrated hydrochloric acid (d = 1.18), 10 ml of water, and 10 ml of 37% formaldehyde was heated at 75° in a water bath for one hour. The mixture first became blue, then green, and finally brown. The mixture was kept at room temperature for several hours, and the precipitate that formed was then separated, washed with water, and dissolved in benzene. The benzene solution was washed with water and with sodium carbonate solution. Benzene was distilled off, and vacuum distillation of the residue gave the fractions:

Fraction I, b.p. 130-150° (7 – 8 mm); 1.5 g
Fraction II, b.p. 150-210° (7 – 8 mm); 2.6 g

The resinous residue in the flask (1.6 g) was not investigated. Fraction I was dissolved in hot heptane, and the solution was placed in a refrigerator. Crystals separated (0.6 g, m.p. 71-72°); they did not contain halogen. After two recrystallizations from heptane they melted at 75-75.5°.

Found %: C 58.67; 58.58; H 6.30; 6.15; S 17.43; 17.51. $C_9H_{12}O_2S$. Calculated %: C 58.69; H 6.52; S 17.40.

The substance did not contain active hydrogen; it sublimed when left in the open at room temperature.

Found: M 181; 179 Calculated: M 184

Fraction II was dissolved in hot heptane. When the heptane solution was cooled, 0.9 g of crystals separated (m.p. 92-120°). After repeated crystallization from heptane the substance melted at 154-155°. In admixture with the substance obtained by the action of water on 3,4-bischloromethyl-2,5-dimethylthiophene there was no depression of melting point.

SUMMARY

1. When 3,4-bischloromethyl-2,5-dimethylthiophene was treated with water, the condensed system 1,3,7,9-tetramethyl-4H, 6H, 10H-dithieno[3,4-c,3',4'-f]oxocin (II) was formed.

2. The structure of this product was confirmed by its synthesis from 3,3'-methylenebis[2,5]dimethylthiophene] by the results of the splitting of the product with thionyl chloride, and by the results of dipole moment measurements.

3. No analogs of the compound (II) could be detected among the hydrolysis products of 2,5-di-tert-butyl-3,4-bischloromethylthiophene and of 3,4-bischloromethyl-2,5-diethylthiophene.

STEREOCHEMISTRY OF CYCLIC COMPOUNDS

COMMUNICATION 14. CONDENSATION OF 1-(1-ACETOXYVINYL)CYCLOHEXENE WITH METHYL ACRYLATE

I. N. Nazarov, V. F. Kucherov, and G. M. Segal

As we have pointed out previously [1], in the condensation of various dienophiles with 1-(1-acetoxyvinyl) cyclohexene[1-(1-cyclohexen-1-yl)ethenol acetic ester] (I), good yields are obtained of adducts which are readily converted by hydrolysis into polycyclic compounds containing an α-keto group in the nucleus. It is characteristic of the diene (I) that in reaction with methyl acrylate it forms a mixture of the stereoisomeric adducts (II) and (III), which are epimeric with respect to the hydrogen at C-8a and which are hydrolyzed to the isomeric decahydro-4-oxo-1-naphthoic acids (IV) and (V), with trans configuration of the rings. This fact prompted us to make a detailed study of the effect of temperature on steric directivity in a diene reaction of this sort with the object of making a further investigation of the stereochemistry of the isomeric decahydro-1-naphthoic acids. It was found that in the condensation of the diene (I) with methyl acrylate the ratio in which the isomeric adducts (II) and (III) are formed depends on temperature, but the character of the dependence is quite different from that found in the case of 1-vinylcyclohexene [2].

In order to isolate the individual isomers we hydrolyzed the liquid mixture of the adducts (II) and (III) with 20% potassium hydroxide solution, and crystallization then gave trans-anti-decahydro-4-oxo-1-naphthoic acid (IV), m.p. 156°; from the liquid residue, after esterification with diazomethane, the isomeric trans-syn keto acid (V) was readily isolated in the form of its ester (VII), m.p. 92°. Treatment of the trans-anti acid (IV) with diazomethane gave the corresponding ester (VI), m.p. 68°, which could be quantitatively hydrolyzed to the original acid. However, attempts to obtain the pure trans-syn keto acid (V) by hydrolysis of its ester (VII) were not successful, since partial isomerization occurred with formation of a mixture of acids that was difficult to separate.

By the use of this method, which is described in detail in the experimental part, we succeeded in showing that, in spite of the possibility of partial isomerization of the syn adduct (III) in the course of hydrolysis, the amount formed of the anti isomer (II) diminishes with rise in the temperature of the condensation. The relative amounts of the isomers can be seen from the table.

TABLE

Condensation temperature (°C)	Duration of condensation	Total yield of adduct (%)	Amount of isomers Keto acid (IV)	Keto ester (VII)
20	65 days	24	62	6
80	20 hrs	57	46	22
100	15 hrs	80	43	23
180	6 hrs	65	37	24

The results show that, in contrast to the behavior of 1-vinylcyclohexene, condensation of 1-(1-acetoxyvinyl)cyclohexene with methyl methacrylate yields mainly the anti isomer (II), readily isolated in the form of the trans-anti keto acid (IV). However, the amount of this diminishes appreciably with rise of temperature, whereas the yield of the syn isomer (III), isolated in the form of the trans-syn keto ester (VII), increases very greatly, attaining 24% at 180°. The trans-anti keto ester (VI) is very stable thermally, and after being heated at 250° for two hours it can be recovered unchanged almost quantitatively. On the other hand, the trans-syn isomer (VII) is isomerized considerably under these conditions, being converted to an extent of more than 50% into an inseparable mixture of isomeric keto esters.

The spatial structures of the isomeric adducts were readily proved by Clemmensen reduction of the keto esters (VI) and (VII). It was found that the trans-anti keto ester (VI) gives a good yield of the previously prepared [2] trans-anti-decahydro-1-naphthoic acid (VIII), m.p. 88°, m.p. of amide 223° [3]. Similar reduction of the trans-syn keto ester (VII) gives the new, isomeric trans-syn-decahydro-1-naphthoic acid (IX), m.p. 126-127°, m.p. of amide 192-193°.

In order to confirm the configuration of the trans-syn acid (IX) it was converted by the Schmidt reaction into the known trans-syn-decahydro-1-naphthylamine (X), from which the acetyl derivative, m.p. 128-130°, and benzoyl derivative, m.p. 110-111°, were prepared; their properties coincided with those reported in the literature. These results show that alkaline hydrolysis of the acetylated enol group in the epimeric adducts (II) and (III) leads exclusively to compounds of the tran-decahydronaphthalene series, so that the use of 1-(1-acetoxyvinyl)cyclohexene (I) in various diene condensations is of particular interest.

The fact that the main product of the diene reaction of 1-(1-acetoxyvinyl) cyclohexene with methyl acrylate is the anti isomer (II) can be explained by the steric and electrostatic effects of the electronegative acetylated enol group present in the molecule of the diene (I). As a result of these effects the mutual spatial orientation of the components according to scheme (a) is rendered difficult, whereas favorable conditions are created

for orientation in accordance with scheme (b) (contrary to the rule of "accumulation of unsaturation") with formation of the anti isomer (II).

With rise in the condensation temperature there is a rise also in the probability of the molecules' coming together according to scheme (a) with formation of the syn isomer (III).

EXPERIMENTAL

Condensation of 1-(1-Acetoxyvinyl)cyclohexene with Methyl Acrylate

a) A solution of 28 g of 1-(1-acetoxyvinyl) cyclohexene (I) [1] and 13.8 g of methyl acrylate in 60 ml of dry benzene was boiled in presence of a little pyrogallol for 20 hours. Solvent was distilled off, and vacuum distillation of the residue gave 12.5 g of the original diene (I) and 23.2 g (57.4%) of a liquid mixture of adducts (II) and (III), b.p. 130-132.5° (2 mm) and n_D^{20} 1.4910.

Found %: C 66.34; 66.33; H 8.00; 8.04. $C_{14}H_{20}O_4$. Calculated %: C 66.24; H 7.99.

b) Similarly, a solution of 8 g of the diene (I) and 4 g of methyl acrylate in 15 ml of dry toluene was boiled for 15 hours. Vacuum distillation of the product gave 9.4 g (80%) of a mixture of adducts (II) and (III), b.p. 133-135° (2 mm); n_D^{20} 1.4910; d_4^{20} 1.1050.

c) A mixture of 10 g of the diene (I), 5 g of methyl acrylate, and 15 ml of dry benzene was heated in a steel tube at 175-180° for six hours. Vacuum distillation gave 10.3 g (65%) of a mixture of adducts (II) and (III), b.p. 133-135° (2 mm).

d) A solution of 10 g of the diene (I) and 5 g of methyl acrylate in 15 ml of benzene was left at 20° for 65 days. Distillation gave 6.4 g of the original diene (I) and 3.65 g of liquid adduct, b.p. 135-137° (3 mm) and n_D^{20} 1.4920. The yield was 24% on the amount of diene taken and 69% on the amount that reacted.

Isolation of trans-anti-Decahydro-4-oxo-1-naphthoic Acid (IV) and the Methyl Ester of the trans-syn Isomer (VII)

The mixture of the adducts (II) and (III) obtained by the condensation of 1-(1-acetoxyvinyl) cyclohexene with methyl acrylate at 80° (23.2 g) was boiled for three hours with a solution of 46 g of potassium hydroxide in 200 ml of water. The mixture was then acidified with hydrochloric acid, and the semisolid product was extracted with ether. After distillation of the ether, the product was treated with 25 ml of a 2 : 1 mixture of ether, and petroleum ether, and in this way 7 g of the crystalline trans-anti keto acid (IV), m.p. 152-154°, was obtained. When the mother liquor was set aside overnight, a further 0.15 g of the same acid, m.p. 149-151°, separated. Crystallization from a mixture of diethyl ether and petroleum ether gave pure trans-anti-decahydro-4-oxo-1-naphthoic acid (IV), melting constantly at 155-156°.

Found %: C 67.42; 67.59; H 8.20; 8.18. $C_{11}H_{16}O_3$. Calculated %: C 67.32; H 8.21.

The amide was prepared; m.p. 201-202° after two recrystallizations from alcohol.

The residue after the separation of the trans-anti acid (IV) was treated with ethereal diazomethane, ether was distilled off, and the liquid product was dissolved in 15 ml of petroleum ether. Standing overnight gave 2.65 g of methyl trans-syn-decahydro-4-oxo-1-naphthoate (VII), m.p. 87-89°. A further 0.65 g of the same ester, m.p. 85-87°, was obtained by partial evaporation of solvent. Crystallization from petroleum ether gave pure trans-syn ester (VII), m.p. 91-92°.

Found %: C 68.72; 68.77; H 8.85; 8.71. $C_{12}H_{18}O_3$. Calculated %: C 68.54; H 8.63.

An attempt to hydrolyze the ester (VII) by boiling it with a 20% solution of potassium hydroxide resulted in the formation of a mixture of isomeric acids, from which, by treatment with diazomethane, we succeeded in isolating only about 60% of the original trans-syn keto ester (VII).

The semicarbazone of the keto ester (VII) was prepared in the usual way; m.p. 222-223° (from methanol).

Found %: N 15.58; 15.57. $C_{13}H_{21}O_3N_3$. Calculated %: N 15.72.

With the object of obtaining further amounts of the crystalline isomers, the residue after the isolation of the ester (VII) was again hydrolyzed with 20% sodium hydroxide solution, and the procedure described above was repeated. As a result, a further 1.1 g of the trans-anti keto acid (IV) and a further 1.15 g of the trans-syn keto ester (VII) were obtained.

By a similar method the isomers were isolated also from the mixtures of adducts (II) and (III) formed at other temperatures. Thus, from 3.65 g of adduct prepared at 20°, 1.75 g of the trans-anti keto acid (IV) and 0.18 g of the trans-syn keto ester (VII) were isolated, whereas from 8 g of adduct prepared at 180° the amounts of these isomers were 2.35 g and 1.6 g, respectively.

Methyl trans-anti-Decahydro-4-oxo-1-naphthoate (VI)

A solution of 2 g of the trans-anti keto acid (IV) in ether was treated with excess of ethereal diazomethane. Removal of solvent gave 1.9 g of the trans-anti keto ester (VI), m.p. 66-68°. Crystallization from petroleum ether did not affect the melting point (67-68°).

Found %: C 68.73; 68.74; H 8.69; 8.53. $C_{12}H_{18}O_3$. Calculated %: C 68.54; H 8.63.

Hydrolysis of this ester with boiling 20% potassium hydroxide solution gave the original trans-anti keto acid (IV). The semicarbazone prepared in the usual way from the trans-anti keto ester (VI) melted at 225-226° after crystallization from methanol; the melting point was depressed by admixture of the semicarbazone of the trans-syn keto ester (VII) (205-211°).

Found %: N 15.96; 16.08 $C_{13}H_{21}O_3$. Calculated %: N 15.72.

trans-anti-Decahydro-1-naphthoic Acid (VIII)

A mixture of 0.35 g of the trans-anti keto ester (VI), 2 g of amalgamated zinc, and 5 ml of concentrated hydrochloric acid was boiled for five hours. The crystalline product obtained on cooling was filtered off: 0.25 g of the trans-anti acid (VIII), m.p. 85-87°, raised to 87-88° by crystallization from petroleum ether; a mixture test with a known sample [2] showed no depression. The amide of the acid had m.p. 222-223°, undepressed by admixture of a known sample [3].

trans-syn-Decahydro-1-naphthoic Acid (IX)

Analogous reduction of 3 g of the trans-syn keto ester (VII) gave 1.5 g of the trans-syn acid (IX), which, after two crystallizations from a mixture of diethyl ether and petroleum ether had a constant melting point of 126-127°, which was depressed by admixture of the previously described [2] cis-syn-decahydro-1-naphthoic acid (98-105°).

Found %: C 72.12; 72.29; H 9.74; 9.79 $C_{11}H_{18}O_2$. Calculated %: C 72.49; H 9.95

The amide was prepared; after crystallization from alcohol it melted at 192-193°.

Found %: C 72.67; 72.88; H 10.45; 10.63 $C_{11}H_{19}ON$. Calculated %: C 72.76; H 10.56.

trans-syn-Decahydro-1-naphthylamine (X) and its Derivatives

Concentrated sulfuric acid (11 ml) was added to a solution of 1 g of trans-syn-decahydro-1-naphthoic

acid (IX) in 28 ml of dry chloroform. The mixture was heated to 40°, and with constant stirring 0.8 g of sodium azide was gradually added in small portions. The mixture was heated at 50° for one hour and then poured into 30 ml of cold water. The aqueous layer was separated, subjected to extraction with ether, and saturated with solid sodium hydroxide. The amine that separated was extracted with ether, and the extract was dried with potassium carbonate. Ether was distilled off, leaving 0.65 g of trans-syn-decahydro-1-naphthylamine, which was used for the preparation of derivatives without further purification.

By treatment with acetic anhydride in boiling benzene solution in the usual way, 0.35 g of the amine gave 0.35 g of its acetyl derivative, which, after crystallization from a 2 : 1 mixture of petroleum ether and diethyl ether, had m.p. 129-130°, which coincides with that reported in the literature [4].

Found %: N 7.10; 7.23 $C_{12}H_{21}ON$. Calculated %: N 7.17.

Benzoylation of 0.3 g of the amine in the usual way gave 0.3 g of its benzoyl derivative, which, after crystallization from petroleum ether had m.p. 110-111°, which coincides with that reported in the literature [4].

Found %: N 5.61; 5.65. $C_{17}H_{23}ON$. Calculated %: N 5.44.

Thermal Transformation of the Isomeric Decahydro-4-oxo-1-naphthoic Acids (VI) and (VII)

a) The trans-anti keto ester (VI) (1 g) was heated for two hours at 250°. Vacuum distillation of the product gave 0.9 g of a liquid, which immediately solidified and had m.p. 66-68°, undepressed by admixture of some of the original keto ester (VI).

b) The trans-syn keto ester (VII) (0.6 g) was heated for two hours at 240-250°. Crystallization of the dark-colored product from petroleum ether gave 0.25 g of the original keto ester (VII), m.p. 90-92°, and 0.3 g of a mixture of keto esters which could not be separated by crystallization.

SUMMARY

1. A study was made of the condensation of 1-(1-acetoxyvinyl)cyclohexene (I) with methyl acrylate, and it was shown that the ratio in which the epimeric adducts (II) and (III) are formed is dependent on the condensation temperature. It was shown that, in contrast to the case of the condensation of 1-vinylcyclohexene, the main product is the anti isomer (II), the amount of which diminishes with rise in temperature, there being a simultaneous increase in the yield of the isomeric syn adduct (III).

2. By alkaline hydrolysis of the mixture of adducts (II) and (III), the isomeric decahydro-4-oxo-1-naphthoic acids were isolated in the form of the trans-anti acid (IV) and the trans-syn ester (VII). The spatial configuration of these products were proved by Clemmensen reduction into the known isomeric acids of the trans-decahydronaphthalene series (VIII) and (IX).

COMMUNICATION 176. SYNTHESIS OF 2-CARBOXYETHYL ETHERS OF ACETYLENIC ALCOHOLS AND OF THEIR ACID CHLORIDES AND AMIDES

I. N. Nazarov and G. A. Shvekhgeimer

The hydrolysis of 2-cyanoethyl ethers of saturated alcohols and glycols to the corresponding 2-carboxyethyl ethers can be effected smoothly by heating them with concentrated hydrochloric acid [1]. On the other hand, when attempts are made to effect the acid hydrolysis of 2-cyanoethyl ethers of acetylenic alcohols under various conditions (treatment with concentrated hydrochloric acid at temperatures ranging from 20° to 100°, both without solvent, and also in presence of ether or glacial acetic acid), complete resinification occurs. Alkaline hydrolysis of 2-cyanoethyl ethers of acetylenic alcohols in aqueous or methanolic solution gives the expected acids, but in low yield. When alkaline hydrolysis is carried out in 50% aqueous methanol, transcyanoethylation occurs and 3-methoxypropionic acid is formed. As a convenient method is available for the conversion of 2-cyanoethyl ethers of acetylenic alcohols into the corresponding 2-(methoxycarbonyl)ethyl ethers [2], we decided to hydrolyze the latter with the object of preparing the 2-carboxyethyl ethers that we required. It was found that 2-(methoxycarbonyl)ethyl ethers of acetylenic alcohols are smoothly hydrolyzed at room temperature by methanolic sodium hydroxide with formation of the corresponding 2-carboxyethyl ethers in high yield:

The 2-carboxyethyl ethers of acetylenic alcohols prepared in this way are listed in Table 1. Results of analysis and molecular-weight determination (by titration) are given in Table 2.

When treated with diazomethane, the 2-carboxyethyl ethers of acetylenic alcohols are reconverted almost quantitatively into the original 2-(methoxycarbonyl)ethyl ethers.

When treated with thionyl chloride at 60°, the 2-carboxyethyl ethers are converted into the corresponding acid chlorides in more than 90% yield, and treatment of the products with ammonia or amines in ethereal solution gives the corresponding amides in almost theoretical yield:

When the 2-carboxyethyl ethers of acetylenic alcohols were treated with thionyl chloride in presence of pyridine by the method described previously [3], the main products were the acid anhydrides:

• From petroleum ether.

•• From cyclohexane.

Hydrolysis of the 2-cyanoethyl ethers of acetylenic alcohols with alkaline hydrogen peroxide [4] provided another method of preparing the corresponding amides:

However, this reaction is not very smooth and the amides are obtained in the form of viscous oils that are difficult to purify.

The acid chlorides and amides of 2-carboxyethyl ethers of acetylenic alcohols which we prepared are listed in Tables 3-5 (the numbering of the compounds corresponds to that of the original acids except in the case of substituted amides).

We synthesized amides of 2-carboxyethyl ethers of acetylenic alcohols (Tables 4 and 5) with the object of testing their physiological activity, particularly in connection with the search for new soporifics, it being noteworthy that data have recently appeared in the literature concerning the soporific action of certain acetylenic alcohols and their derivatives [5].

EXPERIMENTAL

Hydrolysis of the previously described [2] 2-(methoxycarbonyl)ethyl ethers of acetylenic alcohols, and also the conversion of the resulting acids into acid chlorides and amides, was carried out by a standard procedure, which will now be described for the case of the 2-(methoxycarbonyl)ethyl ether of 2-methyl-3-butyn-2-ol.

Hydrolysis of the 2-(Methoxycarbonyl)ethyl Ether of 2-Methyl-3-butyn-2-ol.

To a solution of 25 g of sodium hydroxide in 25 ml of water and 475 ml of methanol, 17 g of the 2-(methoxycarbonyl)ethyl ether of 2-methyl-3-butyn-2-ol (b.p. 83-84°, 12 mm) [2] was added. After careful stirring, the mixture was left for 20 hours at room temperature. A current of carbon dioxide was then passed through the mixture for 90 minutes in order to neutralize the alkali, the precipitate formed was filtered off, and the filtrate was evaporated to dryness under reduced pressure. The residue and the precipitate on the filter were dissolved in water, and the aqueous solution was subjected to extraction by ether, was acidified to Congo red with hydrochloric acid, and was saturated with sodium chloride. The solution was extracted with three portions of ether, and the ether extract was dried with magnesium sulfate and vacuum-fractionated. The product, amounting to 14 g was the 2-carboxyethyl ether of 2-methyl-3-butyn-2-ol (IV), b.p. 108-110° (3.5 mm); n_D^{20} 1.4419; d_4^{20} 1.0263; found MR 40.21; calculated MR 40.26; found M 157, 158.2 (by titration); calculated M 156.

Found %: C 60.93; 60.78; H 7.94; 7.84. $C_9H_{12}O_3$. Calculated %: C 61.54; H 7.69.

The 2-carboxyethyl ethers of the other acetylenic alcohols (Table 1) were prepared similarly.

Alkaline Hydrolysis of the 2-Cyanoethyl Ether of 2-Methyl-3-butyn-2-ol

a) A mixture of 10 g of the 2-cyanoethyl ether of 2-methyl-3-butyn-2-ol (b.p. 96-97°, 18 mm) [6], 15 g of potassium hydroxide, and 100 ml of water was stirred at 50-60° for 15 hours. The cooled mixture was acidified with hydrochloric acid, and the acid solution was saturated with sodium chloride. The solution was then extracted with three portions of ether, and the ether extracts were dried with magnesium sulfate. Vacuum fractionation gave 2.1 g of the 2-carboxyethyl ether (IV), b.p. 104-107° (3 mm) and n_D^{20} 1.4406.

b) A mixture of 10 g of the 2-cyanoethyl ether of 2-methyl-3-butyn-2-ol, 12 g of potassium hydroxide, 50 ml of methanol, and 50 ml of water was boiled for 20 hours. Methanol was distilled off under reduced pressure, and the aqueous residue was acidified with hydrochloric acid, saturated with sodium chloride, and extracted with three portions of ether. The ether extracts were dried with magnesium sulfate. Vacuum distillation gave 4.5 g of 3-methoxypropionic acid, b.p. 96-97° (7 mm) and n_D^{20} 1.4208.

c) A mixture of 10 g of the 2-cyanoethyl ether of 2-methyl-3-butyn-2-ol, 8 g of potassium hydroxide, and 100 ml of methanol was boiled for 35 hours. Alkali was neutralized with hydrochloric acid, methanol was distilled off, and the residue was acidified with hydrochloric acid and extracted with three portions of ether. The ether extracts were dried with magnesium sulfate. Vacuum fractionation gave 3.1 g of the 2-carboxyethyl ether (IV), b.p. 112-115° (5 mm) and n_D^{20} 1.4397.

Reaction of the 2-Carboxyethyl Ether of 2-Methyl-3-butyn-2-ol (IV) with Diazomethane.

An ethereal solution of diazomethane was prepared from 5 g of 1-nitroso-1-methylurea, 15 ml of 40% aqueous potassium hydroxide, and 50 ml of ether, and 5.2 g of the 2-carboxyethyl ether of 2-methyl-3-butyn-2-ol (IV) (b.p. 116-118°, 6 mm) was added gradually at 5°. The ether layer was separated, dried with magnesium sulfate, and vacuum-fractionated. The product, amounting to 5.6 g, was the 2-(methoxycarbonyl)ethyl ether of 2-methyl-3-butyn-2-ol, b.p. 85-87° (16 mm) and n_D^{20} 1.4296.

Preparation of the Acid Chloride of the 2-Carboxyethyl Ether of 2-Methyl-3-butyn-2-ol

A mixture of 26.5 g of the 2-carboxyethyl ether of 2-methyl-3-butyn-2-ol (IV) (b.p. 108-110°, 3.5 mm) and 21 ml of thionyl chloride was heated under reflux at 50-60° in a round-bottomed flask for 1.5-2 hours. Vacuum fractionation of the product gave 28.2 g of the acid chloride, b.p. 85-87° (24 mm); n_D^{20} 1.4432; d_4^{20} 1.0510; found MR 43.94; calculated MR 43.97.

The acid chlorides of the other 2-carboxyethyl ethers of acetylenic alcohols were prepared similarly (Table 3).

Reaction of the 2-Carboxyethyl Ether of 2-Methyl-3-butyn-2-ol with Thionyl Chloride in presence of Pyridine

a) A solution of 2.4 g (0.02 mole) of thionyl chloride in 10 ml of dry ether was added in small portions at −5° to a stirred cooled solution of 3.12 g (0.02 mole) of the 2-carboxyethyl ether of 2-methyl-3-butyn-2-ol and 1.6 g (0.02 mole) of pyridine in 10 ml of dry ether. The mixture was left for one hour at room temperature, ether was distilled off, and the product was vacuum fractionated, yielding 1 g of the acid chloride of the 2-carboxyethyl ether of 2-methyl-3-butyn-2-ol (IV), b.p. 85-86° (24 mm) and 2.1 g of the corresponding anhydride, b.p. 155-157° (3.5 mm); n_D^{20} 1.4518; d_4^{20} 1.0361; found MR 76.52; calculated MR 75.91

Found %: C 64.45; 64.37; H 7.52; 7.48. $C_{18}H_{22}O_5$. Calculated %: C 65.30; H 7.48.

b) A mixture of 3.12 g (0.02 mole) of the 2-carboxyethyl ether of 2-methyl-3-butyn-2-ol, 1.6 g (0.02 mole) of pyridine, and 2.4 g (0.02 mole) of thionyl chloride in 20 ml of dry ether was left at room temper-

ature, for 18 hours, and 2.8 g of the corresponding anhydride, b.p. 155-157° (3.5 mm) was obtained.

Preparation of the Amide of the 2-Carboxyethyl Ether of 2-Methyl-3-butyn-2-ol

Dry ether (50 ml) was placed in a three-necked flask fitted with mechanical stirrer having a glycerol seal, dropping funnel, and tube for passage of gas, which reached almost to the bottom of the flask. The ether was stirred and cooled with ice water while ammonia gas was passed to saturation, and a solution of 7 g of the acid chloride of the 2-carboxyethyl ether of 2-methyl-3-butyn-2-ol (IV) in 30 ml of dry ether was added at 0° over a period of 90 minutes with continuous passage of ammonia gas. The reaction mixture was then stirred at room temperature for a further 90 minutes, and the precipitated ammonium chloride was then filtered off and washed on the filter with ether. The ether solutions were combined, and ether was distilled off under reduced pressure. The residue was dissolved in dry ether and reprecipitated with petroleum ether. The product (6.25 g) was the amide, m.p. 51-52.5°.

Found %: N 9.15; 9.17; C 61.47; 61.59; H 8.37; 8.50. $C_9H_{15}NO_3$. Calculated %: N 9.03; C 61.93; H 8.38.

All the other amides of 2-carboxyethyl ethers of acetylenic alcohols were prepared by this method (Table 4).

Preparation of the Methylamide of the 2-Carboxyethyl Ether of 2-Methyl-3-butyn-2-ol (XVII)

A solution of 8.7 g (0.05 mole) of the acid chloride of the 2-carboxyethyl ether of 2-methyl-3-butyn-2-ol (IV) in 30 ml of dry ether was added over a period of two hours to a stirred cooled (ice water) solution of 3.2 g (0.1 mole) of methylamine in 25 ml of methanol contained in a three-necked flask. The mixture was stirred at the room temperature for two hours, and methylamine hydrochloride was filtered off and washed on the filter with ether. Ether and methanol were removed under reduced pressure. Vacuum fractionation of the residue gave 8.4 g of the methylamide (XVII), b.p. 133-137° (5 mm); n_D^{20} 1.4622; d_4^{20} 1.0002.

Found %: N 8.09; 8.12. $C_9H_{15}NO_3$. Calculated %: N 8.28.

* From ether by precipitation with petroleum ether.

** From cyclohexane.

*** From a mixture of isooctane and benzene.

The methylamide (XXI) was prepared in the same way (Table 5).

Preparation of the Dimethylamide of the 2-Carboxyethyl Ether of 2-Methyl-3-butyn-2-ol (XVIII)

Gaseous dimethylamine (4.5 g, i.e. 0.1 mole) was passed into a stirred cooled (ice water) solution of 5g (0.03 mole) of the acid chloride of the 2-carboxyethyl ether of 2-methyl-3-butyn-2-ol (IV) over a period of two hours. The reaction mixture was stirred at room temperature for two hours, and dimethylamine hydrochloride was filtered off and washed with ether. After removal of ether, the product was vacuum fractionated and gave 5.1 g of the dimethylamide (XVIII), b.p. 117-121° (5 mm); n_D^{20} 1.4630; d_4^{20} 0.9863.

Found % N 7.75; 7.83. $C_{10}H_{17}NO_3$. Calculated % N 7.65.

Preparation of the Diethylamide of the 2-Carboxyethyl Ether of 2-Methyl-3-butyn-2-ol (XIX)

A solution of 5 g (0.03 mole) of the acid chloride of the 2-carboxyethyl ether of 2-methyl-3-butyn-2-ol (IV) in 25 ml of dry ether was added to a stirred cooled (ice water) solution of 5 g (0.07 mole) of diethyl-

* From a mixture of isooctane and benzene.

** Cannot be distilled, and crystallizes with great difficulty.

amine in 25 ml of dry ether over a period of 90 minutes. The mixture was then stirred at room temperature for two hours. Diethylamine hydrochloride was filtered off and washed with ether. After removal of ether, the product was vacuum-fractionated and gave 5.9 g of the diethylamide (XIX), b.p. 127-131° (5 mm); n_D^{20} 1.4575; d_4^{20} 0.9584.

Found %: N 6.90; 6.69. $C_{12}H_{21}NO_2$. Calculated %: N 6.63.

Preparation of the Piperidide of the 2-Carboxyethyl Ether of 2-Methyl-3-butyn-2-ol (XX)

A solution of 5 g (0.03 mole) of the acid chloride of the 2-carboxyethyl ether of 2-methyl-3-butyn-2-ol (IV) in 25 ml of dry ether was added to a stirred cooled (ice water) solution of 5.5 g (0.065 mole) of piperidine in 25 ml of dry ether over a period of two hours. The mixture was then stirred at room temperature for one hour. Piperidine hydrochloride was filtered off and washed with ether. After removal of ether, the product was vacuum fractionated and gave 6.3 g of the piperidide (XX), b.p. 154-157° (5 mm); n_D^{20} 1.4870.

Found %: N 6.55; 6.59. $C_{13}H_{21}NO_2$. Calculated %: N 6.28

Preparation of the Anilide of the 2-Carboxyethyl Ether of 2-Methyl-3-butyn-2-ol (XXII)

A solution of 5 g (0.03 mole) of the acid chloride of the 2-carboxyethyl ether of 2-methyl-3-butyn-2-ol (IV) in 25 ml of dry ether was added over a period of one hour to a solution of 6 g (0.064 mole) of aniline in 25 ml of dry ether with stirring and cooling with ice water. The mixture was then stirred at room temperature for 2 hours 30 minutes, aniline hydrochloride was filtered off and washed with ether, and ether was distilled off under reduced pressure. The product, amounting to 6.4, was the anilide (XXII), m.p. 87-88° (from a mixture of isooctane and benzene).

Found %: N 6.42; 6.64. $C_{14}H_{17}NO_2$. Calculated %: N 6.06.

All the other anilides described in Table 5 were synthesized similarly.

Hydrolysis of 2-Cyanoethyl Ethers of Acetylenic Alcohols with Alkaline Hydrogen Peroxide

a) A solution of 1.5 g of potassium hydroxide in 200 ml of 5% hydrogen peroxide was prepared in a three-necked flask fitted with mechanical stirrer, dropping funnel, and thermometer. The solution was stirred vigorously while 13.5 g of the 2-cyanoethyl ether of 2-methyl-3-butyn-2-ol (b.p. 96-97°, 18 mm) [6] was added at such a rate that the temperature of the mixture did not rise above 40°. When the whole of the 2-cyanoethyl ether had been added, the reaction mixture was stirred at 45-50° for three hours, in the course of which the solution became quite clear. The solution was saturated with potassium carbonate and extracted with ethyl acetate. The solution of the product in ethyl acetate was dried with magnesium sulfate, and ethyl acetate was distilled off in the vacuum of a water pump at a temperature of not above 40°. The product was dissolved in dry ether and precipitated with petroleum ether. The amide of the 2-carboxyethyl ether of 2-methyl-3-butyn-2-ol (IV), amounting to 13.4 g, melted at 49-51°.

b) Similarly, from 10 g of the 2-cyanoethyl ether of 1-ethynylcyclohexanol (b.p. 92-95°, 3 mm) [7], 250 ml of 5% hydrogen peroxide, and 2 g of potassium hydroxide, 9.8 g of the amide of the 2-carboxyethyl ether of 1-ethynylcyclohexanol (XIII), m.p. 68-71° (from cyclohexane), was obtained.

SUMMARY

1. In acid hydrolysis 2-cyanoethyl ethers of acetylenic alcohols are almost completely resinified, and in alkaline hydrolysis the expected 2-carboxyethyl ethers of acetylenic alcohols are obtained, but in poor yield (30-40%).

2. 2-Carboxyethyl ethers of acetylenic alcohols are formed smoothly and in good yield (76-94%) by the hydrolysis of the readily accessible 2-(methoxycarbonyl) ethyl ethers of acetylenic alcohols by treatment with

aqueous-methanolic sodium hydroxide at room temperature.

3. In order to be able to test their physiological, particularly soporific, activities, some amides of 2-carboxyethyl ethers of acetylenic alcohols were synthesized by the action of ammonia or amines on the corresponding acid chlorides.

FREE-RADICAL POLYMERIZATION AND COPOLYMERIZATION OF 2-BUTOXYETHYL VINYL SULFIDE

M. F. Shostakovsky, E. N. Prilezhaeva, and A. M. Khomutov

There has been some interest in the synthesis of polymers containing sulfur. It has been shown, for example, that the introduction of sulfone groups improves the gasoline-resistance of polymers [1] and that the presence of sulfide sulfur improves dielectric properties [2] and makes the polymer thermoplastic [3]. A comparatively little studied source for the preparation of sulfur-containing polymers is formed by alkyl vinyl sulfides. It is stated in patents [3] that ethyl vinyl sulfide, and also various aryl vinyl sulfides, can yield polymers under the influence of light and in presence of catalysts such as peroxides, Friedel-Crafts catalysts, sulfur dioxide, etc. However, in Scheidknecht's review [4] it is justifiably stated that, for practical purposes, the polymerization characteristics for compounds of this class remain uncertain. Since then, two of the authors of the present paper have shown that ethyl vinyl sulfide and 2-butoxyethyl vinyl sulfide polymerize slowly under the action of light and atmospheric oxygen [5, 6] and 2-butoxyethyl vinyl sulfide gives a fairly high yield of polymer when heated with 2,2'-azobis[2-methylpropionitrile] [5]. As regards copolymerization reactions, recommendations have been made that benzoyl peroxide should be used in the copolymerization of alkyl vinyl sulfides with acrylonitrile [7] and also in the copolymerization of methyl vinyl sulfide with methyl acrylate and with styrene [8]. The yields of the acrylonitrile copolymers are not given, but in the copolymerizations with methyl methacrylate and with styrene the process came to an end at a progress of reaction of 10-20%.

From a comparison of these isolated results with data on the behavior of alkyl vinyl sulfides in other addition reactions [6, 9, 10] we may infer that, in spite of the considerable nucleophilic character of the double bonds in alkyl vinyl sulfides, these sulfur compounds are more reactive toward free radicals and less active toward ions than their oxygen analogs, the vinyl ethers. We therefore undertook a more systematic investigation of the free-radical polymerization reactions of alkyl vinyl sulfides.

In the present investigation we studied the polymerization and copolymerization of 2-butoxyethyl vinyl sulfide, which we synthesized from butyl vinyl sulfide by the method already developed [5, 11]:

$$CH_2{=}CHOC_4H_9 + H_2S \rightarrow CH_2SH - CH_2OC_4H_9 + CH \equiv CH \rightarrow CH_2{=}CHSCH_2CH_2OC_4H_9$$

As the second component in copolymerization we took methyl methacrylate, which has been studied previously in copolymerization with various vinyl ethers [12, 13].

Two initiators were used - benzoyl peroxide and 2,2'-azobis[2-methylpropionitrile]. It was shown that, in the polymerization of 2-butoxyethyl vinyl sulfide, benzoyl peroxide is a considerably less active initiator than the azo dinitrile this being evidenced not only in the yield of polymer, but also in its molecular weight (Table 1). In presence of the dinitrile, polymers of somewhat greater molecular weight are formed in considerably higher yields than in the case of vinyl ethers under the same conditions. The polymers are very viscous liquids, soluble in most organic solvents apart from the lower alcohols. In the freshly purified form the polymers are free from odor, but after prolonged keeping in presence of air a feeble odor of the original thiol appears.

Like the polymerization experiments, the experiments on the copolymerization of 2-butoxyethyl vinyl sulfide with methyl methacrylate were carried out at 60° in presence of 0.2% of initiator. At higher concentrations of initiator (Table 2) and at lower temperatures (Table 3) the yield of copolymer was appreciably less.

TABLE 3

Effect of Temperature on the Copolymerization of 2-Butoxyethyl Vinyl Sulfide with Methyl Methacrylate $M_1 : M_2$ (mole %) = 61.5 : 38.5; dinitrile 0.2%; total weight 5 g

Polymerization conditions		Yield of copolymer (% on weight of monomers	Composition of copolymer	
Temperature (°C)	Time (hours)		S found (%)	Mole % of M_2
40	100	84.4	9.3	35.2
60	24	85.2	8.9	32.6
90*	40	45.6	8.2	30.3

* The polymer turned yellow.

The yield of copolymers are shown graphically in Fig. 1 as a function of the composition of the mixture of monomers for both of the initiators used. The dinitrile, being the more active initiator, gives copolymers in yields of up to 80-90%.

In Fig. 2, the compositions of the copolymers – in their relationship to the composition of the mixture of monomers – are compared with the data obtained by two authors of this paper for copolymers of methyl methacrylate with vinyl ethers [12, 13]. In accord with its higher reactivity toward free radicals of the other monomer, the vinyl sulfide is drawn into the copolymer to a much greater degree than an alkyl vinyl ether.

The yield of 2-butoxyethyl vinyl sulfide copolymer falls as we pass from mixtures of monomers having a high methyl methacrylate content to mixtures containing a smaller proportion of this component. There is a simultaneous increase in the mole fraction of sulfur-containing units in the copolymer. It will be clear that the most probable mechanism for the initiation of the polymer chain is the formation of a free radical from methyl methacrylate $RCH_2-\underset{\displaystyle COOCH_3}{\overset{\displaystyle CH_3}{\overset{|}{C}}}$, in which R is a radical initiator, with subsequent participation of vinyl sulfide and methyl methacrylate molecules in the process*. It will be seen from Table 4 that copolymer formed in the early stages of the process is somewhat enriched in methyl methacrylate, although a stationary composition is rapidly established.

* The reverse order is not, of course, completely excluded.

Fig. 1. Yields of copolymers of methyl methacrylate (M_1) and 2-butoxyethyl vinyl sulfide (M_2) obtained: 1) with Bz_2O_2 (80 hours at 60°); 2) with dinitrile (24 hours at 60°).

Fig. 2. Compositions of copolymers of methyl methacrylate (M_1) with vinyl sulfides or vinyl ethers (M_2): 1) Bz_2O_2; $M_2 = CH_2 = CHSCH_2CH_2OC_4H_9$; 2) Bz_2O_2; $M_2 = CH_2 = CHOC_2H_5$; 3) Bz_2O_2; $M_2 = CH_2 = CHOC_4H_9$-t; 4) dinitrile; $M_2 = CH_2 = CHSCH_2CH_2OC_4H_9$; 5) dinitrile; $M_2 = CH_2 = CHOC_4H_9$ t.

The copolymers obtained vary in physical properties; thus they range from brittle solids, through plastic solids, to viscous, sticky masses (with high sulfur content). The copolymers are soluble in most organic solvents, except the lower alcohols. Unlike polymethyl methacrylate, copolymers containing more than 5 mole % of vinyl sulfide units are readily soluble in ether and in a mixture of butyl alcohol and butyl vinyl ether. The dependence of the viscosities of the copolymers on their composition and method of preparation is shown in Fig. 3.

TABLE 4

Yields of Compositions of Copolymers Obtained from an Equimolecular Mixture (reaction temperature 60°; Bz_2O_2 0.2% total weight 5.0 g)

Time (hours)	Yield of copolymer (% weight of monomers)	Mole % of M_2 in copolymer
2	10.2	35.0
4	18.6	35.0
8	24.4	37.5
30	42.0	37.5
54	45.6	37.5
80	47.6	37.5
96	50.6	37.5

The course of the polymerization or copolymerization process can be readily followed by titration of unchanged vinyl sulfide by the acidometric method suggested previously [5]; this is based on the reaction:

$$RSCH=CH_2 + HgCl_2 + 2C_2H_5OH \rightarrow RSHgCl + HCl + CH_3CH(OC_2H_5)_2.$$

EXPERIMENTAL*

The monomers were freshly distilled for use. Benzoyl peroxide was reprecipitated from chloroform with methanol, and commercial 2,2'-azobis[2-methylpropionitrile] was recrystallized twice from methanol. The reactions were carried out in sealed tubes, 15-20 ml in capacity; these were placed in a water thermostat, temperature 60 ± 1°. The total weight of monomers was 5 g in most of the experiments. The copolymers were dissolved in the least possible amount of benzene (10-20 ml) and precipitated with 150-160 ml of dry methanol. This was repeated, and the copolymers were then dried at 60°. In order to determine unchanged vinyl sulfide, sulfide, after the reprecipitations the total volume of solvent was measured, and an excess of 20% ethanolic mercuric chloride was added to an aliquot (10-20 ml). After 48 hours, the acid liberated was titrated with standard sodium hydroxide solution. The results of preliminary experiments on artifically prepared mixtures (Table 5) showed that, under these conditions of analysis, the presence of benzene and methyl methacrylate did not interfere with the determination of the vinyl sulfide.

By way of example, we give the reaction balance sheet for one of the experiments. The amounts taken were M_1 – 1.92 g and M_2 – 3.08 g (1:1 ratio); copolymerization for 80 hours at 60° (initiator Bz_2O_2).

* L. V. Tsymbal took part in the experimental work.

SUMMARY

1. It was shown that, in free-radical homopolymerization and copolymerization, 2-butoxyethyl vinyl sulfide is more reactive than vinyl ethers.

2. It was shown that 2,2'-azobis[2-methylpropionitrile] is a more reactive initiator in the reactions studied than benzoyl peroxide. In presence of the dinitrile, homopolymers of 2-butoxyethyl vinyl sulfide were prepared in yields of up to 65-68%, and its copolymers with methyl methacrylate were prepared in yields of up to 70-90%.

OLIGOMERIZATION

COMMUNICATION 1. REACTION OF SOME VINYL ETHERS WITH CARBON TETRACHLORIDE

M. F. Shostakovsky, A. V. Bogdanova, M. M. Zverov, and G. I. Plotnikova

It is characteristic of vinyl ethers that they tend to react by an ionic mechanism. However, recent investigations show that these compounds can be caused to take part also in reactions initiated by reagents that are able to break down with formation of free radicals. Examples are the polymerization and copolymerization of vinyl ethers under the influence of 2,2'-azobis[2-methylpropionitrile] [1], the addition of thiols to vinyl ethers in the direction contrary to that required by Markovnikov's rule [2], and the reaction of vinyl ethers with benzoyl peroxide [3,4]. A new example of a reaction that proceeds by a free-radical mechanism is the addition of carbon tetrachloride to vinyl ethers in presence of benzoyl peroxide. This reaction affords the possibility of studying the direction of the addition of the $\dot{C}Cl_3$ radical and Cl atom formed from carbon tetrachloride [5].

The literature [6-8] indicates that ethyl vinyl and butyl vinyl ethers react with carbon tetrachloride in presence of benzoyl peroxide with formation of ethyl tetrachloropropyl and butyl tetrachloropropyl ethers. The authors did not make a detailed study of the conditions for reaction and the question of the possibility of the formation of polymeric products in this reaction remains obscure. There is no information in the literature about the behavior of aryl vinyl ethers toward carbon tetrachloride in presence of benzoyl peroxide and their possible polymerization under these conditions.

Our study of the polymerization of phenyl vinyl ether in presence of 2,2'-azobis[2-methylpropionitrile] [1] showed that, under certain conditions, telomeric products of the type

may be formed. It might be expected, therefore, that again in the reaction of phenyl vinyl ether with carbon tetrachloride in presence of benzoyl peroxide, products of low molecular weight would be formed in accordance with the scheme:

(1)

(I)

A similar reaction occurs between vinyl acetate and carbon tetrachloride and has been described in a patent [9].

The present paper is devoted to an examination of the conditions under which phenyl vinyl, butyl vinyl, and ethyl vinyl ethers react with carbon tetrachloride in presence of benzoyl peroxide and to a study of some of the properties of the products. The experiments showed that, depending on the conditions, phenyl vinyl and alkyl vinyl ethers may react with carbon tetrachloride with formation of the products of equimolecular addition:

$$CH_2=CH-OR + CCl_4 \rightarrow \underset{(II)}{CCl_3-CH_2-CHCl-OR} \quad (2)$$

(R=C_2H_5, C_4H_9, or C_6H_5) or of polymeric products by Equation 1. By variation of reaction conditions (temperature, amount of catalyst, relative amounts of reactants and the order of mixing, carrying out the reaction in a flask with stirrer or in a sealed tube), it was possible to find optimum conditions for the formation of equimolecular-addition products or of polymeric products. Equimolecular-addition products (II) were obtained in good yield when the relative amounts of vinyl ether and CCl_4 were 1:4 and 1:2. In this case it is best to carry out the reaction in a flask fitted with stirrer, adding the vinyl ether dropwise to the carbon tetrachloride. With increase in the amount of vinyl ether the yield of the tetrachloropropyl ether falls, but the amount of polymeric product rises.

The resulting phenyl 1,3,3,3-tetrachloropropyl ether and alkyl 1,3,3,3-tetrachloropropyl ethers are substituted α-chloro ethers, the properties of which we have studied previously [10]. Their structure was proved by hydrolytic scission, carried out under various conditions. Such scission probably occurs in the following way:

$$CCl_3-CH_2-CHCl-OR + H_2O \rightarrow [CCl_3-CH_2-CHO] + ROH + HCl \quad (3)$$

$$[CCl_3-CH_2-CHO] \rightarrow CCl_2=CH-CHO + HCl \quad (4)$$

Experiment showed that it is not possible to separate the two stages (3) and (4) of the hydrolysis of tetrachloropropyl ethers owing to the instability of trichloropropionaldehyde. The quantitative formation of phenol and dichloroacrolein, which is observed when the phenyl tetrachloropropyl ether is boiled with water for one hour, corresponds to the elimination of two molecules of hydrogen chloride from one molecule of the tetrachloro ether.

When the phenyl tetrachloropropyl ether is heated to 100° with alkali, elimination of hydrogen chloride may proceed further to the stage of chloroacetylene, so that a slight explosion occurred when the tube was opened and the hydrolyzate showed a positive reaction for acetylene. Quantitative determinations were made for hydrogen chloride, phenol, and dichloroacrolein on hydrolyzates obtained under various conditions. Hydrogen chloride was determined by titration with 0.1 N NaOH, phenol was determined gravimetrically as tribromophenol, and dichloroacrolein was characterized as its semicarbazone. The mobility of α-chloro in tetrachloropropyl ethers was shown by its replacement by an alkoxy group with formation of the diethyl acetal of 3,3,3-trichloropropionaldehyde (III):

$$CCl_3-CH_2-CHCl-OC_2H_5 + C_2H_5OH \rightarrow CCl_3-CH_2-CH(OC_2H_5)_2 + HCl \quad (5)$$

The structure of the acetal obtained was proved by hydrolysis followed by characterization of dichloroacrolein:

$$CCl_3-CH_2-CH(OC_2H_5)_2 + H_2O \rightarrow CCl_2=CH-CHO + 2C_2H_5OH + HCl \quad (6)$$

The polymeric products of the addition of vinyl ethers to carbon tetrachloride, the yield of which rises with increase in the proportion of vinyl ether in the original mixture, were found to be colorless or feebly colored transparent substances – viscous liquids in the case of alkyl vinyl ethers, and solids in for phenyl vinyl ether. Investigation of their compositions showed that in these polymeric products there are 4-5 monomer molecules per CCl_4 molecule in the case of phenyl vinyl ether and 41 monomer molecules per CCl_4 molecule in the case of butyl vinyl ether.

EXPERIMENTAL

Phenyl vinyl, ethyl vinyl, and butyl vinyl ethers were purified by the method developed in the Vinylic Compounds Laboratory [11] and had the following constants: phenyl vinyl ether, b.p. 155-156°, n_D^{20} 1.5223; d_4^{20} 0.9770; ethyl vinyl ether, b.p. 36-36.5°, n_D^{20} 1.3780; d_4^{20} 0.7530; butyl vinyl ether, b.p. 93-94°, n_D^{20} 1.4030; d_4^{20} 0.7790. Carbon tetrachloride was distilled, washed four times with water, dried over calcium chloride, and redistilled (b.p. 76-76.5°). Benzoyl peroxide was purified by reprecipitation with methanol from chloroform solution; it was dried to constant weight in a vacuum desiccator [12].

** The polymeric product was formed in a sealed tube and was isolated by reprecipitation without first distilling off the liquid products.

Reaction of Phenyl Vinyl Ether with Carbon Tetrachloride at an Initial Ratio of 1 : 4

Preparation of Phenyl 1,3,3,3-Tetrachloropropyl Ether (II). A mixture of 61.4 g (0.4 mole) of carbon tetrachloride, 12 g (0.1 mole) of phenyl vinyl ether, and 1.1 g (0.0045 mole) of benzoyl peroxide was prepared in a two-necked flask fitted with stirrer and thermometer. The mixture was heated with stirring to 70-75°, at which temperature reaction usually set in and continued for two hours. Excess of carbon tetrachloride was distilled off, and vacuum distillation then gave a fraction, amounting to 26.2 g, of b.p. 145 - 145.5°, and 1.5 of polymeric residue. The constants of the fraction collected were b.p. 145-145.5° (9 mm); n_D^{20} 1.5432; d_4^{20} 1.3976; found MR 61.82; calculated for $C_9H_9OCl_3$ MR 61.27.

Found %: C 39.49; 39.61; H 3.10; 2.94; Cl 50.95; 51.08. $C_9H_9OCl_4$. Calculated %: C 39.45; H 2.94; Cl 51.76.

Found: M 252.1; 258.0. $C_9H_9OCl_4$. Calculated: M 273.98.

The product, which was obtained in 95.3% yield, was phenyl 1,3,3,3-tetrachloropropyl ether.

The results of the experiments on the reaction of phenyl vinyl ether with carbon tetrachloride in other proportions are given in Table 1.

Isolation and Characterization of the Polymeric Residue. After removal of unchanged phenyl vinyl ether and of phenyl tetrachloropropyl ether by distillation, there remained a clear orange viscous residue, which could not be distilled at 3 mm. When the residue was heated to 125°, it decomposed with evolution of hydrogen chloride and formation of a resinous substance. The residue was treated with steam until all traces of phenol, phenyl vinyl ether, and hydrogen chloride were gone, and it was then dried and analyzed.

Found %: C 62.45; 62.23; H 4.54; 4.49; C 23.33; 23.26. $C_{39}H_{32}O_4Cl_4$. Calculated %: C 62.54; H 5.09; Cl 22.37.

Found: M 619.3; 628.0. Calculated: M 634.4.

The residue was soluble in ether, methanol, and benzene, but it was insoluble in gasoline.

Reaction of Butyl Vinyl Ether with Carbon Tetrachloride in Presence of Benzoyl Peroxide

A series of experiments on reaction between butyl vinyl ether and carbon tetrachloride was carried out under the above-described conditions (or in sealed tubes heated to 70°) (see Table 1). Depending on the composition of the original mixture of reactants, various yields of the butyl tetrachloropropyl ether and the polymeric residue were obtained. Constants of the butyl tetrachloropropyl ether isolated were: b.p. 96.5 – 98.5° (6 mm); n_D^{20} 1.4695; d_D^{20} 1.2585; found MR 56.26; calculated for $C_7H_{12}OCl_4$, MR 55.64. The literature [7] gives: b.p. 51 – 52° (0.23 mm); n_D^{20} 1.4706; d_D^{20} 1.2610 [7].

The residue remaining after the removal of the butyl tetrachloropropyl ether was a clear viscous light-yellow polymeric product, soluble in ether and other organic solvents, other than methanol. It was purified by two reprecipitations with methanol from ethereal solution, and was dried in a desiccator at 35° and 20 mm.

The colorless viscous polymer had the following composition:

Found %: C 69.68; 69.54; H 11.68; 11.68; Cl 3.35; 3.22. For (I) when n=40 calculated %: C 69.63; H 11.64; Cl 3.32.

Reaction of Ethyl Vinyl Ether with Carbon Tetrachloride

The reaction of ethyl vinyl ether with carbon tetrachloride (in a flask or in sealed tubes) was studied under the same conditions. Ethyl 1,3,3,3-tetrachloropropyl ether and a polymeric residue were obtained (see Table 1). The constants of the ethyl tetrachloropropyl ether were: b.p. 72.5° (8mm); n_D^{20} 1.4700; d_4^{20} 1.3472; found MR 46.79; calculated MR 46.40. The literature [7] gives: b.p. 79–80° (11 mm); n_D^{20} 1.4695 [7].

Found %: C 26.29; 26.29; H 3.43; 3.41. $C_5H_8OCl_4$. Calculated %: C 26.58; H 3.57.

Found: M 212.0; 217.5. Calculated: M 225.94.

The residue was a clear viscous light-yellow substance of molecular weight 890.2; 897.1 (crude product!). As it was soluble in all organic solvents, it did not appear possible to purify it by reprecipitation.

Hydrolysis of Phenyl 1,3,3,3-Tetrachloropropyl Ether

Determination of Hydrogen Chloride in the Hydrolyzate. A mixture of 0.2347 g of the ether and 25 ml of distilled water was sealed in a tube, which was heated in a boiling water bath for one hour with periodic shaking. The contents of the tube were then transferred quantitatively to a 200 ml measuring flask. For the titration of 25 ml of the hydrolyzate, 2.35 ml of 0.0909 N NaOH was used, which corresponds to 0.0623 g of HCl or 1.99 moles of HCl per mole of the ether. The relation between the amount of HCl liberated and the hydrolysis conditions is shown in Table 2.

TABLE 2

No..	Hydrolysis conditions	Duration of hydrolysis	Temperature of hydrolysis (°C)	HCl (moles per mole of ether)	Notes
1	Shaking with water	1 min.	Room	0.01	
2	Shaking with water	1 hr.	Room	0.10	
3	Heating in sealed tube with water	30 min.	60	0.21	
4	Boiling under reflux with water	1 hr	100	1.86	
5	Heating in sealed tube with water	1 hr.	97	1.99	
6	Shaking with alkali	1 hr	Room	0.32	
7	Boiling with alkali	1 hr	100	2.25	Formation of resin
8	Boiling with alkali	1 hr	100	2.90	
9	Heating in sealed tube with alkali	1 hr	97	2.68	Slight explosion

Determination of Phenol in the Hydrolyzate. A mixture of 0.1954 g of the phenyl tetrachloropropyl ether and 25 ml of water was heated in a sealed tube in a boiling water bath for one hour. The contents of the tube were then transferred quantitatively to an Erlenmeyer flask, and bromine water was added with shaking until

precipitation of tribromophenol was complete. The precipitate was filtered off through a weighed glass filter, and it was washed with water (300 ml) until reaction for bromine was negative. The filter with the precipitate was dried to constant weight in a vacuum desiccator. The amount of tribromophenol obtained was 0.2075 g — or 0.2425 g (100.8% of the theoretical value) when allowance was made for dissolution by wash waters (solubility 0.04 g in 100 g of water at 15°). Similarly, from 0.2562 g of phenyl 1,3,3,3-tetrachloropropyl ether, 0.3101 g (98.7%) of tribromophenol was obtained.

Preparation of the Semicarbazone of 3,3-Dichloroacrolein. A mixture of 10.5 g of the phenyl tetrachloropropyl ether and 250 ml of water was prepared in a Favorsky flask attached to a condenser set for distillation. In the course of boiling for two hours a two-layer distillate slowly collected. The upper, aqueous layer of the distillate, and also the aqueous residue in the distillation flask, gave positive reactions for chlorine and phenol. The lower layer of the distillate — an oily liquid — was separated and was found to be 3,3-dichloroacrolein. Equimolecular amounts of semicarbazide and sodium acetate were dissolved in a few milliliters of ethanol. The solution was boiled for ten minutes, filtered, and added to a warm alcoholic solution of the dichloroacrolein. The precipitate of the semicarbazone which then formed was filtered off, recrystallized from boiling ethanol, and dried in a vacuum desiccator; m.p. 164.5-165° (in a sealed capillary).

Found %: N 23.67; 23.52. $C_4H_5N_3Cl_2O$. Calculated %: N 23.10.

Hydrolysis of Ethyl 1,3,3,3-Tetrachloropropyl Ether

A mixture of 0.1185 g of the ether and 25 ml of water was heated in a sealed tube in a boiling water bath for 30 minutes, and the hydrolyzate was then transferred quantitatively to an Erlenmeyer flask and titrated. The amount of 0.0909 N NaOH required was 11.2 ml, which corresponds to 0.0371 g of hydrogen chloride or 1.95 moles of HCl per mole of the ether. A parallel experiment gave 1.94 moles of HCl. The dichloroacrolein was isolated from the hydrolyzate as its semicarbazone, m.p. 164°, undepressed by admixture of an analytically pure specimen.

Reaction of Ethyl 1,3,3,3-Tetrachloropropyl Ether with Ethanol

At 35°, 5.4 g (0.12 mole) of ethanol was added dropwise with good stirring to a solution of 13.1 g (0.06 mole) of the ethyl tetrachloropropyl ether in 6 ml of carbon tetrachloride. The reflux condenser was provided with a trap containing distilled water for the absorption of hydrogen chloride. Cooling was applied in order to maintain the temperature of the reaction mixture at about 35°. When the alcohol had been added, the mixture was stirred for one hour at 60-65°. Fractionation gave 11.7 g (90%) of the diethyl acetal of 3,3,3-trichloropropionaldehyde, which had the following constants: b.p. 80 — 81° (9 mm); n_D^{20} 1.4450; d_4^{20} 1.1836; found MR 53.00; calculated for $C_7H_{13}O_2Cl_3$ MR 52.41. The literature [7] gives: n_D^{25} 1.4454; d_4^{20} 1.1829.

In the titration of the contents of the trap, 47.5 ml 1 N NaOH was required, which corresponds to 90.4% of the amount of HCl theoretically required by Equation 6.

Hydrolysis of the Diethyl Acetal of 3,3,3-Trichloropropionaldehyde (Equation 6)

A mixture of 1.6 g of the acetal and 5 ml of 2% HCl was refluxed for one hour. The hydrolyzate was cooled, and treatment with semicarbazide gave 1.0 g (83.4%) of a precipitate of the semicarbazone of 3,3-dichloroacrolein, m.p. 165.0° in a sealed capillary.

Found %: N 23.31; 23.35. $C_4H_5Cl_2ON$. Calculated %: N 23.10.

SUMMARY

1. A study was made of the conditions under which carbon tetrachloride reacts with phenyl vinyl, butyl vinyl, and ethyl vinyl ethers in presence of benzoyl peroxide.

2. It was found that, in presence of benzoyl peroxide, vinyl ethers are able to react with carbon tetrachloride with formation of both equimolecular-addition products and polymeric products, depending on the original proportions of reactants.

3. The characteristics of the resulting phenyl, ethyl, and butyl 1,3,3,3-tetrachloropropyl ethers were determined. Their hydrolytic decomposition was studied, and it was shown that, in the case of the phenyl ether, it can provide a quantitative method for the determination of the concentration of the ether.

4. The mobility of α-chloro in the 1,3,3,3-tetrachloropropyl ethers was demonstrated in hydrolytic-scission reactions and in the exchange reaction with an alcohol.

5. The polymeric products formed by addition of carbon tetrachloride to phenyl vinyl, ethyl vinyl, and butyl vinyl ethers were isolated and characterized.

OPTICAL INVESTIGATION OF THE Si–H BOND AND PECULIARITIES IN ITS CHEMICAL BEHAVIOR IN VARIOUS COMPOUNDS

M. I. Batuev, A. D. Petrov, V. A. Ponomarenko and A. D. Matveeva

1. Many organosilicon and hydrosilicon compounds containing the Si–H bond have now been prepared, and these have aroused interest both from the theoretical and the practical points of view. The chemical evidence shows that the reactivity of the Si–H bond is greatly dependent on the nature of the other groups and atoms attached to the silicon atom in the given compound. In hydrosilicons the Si–H and Si–Si bonds are notable for their instability, as compared with the C–H and C–C bonds in hydrocarbons. It is sufficient to point out that, until recently, it has been found possible to prepare only the first six homologs of the silane series – as far as hexasilane Si_6H_{14}. Whereas oxygen has only a very feeble action on paraffins at ordinary temperatures, all silanes are spontaneously inflammable or explosive when brought into contact with the air: silane itself (SiH_4) reacts explosively with oxygen with formation of silica even at the temperature of liquid air, i.e. in hydrosilicons the Si–H bond (as also the Si–Si bond) is extremely reactive toward oxygen – and also toward halogens, alkalis, etc. [1]. However, the replacement of even one of the hydrogens of SiH_4 by a hydrocarbon radical greatly reduces the reactivity of the Si–H bonds; these organosilicon compounds are no longer spontaneously inflammable in the air [2]. The extent to which the reactivity of the Si–H bonds is changed depends on the character of the substituent radical. Thus, in compounds of the type R_3SiH, with increase in the length of the radical the rate of reaction with sodium hydroxide diminishes [3]. The rate at which addition occurs between unsaturated compounds and Si–H bonds is also greatly dependent on the identity of the atoms and groups (other than hydrogen) attached to the silicon atom [4].

This sensitivity of Si–H bonds to the structure of the molecule is manifested also in the Raman spectra of compounds containing such bonds, as we have already noted [5]. It is of considerable interest to determine the nature of this sensitivity with the aid of an optical investigation of a series of compounds and a comparison of these and other data with the corresponding data for C–H, and also O–H and F–H, bonds.

2. In the following sense one may speak of the protonization or electronization of the hydrogen atom in X–H bonds (X=Si, C, O, N, F, etc.). As is well known, the hydrogen atom of the hydroxy group varies greatly in its physical and chemical properties according to the nature of the compound in which the group is present. In strong acids, considerable protonization of this hydrogen occurs, i.e. a freeing of it, as a proton, from the electron-orbital system of the hydroxyl bond. On the other hand, in strong bases – particularly in the ion OH^- – electronization of the hydrogen atom occurs, i.e. its deeper involvement, as a proton, in the electron-orbital system of the hydroxyl bond and its screening by this electronic system. Optical investigations by one of us have shown [6] that the greater the protonization of the hydrogen atom of the hydroxyl group, the lower the vibration frequency and bond energy and the greater the O–H distance; on the other hand, the greater the electronization of the hydrogen atom, the higher the vibration frequency and bond energy and the lower the interatomic distance characterizing the hydroxyl bond. The range over which these parameters of the hydroxyl group vary is very considerable, as can be seen from the table given below.

Depending on the nature of R in compounds R–OH, these parameters may assume only intermediate values between those cited, their values being in accordance with the variation in the chemical nature of the O–H bond – in the strongest acids they may lie beyond the values for oxalic acid. In view of the higher Gordy electronegativity of the oxygen atom (3.45) as compared with hydrogen (2.13), in the extreme positions the oxygen atom tends to preserve its electron envelope in the octet form, i.e. almost in the form $(R\dot{\ddot{O}}\dot{X})^-$ $[H^+$ or $R^+|(\dot{X}\,\dot{\ddot{O}}\,\dot{X}H)^-$, whereas

in intermediate positions it approaches one of these forms in some measure or other, but under normal conditions it never approaches the form $R\dot{\ddot{O}}^{+}\ |\dot{\ddot{x}}|^{-}$. For the formation of an octet, the oxygen atom must use two foreign electrons. The presence of free paired electrons in the outer envelope of the oxygen atom and the tendency of the hydrogen atom to undergo protonization determine the donor properties of the oxygen atom and the acceptor properties of the hydrogen atom (possibility of its participation in hydrogen bonds).

	Hydroxyl of crystalline oxalic acid (β-form)	OH^- ion	Range of variation
Vibration frequency (cm^{-1})	2500	4200	1700
Bond energy (kcal/ mole)	51	145	94
Interatomic distance (A)	1.147	0.906	0.241

The tendency of the hydrogen atom to undergo electronization and protonization is apparent also in its bonds with atoms other than oxygen, and it varies greatly according to the nature of these atoms. In the H–F bond we have extreme protonization of the hydrogen atom, for the fluorine atom is still more electronegative (3.95) than the oxygen atom (3.45); hydrofluoric is one of the strongest acids: the octet of the fluorine atom is completed with the aid of only one foreign electron and its proton is almost free, $(:\ddot{\underset{\cdot\cdot}{F}}\dot{x})^{-}\ |\ H^{+}$. However, whereas the hydrogen atom in various R–OH compounds may pass into states varying from powerful protonization to powerful electronization according to identity of R, owing to the univalency of fluorine there can be only one compound containing H–F link–hydrogen fluoride itself. The donor and acceptor properties of fluorine and hydrogen atoms arise by virtue of the same circumstances as those existing in the case of the oxygen and hydrogen atoms of the hydroxy group, but they are manifested to an even higher degree•.

A very different picture is found for C–H bonds. The difference in electronegatively between its component atoms is not as great as in F–H and O–H, although the electronegativity of the H atom (2.13) is still lower than that of the C atom (2.55). This levelling of electronegativities with a certain predominance of electronegativity on the C atom considerably narrows the range over which the parameters of the C–H bond vary due to protonization and electronization of its H atom: there are no strong acids containing an almost completely protonized hydrogen atom $(RC\dot{x})^{-}\ |\ H^{+}$ (R is the remainder of the molecule), and, similarly, there are no compounds approaching $R^{+}\ |\ (CH)^{-}$. This is to be related to the fact that the C atom, unlike O and F atoms, has no unpaired electrons in saturated compounds – four foreign electrons $(\dot{\underset{\cdot}{\overset{\cdot}{x}}}C\dot{x})$, participate in its octet, so that it is firmly linked with the rest of the molecule. Electronization of the H atom in C–H bonds occurs as a result of the further involvement of the H atom in the electron envelope of the C atom without formation of the $(CH)^{-}$ ion and without any tendency for its formation when the C–H interatomic distance is shortened. The narrower range of variation of the parameters of C–H bonds can be seen from a comparison of the above-cited data for O–H bonds with the following data for C–H bonds [7].

The table shows that the introduction of double and triple bonds does not greatly affect the range of variation of the parameters of the C–H bond, which indicates the relative stability of C–H bonds, particularly in saturated compounds.

• It should be noted that the protonization of the hydrogen atoms of O–H and F–H bonds is aided by the rapid increase in the repulsive forces when the atoms of these bonds are brought closer together: as a result, the electron envelope "creeps" from the hydrogen atom and is attracted to the oxygen atom without the proton. This contrasts with the C–H and Si–H bonds: the electronegativity of the carbon atom is only a little greater than that of the hydrogen atom, and the electronegativity of the silicon atom is even less than that of the hydrogen atom; this "creeping" of the electron envelope under the influence of other atoms in the molecule is therefore not bound to occur in such bonds in saturated compounds it is attracted together with the proton, all the more since the "reserves" of interatomic distance in these bonds (in contrast with H–O and F–H bonds) for such attractions are appreciable, i.e. the repulsive forces do not yet prevent the attraction of the proton [6].

	Vibration frequency (cm^{-1})	Bond energy (kcal/mole)	Interatomic distance (A)
In the CH radical	2824	80.0	1.120
In C_2H_6 (6 frequencies in the range)	2730 – 2960	88.4	1.098
In C_2H_4 (4 frequencies in the range)	2988 – 3107	106.0	1.076
In C_2H_2 (2 frequencies in the range)	3288 – 3372	121.0	1.060
Range of variation	464 – 548	41.0	0.060

The Si – H bond is qualitatively different from the F – H, O – H, and C – H bonds in that the electronegativity of the hydrogen atom (2.13) exceeds that of its partner, the silicon atom (1.8); it is as if the latter acquires some of the character of a metal. Consequently, we can no longer speak of the protonization of the hydrogen atom in Si – H bonds in the sense of the formation of compounds of the form $(RSi)^{-}H^{+}$ (R is the remainder of the molecule), but we can now speak of greater or less electronization of the hydrogen atom in the Si – H bond. The acceptor properties of the hydrogen atom are repressed in the Si – H bond, but they are present in the silicon atom on account of its possible sexavalency (it is here, probably, that one of the causes of the instability of – Si – Si – Si – bonds is to be found: the readiness with which coordinational interaction between silicon atoms and atmospheric oxygen occurs results in the breakdown of hydrosilicon chains). We shall now turn to the elucidation of the changes in the electronization of Si – H bonds in various compounds with the aid of optical investigations. Below, we give the Raman spectra of three of these compounds; the spectra were determined on a Soviet ISP-51 spectrograph with a central camera*.

1. $(C_2H_5)_3SiH$, $\Delta\nu$ (cm^{-1}): 123(2), 176(2), 300(4*), 309(2*), 327(2*), 405(o), 584(10b), 642(3*), 672(3*), 709(4**), 723(3**), 813(6), 971(9), 1021(8), 1233(8), 1314(0), 1380(0), 1416(8), 1463(9), 2098(10 b), 2639(1), 2681(0), 2734(3), 2871(10*), 2888(10*), 2908(9*), 2933(4*), 2955(6*)

2. $(CH_3)SiH_2CH_2Cl$, $\Delta\nu$ (cm^{-1}): 176(1), 244(6), 257(0), 489(4), 582(9), 610(6*), 622(6*), 690(9), 731(0*), 746(1*), 753(6*), 764(6*), 815(2), 871(2), 944(5), 960(0), 1107(3), 1180(2), 1257(3), 1378(4*), 1434(4*), 2156(10, band), 2909(7sh), 2938(6*sh), 2968(4**sh), 2983(4**sh)

3. $(C_2H_5)SiHCl_2$, $\Delta\nu$ (cm^{-1}): 177(5*) 188(5*), 226(0), 264(0), 296(4), 493(10b), 548(3*), 566(3*), 660(5), 708(4), 799(5*), 813(5*), 975 (3 db), 1019(3 db), 1073(0), 1093(0), 1236(4), 1405(3), 1463(4), 2204(9b), 2747(1), 2829(1), 2889(7), 2914(2*), 2938(4*), 2973(3**), 2986(1**), (the lines 177-296 are on the background of the wing of the Raleigh line)

Spectra of the C – C – C – Si – C – C – C and C – C – C – C – C – C – Si compounds necessary for comparison have been published by us previously [5].

Before the spectrum measurements all these compounds are redistilled twice through a 35 plate column, and measures were taken to prevent the ingress of moisture into the cell. The compounds had the following boiling points: $(C_2H_5)_3SiH$ – 108.4° at 764.5 mm; $(CH_3)SiH_2CH_2Cl$ – 60° at 745.7 mm; $(C_2H_5)SiHCl_2$ – 74° at 744 mm.

3. We must first of all note the lower degree of interdependence between the vibrations of Si – H bonds when these are accumulated at a silicon atom, as compared with the vibrations of C – H bonds when these are accumulated at a carbon atom. For C – H bonds this interdependence is manifested in the splitting of their vibrations into a symmetrical and an antisymmetrical vibration in the CH_2 and CH_3 groups – and also in the raising of the vibration.

* Intensities are given on a ten-grade scale. The abbreviations used are b – broad line; sh – sharp line; db – double line; the asterisks indicate lines occurring on a background that is common with neighboring lines indicated by the same number of asterisks.

frequencies of C – H bonds as we pass from the methylidyne group, through the methylene and methyl groups, to methane, which is due to the ever increasing interaction of C – H bonds accumulating on a given carbon atom (the electron orbital of one hydrogen atom falls within the field of action of the nucleus of a second hydrogen atom and the electron orbital of the second hydrogen atom falls within the field of action of the nucleus of the first hydrogen atom with a resultant raising of the frequency of the antisymmetrical vibration and a less marked raising - in fact in some bonds, e.g. C – Cl, a lowering - of the frequency of the symmetrical vibration). There is a shortening of the C – H bonds, increase in their energy, etc. (and in the case of C – Cl bonds, lengthening, lowering of energy, etc.)*

In the case of Si – H bonds, their interaction when accumulated at a single silicon atom is not absent altogether, but is weak. The fact that interaction does actually occur is shown in the increase in Si – H vibration frequency as we pass from the SiH group, through SiH_2 and SiH_3, to SiH_4, and the feebleness of this interaction is shown by the fact that splitting of the vibration frequency of an Si – H bond into symmetrical and antisymmetrical vibration frequencies does not occur, only a rather considerable broadening of the Si – H line being observed. It is possible that a spectrograph having a considerably higher resolving power than ISP-51 would reveal the splitting of these frequencies, which is masked in our spectra by the broadening of the Si – H line.

TABLE

Increase in the Vibration Frequencies of C – H and Si – H Bonds in passing from the CH and SiH Groups to the CH_4 and SiH_4 Molecules

C – H bond			Si – H bond		
Compounds	Group	Frequency (cm^{-1})	Compounds	Group	Frequency (cm^{-1})
1. C – H bond	CH	2824	$(C_2H_5)_3$ SiH	SiH	2098
2. Normal paraffins	CH_2	2853s 2909a	C – C – C – Si – C – C – C	SiH_2	2127
3. Normal paraffins	CH_3	2879s 2967a	C – C – C – C – C – C – Si	SiH_3	2152
4. CH_4	CH_4	2915s 3072a	SiH_4 (liquid) [11]	SiH_4	2175
Rise from 1 to 4:		91 – 248	Rise from 1 to 4:		77

The increase in the vibration frequencies of C – H and Si – H bonds as we pass from the first compounds to the fourth is necessarily accompanied by increase in bond energy and decrease in interatomic distance, i.e. by the increased involvement of the nucleus of the hydrogen atom (the proton) in the electron-orbital system of the carbon and silicon atoms – electronization of the H atom of the C–H and Si–H bonds. The increase of electronization in this series of compounds is associated mainly with the interaction of bonds that we have discussed.

A substantial change in molecular structure (introduction of substituents having powerful effects, etc.) may produce the same effect as, or an even greater effect than, the interaction of bonds. Thus, replacement of a hydrogen atom by chlorine in the close vicinity of a silicon atom results in further increase in the electronization of the Si – H bond** - in an increase in frequency and bond energy, and in a reduction in interatomic distance, as will be seen from examples for SiH and SiH_2 groups:

Frequency SiH in $(C_2H_5)_3SiH$	2098 cm^{-1}
Frequency SiH in $(C_2H_5)Cl_2SiH$	2204 cm^{-1}
Increase	+106 cm^{-1}

* The accumulation of identical bonds on one atom results in a reduction in the dipole moment of the molecule, as shown in the work of Smyth and others [8] on the chloroalkanes; this reduction is related to changes in valency angles (mutual repulsion of chlorines), to the mutual induction of the dipoles of neighboring bonds (also called the vicinal effect [9]), etc. However, the dipole aspect of the interaction of these bonds, which would appear to result only in the strengthening of them [9], does not reveal the whole complexity of nucleus-electron interaction manifested, in particular, by the existence of antisymmetrical and symmetrical vibrations, which indicates an extension of the range of the possible physical states of these bonds and of their reactivity (cf., for example, an analogous phenomenon [10], which is shown in the chloroalkanes not only by the strengthening of the C–H bonds in CH_2 and CH_3, but also in their weakening, and not only by increase in their frequencies and energies, but also in decrease in these parameters; we shall not consider this in detail in the present paper).

** But not in its protonization, as is often stated for the C – H bond.

Frequency SiH in $C-C-C-Si-C-C-C$	2127 cm^{-1}
Frequency SiH in $CH_3-SiH_2-CH_2Cl$	2156 cm^{-1}
Increase	+29 cm^{-1}

The frequency of the Si – H bond in $(C_2H_5)Cl_2SiH$ is not only much greater than that in $(C_2H_5)_3SiH$, but is greater also than the Si – H frequencies in the SiH_2 and SiH_3 groups of the other compounds given above and in SiH_4. These data also show that the accumulation of chlorine atoms in the immediate vicinity of a silicon atom results in increase in the vibration frequency of the Si – H bonds, and therefore in an increase in bond energy and decrease in interatomic distance, i.e., it leads to their electronization.

Hence, variation in the reactivity of Si – H bonds in various compounds is to a great extent determined by the changes in the extent of the electronization of these bonds; in particular, its high value in SiH_4, together with the tendency of the silicon atom to enter into a coordination linkage with oxygen (discussed above), results in the high reactivity of this compound, which was discussed at the beginning of the paper.

The increase in the reactivity of the Si – H bond due to increase in its electronization under the influence of the accumulation of chlorine atoms in the close vicinity of the silicon atom, and also the polarization of the silicon atom itself brought about by this effect, is evidently manifested in the considerable increase in the yield of products of addition of R_3SiH to C=C–C–C–C in the following series of compounds: $(C_2H_5)_3CH_3SiH$ (very low yield), $(CH_3)Cl_2SiH$ (10% yield), Cl_3SiH (44% yield) [4]. The vibration frequency of the Si – H bond in Cl_3SiH is 2257 cm^{-1} [7], i.e., owing to its greater electronization in this compound, its frequency is higher than in $(C_2H_5)Cl_2SiH$, and in $(CH_3)Cl_2SiH$, in which there are only two chlorine atoms in the vicinity of the silicon atom (see above).

M. F. Zulina took part in the optical part of the experimental work, and L.L. Mkhitaryan helped in the preparation of the substance required in the investigation.

SUMMARY

1. Unlike O – H and F – H bonds, under normal conditions Si – H bonds cannot be described as protonized - only as more or less electronized.

2. In every concrete case, a change in the electronization of an Si – H bond that affects its chemical behavior must be considered in conjunction with other factors concerned with the structure of the reactant molecules and the reaction conditions.

THERMAL TRANSFORMATIONS OF PIPERYLENE AT VARIOUS PRESSURES

N. I. Shuikin and T. I. Naryshkina

Study of thermal transformations of diene hydrocarbons is of interest not only from the theoretical, but also from the practical point of view. In some petroleum treatments lower conjugated dienes are formed, and knowledge of their behavior under the conditions of thermal treatment may result in improved control of the technological process.

Inadequate attention has been paid to investigation of the transformations of alkadienes. The literature shows that, in presence of various catalysts, diene hydrocarbons undergo dimerization, aromatization, hydrogenation, and polymerization reactions [1-4]. By the thermal treatment of piperylene at 600°, Frank and coworkers [5] obtained, apart from unchanged piperylene, only a light fraction, b.p. 38–41°, in 5% yield.

It was of interest to study the transformations of the diene piperylene at various pressures under high-temperature conditions. We have previously investigated the thermal transformations of piperylene at ordinary pressure [6]. In the present investigation we studied the thermal transformations of piperylene at 450-550°, both at a pressure of 20 mm, and also under 15 atm pressure of nitrogen. Pieces of quartz were used as filler. The experiments showed that changes in pressure and temperature have substantial effects on the transformations of piperylene. With increase in pressure from 20 mm to 15 atm at 550°, the amount of unchanged piperylene is lowered from 83.6% to 6.5%. At elevated pressure piperylene gives aromatic fractions consisting mainly of C_8–C_{10} hydrocarbons, whereas at ordinary pressure the aromatic fractions consist mainly of benzene, toluene, and xylenes. Rise in temperature from 450° to 550° increases the degree of conversion of piperylene; the yield of aromatic and resinous products increases, whereas that of low-boiling hydrocarbons, including unchanged piperylene, falls appreciably. With rise in temperature there is a considerable rise in the proportion of unsaturated hydrocarbons in the gaseous products.

EXPERIMENTAL

Transformations of Piperylene Under 15 atm Pressure of Nitrogen. The piperylene taken for investigation had the following properties: b.p. 42–43° (760mm); n_D^{20} 1.4315; d_4^{20} 0.6830. The literature [7] gives: b.p. 42.4–42.6°; n_D^{20} 0.4309; d_4^{20} 0.6803. The experiments were carried out in a flow-type apparatus, consisting of a feeding device (a "dropper"), a reaction zone filled with broken quartz, and a receiver. In each experiment 150 ml of piperylene was taken and was fed into the reaction zone at a rate of 0.3 hour^{-1}. The experiments were carried out at 450°, 500°, and 550° under a pressure of 15 atm. The compositions of some of the fractions were investigated with the aid of the Raman spectra*. In order to simplify the identification of the hydrocarbons present, some of the fractions were hydrogenated by Lebedev's method [8] and then subjected to adsorptional separation into paraffin–naphthene and aromatic parts—and also to distillation. The cyclopentadiene content of the condensate was determined by Afanasyev's method [9]. The gaseous products were analyzed in an Orsat and Lunge apparatus.

---

* The spectrum analysis was carried out by Yu. P. Egorov, to whom we wish to express our thanks.

TABLE 1

Results of Experiments on the Thermal Transformations of Piperylene at 450°, 500°, and 550°

Temperature (°C)	Yield of condensate (%)	n_D^{20} of condensate	Composition of gas		
			H_2	C_nH_{2n}	C_nH_{2n+2}
450	74	1.4920	18.0	25.0	57.0
500	65	1.4980	20.4	35.0	44.6
550	59	1.5010	26.0	43.0	31.0

Results of typical experiments on the thermal treatment of piperylene at 450°, 500°, and 550° under a nitrogen pressure of 15 atm are presented in Table 1.

The liquid condensates were fractionated through a 30 plate column. All subsequent fractionations were carried out through the same column. The fractional composition and the properties of the fractions are given in Table 2. The fractionation curve of the condensate obtained in Experiment 1 at 450° is presented in Fig. 1. In the fractionation of the condensates, fractions boiling over the same range and having identical properties were obtained, and for the further analysis they were combined.

Investigation of the Fractions. Spectrum analysis of Fraction I and the physicochemical properties of this fraction (Table 2) showed that it consisted predominantly of 1-pentene, but contained also some 2-methyl-1-butene. It was shown that 1,4-pentadiene was also present, this being proved by its conversion into 1,2,4,5-tetrabromopentane, b.p. 162-165° (12 mm) and m.p. 85° [10].

Found %: C 15.63; H 2.21; Br 82.60. $C_5H_8Br_4$. Calculated %: C 15.49; H 2.08; Br 82.43.

Fig. 1. Fractionation curve for the condensate from the thermal treatment of piperylene at 450°.

In the combined Fractions II and III, 2-methyl-1-butene (main component), trans-2-pentene, isoprene, and cyclopentadiene were detected by spectrum analysis. Fraction IV contained trans-piperylene. Fraction V consisted of a mixture of equal amounts of piperylene (cis and trans) and cyclopentadiene*.

The properties of the subsequent fractions showed that they contained a considerable amount of aromatic hydrocarbons in admixture with unsaturated hydrocarbons. Fractions VI, VIII, IX, and X, therefore, were hydrogenated in presence of platinum black [8]. The resulting mixtures of hydrocarbons did not contain any unsaturated compounds.

The hydrogenation results are given in Table 3.

Fraction VII was treated with 82% sulfuric acid, washed with sodium hydroxide solution and with water, and dried over calcium chloride. After being distilled over sodium it had n_D^{20} 1.4990 and b.p. 79-81° (750mm). This fraction, therefore, contained benzene.

After being hydrogenated, Fractions VI, VIII, IX, and X were combined and subjected to chromatographic separation. From 41 g of this mixture, 16 g of paraffins and naphthenes and 22 g of aromatic hydrocarbons were obtained. These were separated by precise fractional distillation and were identified by their physicochemical properties, their Raman spectra, and the results of Ullmann oxidation [11]. The analytical results for the paraffin–naphthene and aromatic parts are given in Tables 4 and 5. The fractionation was carried out in admixture with a decahydronaphthalene carrier.

An examination of the properties of the individual fractions given in Table 4 suggests that the fractions boiling in the range 36-68° contained pentane, 2,3-dimethylbutane, 2-methylpentane, and hexane. Spectroscopic data and the physicochemical properties indicate that the fractions boiling in the range 68-149° contained mainly cyclohexane homologs: methylcyclohexane, ethylcyclohexane, 1,3-dimethylcyclohexane, and 1-ethyl-3-methylcyclohexane.

* Determination of cyclopentadiene in the light part of the condensate (b.p. 26-160°) showed that in all the condensates it was present in a concentration of not more than 2%.

IX	112–125	4.5	3.5	2.7	1.4775	0.8536	m–and p–Xylenes (ratio 1 : 2) and cycloalkenes, the composition of which was established after hydrogenation into the corresponding cycloalkanes (see Table 4)
X	125–160	14.8	20.3	28.6	1.4835	0.8501	
Residue		25.0	36.9	40.7	1.5098	—	
Losses		5.0	3.0	5.0	—	—	

Saturated hydrocarbons were obtained as a result of the hydrogenation of Fractions VI, VIII, IX, and X; thus, taking the spectrum data into account, it may be supposed that, apart from aromatic hydrocarbons, the original fractions contained also alkenes and cycloalkenes.

TABLE 3

Results of the Hydrogenation of Fractions VI, VII, IX, and X

Fraction	Amount taken for hydrogenation (g)	n_D^{20} of original fraction	Amount of hydrogenation product obtained (g)	n_D^{20} of hydrogenation product	Content of aromatic hydrocarbons (%)	Amount of hydrogen required for hydrogenation (liters, S.T.P.)
VI	16.0	1.4650	15.0	1.4380	30	5.8
VII, IX	18.8	1.4780	17.5	1.4690	62	2.1
X	17.5	1.4835	16.5	1.4700	80	3.0

From an examination of the properties of the individual fractions given in Table 5 it will be seen that the fraction of b.p. 78-80° consisted of benzene (6.8%). The succeeding fractions were oxidized to carboxylic acids with potassium permanganate, the amounts taken for oxidation being 3.5 g of the 135-136° fraction, 4 g of the 136-144° fraction, and 3.5 g of the 144-165° fraction. The resulting acids were separated and identified by the melting points of the acids themselves, their anhydrides, or their dimethyl esters. Benzoic acid melted at 119-120°, phthalic anhydride at 103°, dimethyl isophthalate at 62-63°, and dimethyl terephthalate at 136-138°. Hemimellitic and trimellitic acids melted at 188-190° and 210-216° respectively. On the basis of our

calculations we found that the 135-136° fraction contained 35% of ethylbenzene, 41% of m-xylene, and 24% of p-xylene; the 136-144° fraction contained 9% of o-xylene and 91% of p-xylene; the 144-165° fraction contained 43% of propylbenzene, 25% of 1-ethyl-3-methylbenzene, 16% of 1-ethyl-4-methylbenzene, 8% of 1,2,3-trimethylbenzene, and 8% of 1,2,4-trimethylbenzene.

TABLE 4

Fractional Composition of the Paraffin–Naphthene Part of the Hydrogenation Product

Boiling range of fraction (°C)	Amount (%)	Properties of fraction		Hydrocarbons established spectroscopically

144–165	19.0	1.4937	0.8605	40.16	40.65	Propylbenzene, 1-ethyl-3-methylbenzene, 1-ethyl-4-methylbenzene, 1,2,3- and 1,2,4-trimethylbenzenes
Losses	6.5					

All the residues collected in the fractionation of the condensates from all experiments were fractionated at reduced pressure (30 mm) and analyzed by oxidation and molecular weight determination. On the basis of the results it can be assumed that the residue contained not only the dimer, trimer, and tetramer of piperylene, but also C_{10} homologs of benzene and some naphthalene (m.p. 79°; picrate m.p. 148°).

Hence as a result of thermal transformations of piperylene under high-pressure conditions, hydrocarbons of various classes are formed: C_5–C_7 alkenes, cyclohexene homologs, benzene and its homologs, isomerization (isoprene) and dehydrocyclization (cyclopentadiene) products, and also piperylene dimers, trimer, and tetramers and naphthalene.

This great variety of products indicates that, under the selected conditions, the thermal transformations of piperylene are accompanied by synthetic processes. It must be supposed that aromatic hydrocarbons are formed by dehydrogenation and dealkylation of piperylene dimer, which is readily formed at high temperatures [4]. It may be supposed also that the original substance breaks down into radicals of varying degrees of complexity, including methylene radicals, and these effect the alkylation of piperylene or its transformation products.

The compositions of the products of the thermal treatment of piperylene at elevated pressure are represented in the following scheme:

Transformations of Piperylene at Reduced Pressure. In order to determine the effect of reduced pressure on the character of the transformations of piperylene, experiments were carried out in a flow-type apparatus. Passage of the hydrocarbon over the same broken quartz at 550° at a rate of 0.3 hour $^{-1}$ at 20mm gave a condensate having n_D^{20} 1.4310 in 96% yield. The cyclopentadiene content did not exceed 1.5%. Results of the fractionation of 50 g of the condensate through a column (see above) are given in Table 6.

Analogy with the results already obtained on the compositions of the fractions of the condensate obtained under high-pressure conditions and consideration of the resemblance of the properties of fractions boiling over the same temperature range indicated that the first three fractions (26-41°) contained 1,4-pentadiene, 1- and 2-pentenes, 2-methyl-1-butene, cyclopentadiene, and isoprene. All these hydrocarbons were actually found in these fractions when Raman spectrum analysis was carried out. In the residues that accumulated during the fractionation of the condensates, aromatic hydrocarbons (benzene, toluene) were found only in insignificant amounts.

Comparative Characterization of the Thermal Transformations of Piperylene at Different Pressures. Comparison of the results on the thermal transformations of piperylene at different pressures shows that pressure has a substantial effect on the composition of the product (Table 7). For comparison we take the results of experiments carried out at 550°.

An examination of these results shows that the degree of conversion of piperylene into liquid products at low pressure does not exceed 13% and 83.6% of the original piperylene remains unchanged. Under reduced-pressure conditions, side reactions are greatly depressed. In the experiments which were conducted

TABLE 6

Fractional Compositions of the Condensate Obtained by Thermal Treatment of Piperylene at 550° and 20 mm

Fraction	Boiling range (°C)	Yield of fraction (%)	Properties of fraction	
			n_D^{20}	d_4^{20}

II	32–37	6.0	1.3990	0.6641
III	37–41	2.2	1.4058	0.6802
IV	41–43	83.6	1.4320	0.6840
Residue		2.4	1.4520	—
Losses		4.0	—	—

TABLE 7

Dependence of the Fractional Composition of the Transformation Products of Piperylene on Pressure (550°)

Pressure / Boiling point of fraction (°C)	26–41	41–45	45–125	125–160	Residue	Yield of condensate (% on original substance)
20 mm	10.0	83.6	—	—	2.4	96
Atmospheric [6]	22.0	18.0	20.0	8.0	32.0	74
15 atm	4.6	6.5	14.6	28.6	40.7	59

at atmospheric pressure, C_6–C_8 aromatic hydrocarbons are largely formed; 18% of the piperylene remains unchanged, and there is 22% of the pentene–isoprene fraction. Elevated pressure moves the process in the direction of products of higher molecular weight (28.6% of C_8–C_{10}), mainly aromatics with some cyclohexane hydrocarbons; only 6.5% of the piperylene remains unchanged and there is 4.6% of the pentene–isoprene fraction (26-41°). Moreover, a large amount of high-boiling hydrocarbons is formed: cyclicpolymerization and condensation products of piperylene.

SUMMARY

1. The thermal transformations of piperylene were investigated at 450-550° under elevated pressure in a flow system.

2. As a result of these transformations at elevated pressure, a complex mixture of hydrocarbons of various classes was formed: pentenes, hexenes, isoprene, cyclopentadiene, cyclohexene homologs, aromatic hydrocarbons, and products of the cyclic polymerization of piperylene.

3. The presence of these hydrocarbons in the condensates gives reason to suppose that, under the given conditions, isomerization, dehydrocyclization, hydrogenation, polymerization and dimerization, with subsequent dehydrogenation and dealkylation occur.

4. A comparison was made of the compositions of the products of the thermal treatment of piperylene at various pressures (15 atm, atmospheric, and 20 mm).

EFFECT OF THE METHOD OF PREPARATION AND THE PRESENCE OF A CARRIER ON THE CATALYTIC ACTIVITY OF CHROMIC OXIDE IN DEHYDROGENATION AND DEHYDRATION REACTIONS

A. A. Tolstopyatova, K. A. Dulitskaya, and A. A. Balandin

We are at present carrying out investigations on the determination by the kinetic method of the energies of the bonds between reacting molecules and catalysts. Such data may be applied in the development of the theory underlying the selection of catalysts [1]. We decided to investigate the behavior of chromic oxide in the reactions of dehydrogenation of methylcyclohexane, dehydrogenation and dehydration of isopropyl alcohol [2], and dehydrogenation of formic acid. The object of the present investigation was to determine the effects of the following factors on reaction rate, activation energy, and bond energy: 1) the identity of the precipitant used in the preparation of chromic oxide; 2) the presence of asbestos as carrier; 3) the nature of substituents on atoms that participate directly in the reaction (substituents not in sphere of reaction). The existence of such effects can be explained theoretically by the influence of the number and the nature of neighboring atoms on the reacting atoms in the intermediate catalytic complex at an active center.

We have previously studied chromic oxide prepared by precipitation of chromic nitrate with sodium carbonate and subsequent decomposition of the resulting hydroxide into oxide [2]. In order to determine the effect of the identity of the precipitant used in the preparation of the catalyst, in the present investigation chromic oxide was prepared by the same method as before [2], but instead of sodium carbonate, ammonia was used as precipitant (Catalyst No. 1). In order to determine the effect of the presence of a carrier, chromic hydroxide prepared as before [2] was formed on asbestos, the hydroxide then being decomposed into oxide (Catalyst No. 2).

In order to determine the effect of the nature of substituents on atoms that participate directly in the reaction, a comparison may be made between the dehydrogenation of isopropyl alcohol and that of formic acid, for which the indices are identical, i.e. identical atoms participate directly in the reaction, but the substituents are different:

Dehydrogenation of isopropyl alcohol

Dehydrogenation of formic acid

EXPERIMENTAL

Preparation of Catalysts

Catalyst No.1. A 10% solution of chromic nitrate [$Cr(NO_3)_3 \cdot 9H_2O$, pure] was prepared at 80°, 20% ammonia was stirred in, and stirring was continued until precipitation was complete. The precipitate was washed by decantation until reaction of nitrate (with diphenylamine) was negative. The precipite was then filtered off and dried in a drying cupboard at 110 - 120°. A portion of the catalyst was then placed in a catalysis tube and heated in a current of air in an electric furnace with gradual raising of temperature until water ceased to separate (350°).

Catalyst No. 2. Asbestos was impregnated with 10% chromic nitrate [$Cr(NO_3)_3 \cdot 9H_2O$ (pure)] and 10% sodium carbonate solution was added with stirring until precipitation was complete. Both solutions were first heated to 80°. The further treatment was the same as for the preparation of Catalyst No. 1. Proportions of asbestos and chromic oxide 1 : 1.

The asbestos was first purified in the usual way. Fibrous asbestos was placed in a porcelain dish and covered with concentrated sodium hydroxide solution. It was left for 24 hours, washed so as to remove most of the alkali, covered with a 9 : 1 mixture of nitric acid and hydrochloric acids, heated in a water bath for ten hours, washed until reaction for chlorine was negative, dried in a drying cupboard, and roasted in a muffle.

Starting Substances

Methylcyclohexane: b. p. 100.2° (760 mm); n_D^{20} 1.4230; d_4^{20} 0.7692. Isopropyl Alcohol, 96.0%: b. p. 81–82° (763.5 mm); d_4^{20} 0.8002. Formic Acid, 85%: d_4^{20} 1.1950.

Apparatus and Experimental Procedure

The experiments were carried out by the usual flow method. The reactor was a quartz tube, diameter 18 mm, length 90 cm. It was placed in an electric furnace. The temperature was measured within 0.5° with a chromel-alumel thermocouple connected to a potentiometer. The thermocouple pocket was placed in the center of the layer of catalyst. The starting substance was passed in from a medical glass syringe; the rate of feed was controlled by means of a Warren electric motor, and was 0.23 ml per minute for all of the substances.

Gas was collected in a eudiometer having a constant lower level and was analyzed in a VTI apparatus. During the experiments the volume of gas formed was measured accurately within 0.5 ml. Gas for analysis was collected 10-12 minutes after the establishment of a stationary state. The duration of an experiment was 30-40 minutes.

Dehydrogenation of Methylcyclohexane (Catalyst No. 1.)

In the dehydrogenation of methylcyclohexane in the temperature range 366-427°, analysis showed that the gaseous products contained 99% of hydrogen and not more than 1% of other gases. The reaction went in accordance with the equation $C_6H_{11}CH_3 - 3H_2 + C_6H_5CH_3$. The activation energy, calculated by the Arrhenious equation for the dependence of log m_{H_2} (m_{H_2} is the volume of hydrogen (ml at STP) formed per minute) on $1/T$, is found to be ϵ_{H_2} = 22,000 cal/mole. The points for the relation between log m and $1/T$ fit satisfactorily to a straight line (Fig. 1). The experimental results are shown in Table 1 and Fig. 1. As can be seen from Table 1, the reciprocal of the scatter parameter $\frac{\epsilon}{\log k_0} \cdot 10^{-3} = 2.6$; $\log k_0 = \log m_{H_2} + \frac{\epsilon}{4.57T}$.

Dehydrogenation and Dehydration of Isopropyl Alcohol (Catalyst No. 1)

Over chromic oxide in the temperature range 280-340°, isopropyl alcohol undergoes two reactions simultaneously – dehydrogenation and dehydration. In the gas analysis, 70 -80 % of hydrogen and 20-30% of unsaturated hydrocarbons were found; the total amount of CO and CO_2 was less than 1%. The reactions occurring were:

and

16	347	8.5	16.4	33.8	65.2	12.35	23.80	6.29	5.37	2.4	2.19	ε_{H_2} = 980
17	280	1.9	7.53	19.7	79.3	2.72	10.95	6.34	4.76	2.4	2.0	ε_{H_2O}=15 300
20	290	2.6	9.6	21.3	77.1	3.81	13.90	6.36	4.79	2.4	2.0	
18	300	3.1	10.4	22.6	76.4	4.47	15.10	6.33	4.76	2.4	2.0	
19	320	5.4	14.8	26.6	72.4	7.93	21.58	6.38	4.79	2.4	2.0	
21	330	6.0	15.4	27.9	71.1	8.80	22.43	6.33	4.75	2.4	2.0	

The experimental results are given in Table 2 and Fig. 2. As the amount of work done by the catalyst increased, the activation energy for the dehydrogenation reaction diminished; thus for the first ten experiments ε_{H_2} = 12,350 cal/mole, for the next five ε_{H_2} = 11,800 cal/mole, and for the next five ε_{H_2} = 9800 cal/mole. On the other hand, for the dehydration reaction the activation energy increased as the amount of work done by the catalyst increased, and it finally became constant. Thus, for the first ten experiments ε_{H_2O} = 13,950 cal/mole, for the next five ε_{H_2O} = 15,200 cal/mole, and the next five ε_{H_2O} = 15,300 cal/mole (Fig. 2). The value of $\frac{\varepsilon}{\log k_0} \cdot 10^{-3}$ for the dehydration of isopropyl alcohol had the mean value of 2.4, and for the dehydrogenation reaction it varied from 2.2 to 2.0.

Dehydrogenation and Dehydration of Formic Acid (Catalyst No. 1)

The decomposition of formic acid was carried out in the range 227-272°. The gaseous products were found to contain 12.6-32.0% of hydrogen, 37-74% of carbon monoxide, and as much carbon dioxide as hydrogen. This gives reason to suppose that the decomposition of formic acid proceeds in two direction–dehydrogenation and dehydration:

$$HCOOH \rightarrow CO_2 + H_2 \rightleftarrows HCOOH \rightarrow CO + H_2O.$$

For dehydrogenation the activation energy was found to be ϵ_{H_2} = 32,000 cal/mole, and for dehydration ϵ_{H_2O} = 12,700 cal/mole, i.e. dehydration of formic acid proceeds with a much lower activation energy (by 19,300 cal/mole), than its dehydrogenation (Fig.3). The experimental results are given in Table 3 and Fig. 3.

Dehydrogenation of Methylcyclohexane (Catalyst No. 2, Cr_2O_3–asbestos)

The dehydrogenation of methylcyclohexane proceeded in the temperature range 470-540°. Only hydrogen was found in the gas. The activation energy for the dehydrogenation of methylcyclohexane is ϵ_{H_2} = 27,000 cal/mole. The points fit well to a straight line. The quantity $\frac{\epsilon}{\log K_\theta} \cdot 10^{-3} = 3.2$. On Catalyst No. 2 ($Cr_2O_3$–asbestos) this reaction proceeds less readily than on Catalyst No. 1; the difference in activation energies is 5000 cal/mole. The results of the experiments are given in Table 4 and Fig. 4.

Dehydrogenation and Dehydration of Isopropyl Alcohol (Catalyst No. 2, Cr_2O_3–asbestos)

The dehydrogenation and dehydration of isopropyl alcohol was carried out in the range of 340-400°. The gas contained 60-78% of hydrogen and 22-40% of unsaturated hydrocarbons. The other gases present did not amount to more than 1%. The activation energy for the dehydrogenation reaction was ϵ_{H_2} = 17,100 cal/mole and that for dehydration was ϵ_{H_2O} = 28,600 cal/mole. For Catalyst No. 2 the activation energies for dehydrogenation and dehydration were greater than for Catalyst No. 1. The results of the experiments are given in Table 5 and Fig. 5.

Dehydrogenation and Dehydration of Formic Acid (Catalyst No. 2, Cr_2O_3–asbestos)

The decomposition of formic acid over Catalyst No. 2 in the temperature range 244-283° proceeded by dehydration and dehydrogenation. In the gaseous products, carbon monoxide, carbon dioxide, and hydrogen were found, the amounts of carbon dioxide and hydrogen being identical. The activation energy for the dehydration reaction was ϵ_{H_2O} = 35,000 cal/mole, and that for the dehydrogenation reaction was ϵ_{H_2} = 14,200 cal/mole (Fig. 6). The experimental results are given in Table 6.

Determination of the Energies of the Bonds Formed by C, H, and O with Cr_2O_3

The reactions of dehydrogenation of methylcyclohexane and of dehydrogenation and dehydration of isopropyl alcohol and formic acid have been studied in presence of chromic oxide prepared in different ways (Catalysts No. 1 and No. 2). On the basis of the data obtained on the activation energies for these reactions we may calculate the energies of the bonds formed by C, H, and O with chromic oxide Q_{CK}, Q_{HK} and Q_{OK} by the method proposed by Balandin [1]. All these reactions, apart from the dehydration of formic acid, are doublet reactions; their indexes are as follows:

1	2	3	4	5
Dehydrogenation $C_6H_{11}CH_3$	Dehydrogenation i-C_3H_7OH	Dehydration i-C_3H_7OH	Dehydrogenation HCOOH	Dehydration HCOOH

In the dehydration of formic acid the valency of carbon changes, and therefore in the calculation of bond energies the activation energy for the dehydration of formic acid was not taken into consideration: the multiplet theory has not yet been extended to such reactions. Indices 2 and 4 are identical; they differ in the substituents on the carbon. The energy barriers E for these reactions are:

$$E_1 = -2Q_{CH} + 2Q_{CH} + 2Q_{HH}$$
$$E_2 = -Q_{CH} - Q_{OH} + Q_{CH} + Q_{OH} + 2Q_{HH}$$
$$E_3 = -Q_{CH} - Q_{CO} + Q_{HH} + Q_{OH} + 2Q_{CH}$$

Solving these equations, we may find Q_{HK} Q_{CK} and Q_{OK}:

$$Q_{HH} = \frac{1}{2}\left[\frac{1}{2}E_1 + (E_2 - E_3) + \overbrace{Q_{CH} + Q_{OH} - Q_{CO}}^{124.0}\right]$$

$$Q_{CH} = \frac{1}{2}\left[\frac{1}{2}E_1 + (E_3 - E_2) + \overbrace{Q_{CO} + Q_{OH} - Q_{CH}}^{57.0}\right]$$

$$Q_{OH} = \frac{1}{2}\left[(E_2 + E_3) - \frac{3}{2}E_1 + \overbrace{Q_{CO} + Q_{OH} - Q_{CH}}^{97.2}\right]$$

Knowing ϵ, we may calculate E from the formula $\epsilon = 3/4\ E$; the coefficient 3/4 indicates that the bonds may not be completely broken in the reaction, but only deformed. Knowing the bond energies Q_{CK}, Q_{HK}, and Q_{OK}, we may calculate the adsorption potentials q_1, q_2, and q_3 from the formulas $q_1 = 2Q_{CK} + 2Q_{HK}$; $q_2 = Q_{CK} + Q_{CK} + 2Q_{HK}$; $q_3 = Q_{HK} + Q_{OK} + 2Q_{CK}$ for the adsorption potential q is the sum of the energies of all the bonds formed with the catalyst and participating in the reaction. Plotting adsorption potentials on volcano-like curves, we may estimate the efficiency of a given catalyst in any reaction. The volcano-like curves (Fig. 7) are constructed in accordance with the values of $s/2$ and $u/2$, u being the heat of reaction and s the sum of the energies of the reacting bonds. For example, for the dehydrogenation of methylcyclohexane $u_1 = -2Q_{CH} + Q_{HH} + Q_{C=C}$ (second bond) and $s = 2Q_{CH} + Q_{HH} + Q_{C=C}$; u and s for other reactions can be found similarly.

For all the reactions studied the values of the adsorption potentials correspond more closely to the peaks of the volcano-like curves in the case of Catalyst No. 1 than in the case of Catalyst No. 2 (Fig. 7). This means that Catalyst No. 1 is more active than Catalyst No. 2, but is less capable of being improved. This conclusion

must follow from the fact that the nearer the intersect of the adsorption potential to the peaks of the volcano-like curves, the more active the catalyst; when the intersect passes through the maximum of the curve, the catalyst is of maximum activity for the given reaction. It should be noted also that the more active catalyst (No. 1) has a lower energy of activation than Catalyst No. 2.

Fig. 7. Volcano-like curves: I—dehydrogenation of methylcyclohexane; II— dehydrogenation of isopropyl alcohol and formic acid; III—dehydrogenation of isopropyl alcohol.

In the calculation of the energies of bonds formed with the catalyst, the energies of bonds between atoms in the molecules taking part in the reaction were taken from Cottrell's data [3] (cal/ mole): Q_{CH} = 90.5; Q_{OH} = 110.6; Q_{CO} = 77.1; for calculation of the values of $\underline{u}$ and $\underline{s}$: Q_{HH} = 104.2; $Q_{C=O}$ = 83.4 (second bond); $Q_{C=C}$ = 46.9 (second bond).

Table 7 gives values of activation energies, energies of bonds with catalysts, and adsorption potentials for the catalysts: No. 1—Cr_2O_3 from chromic nitrate precipitated with ammonia, and No. 2—Cr_2O_3—asbestos from chromic nitrate precipitated with sodium carbonate. For comparison, our previous results [2] with Catalyst No. 3 (Cr_2O_3 from chromic nitrate precipitated with sodium carbonate) are given. As will be seen, change in the nature of the precipitating agent, i.e. replacement of sodium carbonate by ammonia, greatly affects the activation energy for the dehydrogenation of methylcyclohexane: for Catalyst No.1, ϵ_1 = 22.0; for Catalyst No. 3, ϵ_1 = 38.0 and 38.6— a change of 16-17 kcal/mole. In the dehydrogenation of isopropyl alcohol: for Catalyst No. 1, ϵ_2 = 12.35, 11.8, and 9.8; for Catalyst No. 3, ϵ_2 = 6.4 and 6.7. There is almost no change in the activation energy for the dehydration of isopropyl alcohol: for Catalyst No. 1, ϵ_3 = 13.9, 15.2, and 15.3; for Catalyst No. 3, ϵ_3 = 13.1 and 15.0. This may occur because the reactions of dehydrogenation and dehydration of the alcohol proceed at different active centers.

The variations in the bond energies are again not constant from one catalyst to another. The variation in Q_{HK} is insignificant, the maximum variation being 4 kcal/mole; it is highest for Catalyst No. 1. The bond energy Q_{CK} varies more than Q_{HK}; for Catalyst No. 1 it is 20.0, 18.8, and 17.5 kcal/mole, and for Catalyst No. 3,11.3 and 10.0 kcal/mole; the maximum variation is 10 kcal/mole. The bond energy Q_{OK} varies greatly; for Catalyst No. 1 it is 52.9, 52.4, and 53.7 kcal/mole, and for Catalyst No. 3 it is 73.5 and 72.6 kcal/mole, a maximum variation of 21 kcal/mole. The effect of asbestos as carrier can be judged by a comparison of the results obtained with Catalysts No. 2 and No. 3. The activation energy for the dehydrogenation of methylcyclohexane over Catalyst No. 2 is ϵ_1 = 27.0 kcal/mole, and over Catalyst No. 3 it is ϵ_1 = 38.0 and 38.6 kcal/mole, i.e. greater by 11-12 kcal/mole.

For the dehydrogenation of isopropyl alcohol over Catalyst No. 2, ϵ_2 = 17.1 kcal/mole, and over Catalyst No. 3, ϵ_2 = 6.4 and 6.7 kcal/mole, i.e. less by about 11 kcal/mole for Catalyst No. 3. There was a similar change in the activation energy for the dehydration of the alcohol: for Catalyst No. 2, ϵ_3 = 28.6 kcal/mole, and for Catalyst No. 3, ϵ_3 = 13.1 and 15.0 kcal/mole, i.e. ϵ_3 is 13.6 and 15.5 kcal/mole less for Catalyst No. 3. The introduction of the asbestos carrier caused Q_{HK} to be increased by 6-7 kcal/mole, had

$s_{1/2} = 165.9$; $u_{1/2} = -15.0$; $s_{2/3} = 194.3$; $u_{2/3} = -6.7$; $s_{3/3} = 162.4$; $u_{3/3} = -5.1$

little effect on Q_{CK} (a maximum increase of 1.9 kcal/mole) and caused a great change in Q_{OK}, which was 28.6 kcal/mole less for Catalyst No. 2 than for Catalyst No. 3. The value of Q_{OK} was found to be the most sensitive to the introduction of carrier.

Catalysts No. 1, 2, and 3 differed greatly from one another, as can be seen from the adsorption potentials and their positions on volcano-like curves (Fig. 7)— I is the curve for the dehydrogenation of methylcyclohexane, II is the curve for the dehydrogenation of isopropyl alcohol and of formic acid, and III is the curve for the dehydration of alcohol.

Hence, the nature of the precipitant and the carrier can greatly affect the energies of the bonds formed with the catalyst.

The effect of substituents situated outside the sphere of reaction can be seen from a comparison of data on the dehydrogenation of isopropyl alcohol and of formic acid (on Catalysts No. 1 and 2) relating to the energies of bonds formed by reacting atoms with the catalyst. The indices of these reactions are identical, but with different substituents at C values of all the bond energies changed, both for Catalyst No. 1 and No. 2 2 (Table 7), and consequently the adsorption potentials q also changed. Hence, bond energies and adsorption potentials depend not only on the nature of the catalyst, but also on the nature of the substituents in the reacting molecule. In the case of formic acid, the carbonyl group evidently has a powerful effect.

SUMMARY

1. Activation energies were determined for the dehydrogenation of methylcyclohexane, isopropyl alcohol, and formic acid and the dehydration of isopropyl alcohol and formic acid over chromic oxide prepared in different ways. From these data the energies of the bonds formed by hydrogen, carbon, and oxygen with the chromic oxide surface were found.

2. The effect of molecular structure and the method of preparing the catalyst were investigated for these reactions.

BRIEF COMMUNICATIONS

MAIN DIRECTION OF REACTION IN THE THERMAL DECOMPOSITION OF CELLULOSE IN A VACUUM

V. I. Ivanov, O. P. Golova, and A. M. Pakhomov

The chemistry of the thermal decomposition of cellulose is of great scientific interest. We have made a systematic study of the thermal decomposition of cellulose in a vacuum with the object of determining the main reactions occurring. The effects of many factors were investigated: oxidative processes, hydrolysis, molecular weight, chemical heterogeneity, the structure of the cellulose, conditions of treatment, such as temperature and residual pressure, etc.

Already in 1918, Pictet [1] carried out experiments on the thermal decomposition of cellulose in a vacuum, and from the numerous decomposition products he isolated, for the first time, the substance levoglucosan (1,6-anhydro-β-D-glucopyranose) in about 30% yield. This compound has the same chemical composition as the cellulose monomer unit (I), but in place of the hydroxyl at C-6 there is one at C-4, and the intermolecular 1,4 oxygen bridge is replaced by an intramolecular bridge in the 1,6-position (II):

(I) (II)

According to Irvine and Oldham [2], who made use of Karrer's data [3], formation of levoglucosan in the thermal decomposition of cellulose passes through the formation of glucose, which under the decomposition conditions is dehydrated to levoglucosan. This is the prevalent view on the reaction, and it is expounded in monographs on cellulose chemistry [4] and textbooks on organic chemistry [5]. Korshak [6], in a discussion of the thermal decomposition of high polymers, states that those containing hydroxy groups, including cellulose and starch, are dehydrated during thermal decomposition with formation of a mixture of products of far-reaching decomposition.

The importance of hydrolysis in the thermal decomposition of cellulose to levoglucosan was estimated in three ways: 1) some readily hydrolyzable cellulose was prepared (form of regenerated cellulose), and the thermal decomposition of this resulted in a low yield of levoglucosan; 2) experiments on the thermal decomposition of cellulose in presence of water were carried out; it was shown that the yield of levoglucosan did not increase; 3) on the view that glucose is an intermediate compound, the cellulose was impregnated with 2-20% of glucose, but the yield of levoglucosan was considerably reduced. Taking these results into account, we were able to find conditions under which the yield of levoglucosan was 60% or higher. We confirmed this yield by numerous experiments; our results are presented in the table.

Our results prove that the main direction of reaction in the thermal decomposition of cellulose in a vacuum is breakdown at the weak 1,4 glucoside links into elementary fragments that are subsequently isomerized into levoglucosan. We are carrying out further investigations on the decomposition of cellulose to levoglucosan with the object of attaining a yield close to the theoretical value. Our results open up new ways for the scientific treatment of the thermal decomposition of organic compounds, particularly carbohydrates.

TABLE

Relation of Yield of Levoglucosan to Experimental Conditions

Cellulose preparation	Experimental conditions	Yield of levoglucosan
Cotton cellulose	In a vacuum	60
Cotton cellulose	In a vacuum in presence of water	58–60
Cotton cellulose	In a vacuum in presence of glucose	25–30
Readily hydrolyzable cellulose (regenerated cellulose)	In a vacuum	5–14

SUMMARY

1. It was shown that in the thermal decomposition of cellulose the yield of levoglucosan may attain 60% or higher.

2. In the thermal decomposition of cellulose, hydrolysis, oxidation, and dehydration processes are side reactions.

3. In the thermal decomposition of cellulose in a vacuum the main direction of reaction is breakdown at 1,4 glucoside links into elementary fragments that isomerize into levoglucosan.

SYNTHESIS OF 2-CYCLOPENTYLOCTANE AND 5,5-DIMETHYLUNDECANE

G. A. Tarasova, G. S. Talts, and A. F. Plate

In the course of the development of methods for the investigation of ligroins in the N. D. Zelinsky Institute of Organic Chemistry of the Academy of Sciences of the USSR, various hydrocarbons were synthesized so as to provide standards for use in Raman-spectrum studies. The present paper describes the preparation of two hydrocarbons containing thirteen carbon atoms—a cyclopentane hydrocarbon with a branched side chain, 2-cyclopentyloctane, and a paraffin containing a tertiary carbon atom, 5,5-dimethylundecane. Neither of these hydrocarbons is described in the literature.

2-Cyclopentyloctane. The most convenient method of preparing monosubstituted cyclopentane homologs with a branched side chain is by hydrogenation of the corresponding fulvenes. This method has been used by several authors [1]. The best results on the hydrogenation of fulvenes (90-95% yield) were obtained by Kazansky and Terentyeva [2], who carried out the hydrogenation in the cold under a pressure of hydrogen in presence of Raney nickel. It is by this method that we prepared 2-cyclopentyloctane, starting from 6-hexyl-6-methylfulvene, which was itself prepared by Thiele's method [3] by the condensation of 2-octanone with cyclopentadiene:

5,5-Dimethylundecane. This hydrocarbon was prepared from butylmagnesium bromide and 2-chloro-2-methyloctane in presence of mercuric chloride. The necessary chloro compound was prepared from the corresponding alcohol, 2-methyl-2-octanol, which was synthesized by the Grignard reaction from hexylmagnesium bromide and acetone:

$$n\text{-}C_6H_{13}MgBr + (CH_3)_2CO \rightarrow n\text{-}C_6H_{13}C(CH_3)_2OH \xrightarrow{+HCl} n\text{-}C_6H_{13}C(CH_3)_2Cl$$

$$n\text{-}C_4H_9MgBr + n\text{-}C_6H_{13}C(CH_3)_2Cl \xrightarrow{HgCl_2} n\text{-}C_6H_{13}C(CH_3)_2\,C_6H_{13}\text{-}n$$

EXPERIMENTAL

2-Octanone. This was purified through the bisulfite compound and had the following properties: b.p. 173.0° (760 mm); n_D^{20} 1.4156; d_4^{20} 0.8186. The literature [4] gives: b.p. 172.6-173.1° (752 mm); n_D^{20} 1.41613; d_4^{20} 0.8185.

Cyclopentadiene. This was prepared by the depolymerization of its dimer, and it had the following properties: b.p. 39-42°, n_D^{20} 1.4445.

6-Hexyl-6-methylfulvene. A mixture of 178 g (1.39 moles) of 2-octanone and 100 g (1.51 moles) of cyclopentadiene was added dropwise at 10-14° to a solution of sodium ethoxide prepared from 33 g of sodium (1.43 moles) in absolute ethanol. The mixture was allowed to stand for one hour and then poured into cold water (1 liter). The upper layer was separated and washed with water to remove alkali. The fulvene, which was yellow in color, was distilled with superheated steam, separated from water, rapidly dried with calcium chloride, and vacuum-distilled; b.p. 94-96° (3mm); yield 64.1 g (44.3%).

2-Cyclopentyloctane. Shortly after being distilled, the fulvene was loaded into a rotating autoclave and hydrogenated in ethanolic solution in presence of Raney nickel at room temperature under an initial hydrogen pressure of 110 atmospheres. As soon as the pressure had fallen to fifty to sixty atmospheres, further hydrogen was pumped in. The hydrogenated hydrocarbon was steam-distilled, boiled with sodium, and repeatedly shaken with concentrated sulfuric acid and with sodium bisulfite solution. The 2-cyclopentyloctane was then passed through a silica-gel column and vacuum-distilled through a 40-plate column. The main distillate had the following properties: b.p. 236.0-236.5° (760 mm); 120.5° (19 mm); n_D^{20} 1.4475; d_4^{20} 0.8118; found MR 60.03; calculated for $C_{13}H_{26}$ MR 60.03. The yield of 2-cyclopentyloctane was about 70%.

Hexyl Bromide. Reaction between 112 g (1.1 moles) of hexyl alcohol (b.p. 157.8-158.5° (760 mm); n_D^{20} 1.4180; d_4^{20} 0.8184), 480 g of 48% hydrobromic acid, and 68 ml of concentrated sulfuric acid gave 167 g of hexyl bromide b.p. 53.7-54.7° (20mm); n_D^{20} 1.4472; d_4^{20} 1.1727. The literature [5] gives: b.p. 153.5° (746 mm); n_D^{20} 1.4478; d_4^{20} 1.1748.

2-Methyl-2-octanol. This tertiary alcohol was prepared by the Grignard reaction from hexylmagnesium bromide and acetone, which was first distilled through a 30-plate column. Three fractionations from a Favorsky flask gave an 87.5% yield of 2-methyl-2-octanol, b.p. 91.0-91.5° (24 mm); n_D^{20} 1.4281; d_4^{20} 0.8239; found MR 45.04; calculated $C_9H_{20}O$ MR 45.29. The literature [6] gives: b.p. 82-85° (20 mm); n_D^{20} 1.427.

2-Chloro-2-methyloctane. 2-Methyl-2-octanol was saturated in the cold with gaseous hydrogen chloride until the increase in weight reached the necessary value. The yield was 88.8%; b.p. 66.4-67.1° (14 mm); n_D^{20} 1.4295; d_4^{20} 0.8566; found MR 49.01; calc. for $C_9H_{19}Cl$ MR 48.63. This compound has not been described in the literature.

5,5-Dimethylundecane. A Grignard reagent was prepared from 264.3 g (1.73 moles) of butyl bromide and 46.93 g (1.93 g-atoms) of magnesium in ether; 10 g of mercuric chloride and then 157.5 g (0.97 mole) of 2-chloro-2-methyloctane were added at 20-22°. Toward the end of the addition there was noticeable evolution of gas and the mass thickened. After the usual treatment the ether was distilled off and the residue was heated with sodium to free it from mercury salts. After vacuum fractionation it was found that the head fraction contained 2-methyl-2-octene. 5,5-Dimethylundecane was freed from olefin impurities by chromatographic adsorption on silica gel and was then distilled through a 30-plate column. The main fraction had the following properties: b.p. 101.0° (16 mm); n_D^{20} 1.4272; d_4^{20} 0.7601; found MR 62.25; calc. for $C_{13}H_{28}$ MR 62.23. The yield of pure product was 34 g i.e., about 20% on the amount of 2-chloro-2-methyloctane taken.

SUMMARY

2-Cyclopentyloctane and 5,5-dimethylundecane were prepared for the first time. Their synthesis and properties are described.

SYNTHESIS AND REACTIONS OF OXYGEN-CONTAINING ORGANOSILICON COMPOUNDS

COMMUNICATION 6.* REACTION OF ALCOHOLS WITH ALKYL- AND ARYL-DICHLOROSILANES CONTAINING SILICON-ATTACHED HYDROGEN

M. F. Shostakovsky, D. A. Kochkin, V. L. Vinogradov, and V. A. Neterman

The reaction of alkyl—and aryl—chlorosilanes $R_nSiH_mX_{4-(n-m)}$ with alcohols has not been described in the literature. We have shown that dichloromethyl—and dichloroethyl—silanes $RSiHCl_2$ react with ethyl and butyl alcohols with formation of mono-, di-, and tri—alkoxy compounds—RSiH (Cl) (OR'), $RSiH(OR')_2$, and $RSi(OR')_3$—the predominant product depending on the amount of alcohol taken for reaction. The formation of these products can be represented as follows:

$$RSiHX_2 + R'OH \rightarrow RSiH(OR')X + HX.$$
$$RSiHX_2 + 2R'OH \rightarrow RSiH(OR')_2 + 2HX.$$
$$RSiHX_2 + 3R'OH \rightarrow RSi(OR')_3 + 2HX + H_2.$$

Thus, when the alkylhalosilane: alcohol ratio is 1 : 1, the alkoxyalkylhalosilane is formed (Equation 1), for a ratio of 1 : 2 the product is the dialkoxyalkylsilane (Equation 2), and for 1 : 3 and still lower ratios the product is the trialkoxyalkylsilane (Equation 3). In the last case the hydrogen is replaced by alkoxy. The formation of these compounds can be represented also by the following equations, which show the successive formation of these products:

$$RSiHX_2 + R'OH \rightarrow RSiH(OR')X + HX.$$
$$RSiH(OR')X + R'OH \rightarrow RSiH(OR')_2 + HX.$$
$$RSiH(OR')_2 + R'OH \rightarrow RSi(OR')_3 + H_2.$$

or

$$RSiHX_2 \xrightarrow{R'OH} RSiH(OR')X \xrightarrow{R'OH} RSiH(OR')_2 \xrightarrow{R'OH} RSi(OR')_3$$

We isolated the intermediate compounds by fractionation of the product obtained by reaction of the chlorosilane with excess of alcohol(Equation 3) or with a limited amount of alcohol (Equations 1 and 2). Our investigations indicate the high reactivity of silicon—attached hydrogen atoms in alkyl—and aryl—halosilanes. We have previously established the readiness with which such a hydrogen atom is hydrolyzed in an alkaline medium with formation of solid macromolecular products for which the following structure has been proposed:

** Reported data for tributoxymethylsilane: b.p. 115° (10 mm); n_D^{20} 1,4106; d_4^{20} 0,8775 [3].

*** Reported data for tributoxyethylsilane: b.p. 235—238°; n_D^{20} 1,4128; [4].

The high reactivity of compounds containing silicon–attached hydrogen was established by the vinylation reaction that we have developed: $RSiHX_2 + CH \equiv CH \rightarrow R(CH = CH_2)SiX_2$ [1]. It has been shown also that the hydrolysis of compounds of structure R_2SiHCl under mild conditions gives the corresponding silanols [2].

Alkoxyalkylhalo–, dialkoxyalkyl–, and trialkoxyalkyl–silanes are mobile liquids of sharp odor; they can be distilled without decomposition only in a vacuum. Alkoxyalkylhalosilanes are readily hydrolyzed and fume in the air. Fractionation of the reaction products was carried out through a 20-plate column under reduced pressure in a stream of dry nitrogen. Some of the properties of the products are given in the table.

EXPERIMENTAL

1. Preparation of Butoxychloroethylsilane $C_2H_5SiH(Cl)(OC_4H_9\text{-}n)$. Butyl alcohol (79.04 g) was added dropwise to 129.0 g of dichloroethylsilane (b.p. 74–76° (746 mm); n_D^{20} 1.4216)* contained in a three-necked flask cooled with ice and salt and fitted with dropping funnel and reflux condenser. The reaction mixture was then heated until hydrogen chloride ceased to be evolved (30–40 minutes). The boiling point of the reaction products rose to 80–90°. Fractionation of the products gave 116.8 g (85.0%) of butoxychloroethylsilane, 8.4 g of dibutoxyethylsilane, 10.4 g of tributoxyethylsilane, and 18.0 g of highly viscous resinous products.

2. Preparation of Dibutoxymethylsilane $CH_3SiH(OC_4H_9\text{-}n)_2$ and Tributoxymethylsilane $CH_3Si(OC_4H_9\text{-}n)_3$. The procedure was as described above. For the preparation of dibutoxymethylsilane, 115.0 g (1 mole) of dichloromethylsilane and 148.0 g (2 moles) of butyl alcohol were taken. Fractionation gave 95.1 g (50.2%) of dibutoxymethylsilane, 11.4 g of tributoxymethylsilane, and 50.3 g of high-boiling viscous products. For the preparation of tributoxymethylsilane 115.0 g (1 mole) of dichloromethylsilane and 225.0 g (3 moles) of butyl alcohol were taken. After addition of the alcohol the products were heated at the boil for 10-12 hours; the boiling point rose to 160–180°. Fractionation gave 5.6 g (3.7% on the amount of chloro compound) of butoxychloromethylsilane, 18.9 g (10% on the amount of chloro compound) of dibutoxymethylsilane, 115.5 g (44.0%) of tributoxymethylsilane, and 56.7 g of high-boiling resinous products. The high-boiling products were macromolecular condensed products, sparingly soluble in ethers and esters, but readily soluble in alcohols.

SUMMARY

1. It was shown that reaction between alkyldichlorosilanes containing silicon–attached hydrogen and alcohols in a ratio of 1 : 1 gives mainly alkoxyalkylhalosilanes $RSiH(Cl)(OR')$, for a ratio of 1 : 2 it gives mainly dialkoxyalkylsilanes $RSiH(OR')_2$, and for a ratio of 1 : 3 and for an excess of the alcohol it gives mainly trialkoxyalkylsilanes $RSi(OR')_3$.

2. The silicon–attached hydrogen atom of such alkylhalosilanes is readily converted into an alkoxy group.

3. A stepwise esterification scheme is proposed which is valid for alkyl–and aryl–halosilanes containing silicon–attached hydrogen.

SYNTHESIS AND REACTIONS OF UNSATURATED ORGANOSILICON COMPOUNDS

COMMUNICATION 1.* SYNTHESIS AND REACTIONS OF TERTIARY ORGANOSILICON ACETYLENIC ALCOHOLS

M. F. Shostakovsky, I. A. Shikhiev, and N. V. Komarov

The present investigation forms a continuation of our investigations on the synthesis and reactions of organosilicon γ-alcohols. In our previous investigations [1-3] we studied the synthesis and reactions of primary organosilicon γ-alcohols, and we now turn our attention to tertiary acetylenic γ-alcohols. Synthesis of these alcohols was based on the reaction of Iotsich's organomagnesium complex [4] with chlorotrialkylsilanes:

The structure of the resulting organosilicon acetylenic γ-alcohols was proved by stepwise hydrogenation and by conversion into acetals:

The physicochemical constants of the γ-alcohol (II) are in accord with reported data [5].

EXPERIMENTAL

1. Synthesis of 2-Methyl-4-(trimethylsilyl)-3-butyn-2-ol. With cooling and vigorous stirring, 42 g

* A previous communication by this school of authors under the same general title is also numbered 1 (Bull. Acad. Sci. USSR, Div. Chem. Sci. 1954, 174; C. B. pagination 145)—Publisher.

(0.5 mole) of 2-methyl-3-butyn-2-ol was added to a Grignard reagent prepared from 24.3 g of magnesium and 109 g of ethyl bromide. The reaction mixture was then stirred for three hours. On the next day catalyst (0.5 g Cu_2Cl_2 + 1.0 g HgCl) was added to the reaction mixture, which was cooled while 54 g (0.5 mole) of chloroptrimethylsilane was added dropwise. The reaction mixture was then stirred for three hours at room temperature and for six hours in a hot water bath. The reaction mixture was then decomposed with 10% hydrochloric acid and neutralized with sodium carbonate solution. The ether layer was separated, washed three times with water, and dried over calcined potassium carbonate. Distillation of the solid residue remaining after removal of ether gave 48.6 g (62%) of product, b.p. 71° (8mm). It formed white needles, m.p. 42-42.5°, readily soluble in organic solvents and completely insoluble in water. It gave no precipitate with ammoniacal silver nitrate, but reacted with sodium.

Found %: C 61.56, 61.75; H 10.25, 10.24; Si 17.85, 17.75 $C_8H_{16}SiO$. Calculated %: C 61.50; H 10.32; Si 17.98.

Our results correspond to an organosilicon acetylenic alcohol of the above structure.

2. Synthesis of the Acetylenic Organosilicon Acetal. A mixture of 15.63 g (0.1 mole) of 2-methyl-4-(trimethylsilyl)-3-butyn-2-ol and 9.1 g (0.1 mole) of butyl vinyl ether was stirred vigorously while 0.2 ml of 33% hydrochloric acid was added; the temperature of the reaction mixture rose to 86°. The reaction mixture was then heated at 90° for 30 minutes and set aside overnight, when it was neutralized with calcined potassium carbonate. Three distillations gave 16.5 g (66.4%) of product, b.p. 85-86° (3mm); n_D^{20} 1.4331; d_4^{20} 0.8541. The results correspond to an acetylenic organosilicon acetal of the structure given above.

Hydrolysis of the acetal. A mixture of the acetal (0.1-0.2 g) and 2% sulfuric acid was heated in a sealed tube in a boiling water bath for six hours, and the acetaldehyde formed was determined by the bisulfite method [8]: 93.8% and 92.1% of acetaldehyde were found.

3. Synthesis of 2-Methyl-4-(trimethylsilyl)-3-buten-2-ol. This was prepared by partial hydrogenation of 2-methyl-4-(trimethylsilyl)-3-butyn-2-ol in an ethanol medium over a palladium catalyst prepared by Buesh's method [6]. In the hydrogenation of 10 g of the organosilicon acetylenic alcohol in presence of 10 g of catalyst, 1420 ml of hydrogen was absorbed (the theoretical amount for hydrogenation to the double-bond state is 1434 ml). The hydrogenation product was filtered from catalyst, washed free from alcohol with water, dried over sodium sulfate, and distilled. The product, amounting to 9.4 g (95.7%), had b.p. 72-73° (23.5mm); n_D^{20} 1.4430; and d_4^{20} 0.8377.

4. Synthesis of 2-Methyl-4-(trimethylsilyl)-2-butanol. This was prepared by hydrogenation of the corresponding ethylenic alcohol over Raney nickel by the above-described procedure. In the hydrogenation of 9.1 g of the organosilicon ethylenic alcohol, 1293 ml of hydrogen was absorbed (the theoretical amount for the hydrogenation of the double bond is 1287 ml). The usual treatment gave 8.8 g (92.8%) of product of b.p. 56° (6mm); n_D^{20} 1.4319; d_4^{20} 0.8265. Literature data [5]: b.p. 48° (4 mm); n_D^{20} 1.4315; d_4^{20} 0.8255.

By the above procedures other acetylenic, ethylenic, and saturated organosilicon tertiary γ-alcohols were prepared; their physicochemical constants are given in the table.

SUMMARY

1. Methods were developed for the synthesis of new classes of organosilicon compounds: tertiary acetylenic and ethylenic γ-alcohols. The presence of a triple bond in the acetylenic alcohols was proved by stepwise hydrogenation to saturated alcohols. The presence of a hydroxy group was proved by conversion into an acetal.

2. Six new organosilicon compounds were prepared.

3. In the physicochemical properties of the acetylenic, ethylenic, and saturated organosilicon alcohols obtained, the same general regularities were observed as in the case of the corresponding organic compounds [7]: the boiling points of acetylenic alcohols are higher than those of ethylenic alcohols, and the boiling points of ethylenic alcohols are lower than those of saturated alcohols. Refractive indices and densitites fall as we pass from acetylenic to saturated alcohols.

CATALYTIC HYDROGENATION OF ISOPROPYL AND ISOPROPENYL-CYCLOBUTANE

B. A. Kazansky, M. Yu. Lukina, and L. A. Nakhapetyan

Taking the examples of methylcyclobutane [1] and ethylcyclobutane [2], we have previously shown that the hydrogenolysis of cyclobutane hydrocarbons in presence of platinized charcoal proceeds to an equal extent at all bonds of the ring at about 250°. In the present investigation a hydrocarbon having a branched alkyl substituent—isopropylcyclobutane—was subjected to hydrogenolysis. It was found that, in this case also, the two possible paraffins are formed, but bond scission occurs to a greater extent at the C—C bond more remote from the substituent:

The predominance of this mode of hydrogenolysis is probably to be explained by the screening effect of the isopropyl group.

It is known that a three-membered carbon ring is reminiscent of an olefinic double bond in some chemical properties [3]. For example, this analogy is shown in the phenomenon of conjugation of a cyclopropane ring with a double bond between the first and second atoms of a side chain, the system being reminiscent of a conjugated diene [4]. The occurrence of such conjugation in the catalytic hydrogenation of isopropenylcyclopropane was recently proved by us [5]. The four-membered carbon ring is in many respects similar to the three-membered ring, and it was considered to be of interest for purposes of comparison to study the behavior of the analog of isopropenylcyclopropane—isopropenylcyclobutane—in this reaction.

It was found that, unlike isopropenylcyclopropane, isopropenylcyclobutane—both in the cold [6], and also in the vapor phase at 120°—reacts with hydrogen only at the double bond, with formation of isopropylcyclobutane. At higher temperatures this process is followed by hydrogenolysis of the ring in accordance with the scheme given above. Hence, the products of the hydrogenation of isopropenylcyclobutane and of isopropylcyclobutane in presence of platinized charcoal at 250° and at a space velocity of 0.2 hour^{-1} are identical in composition. This course of the hydrogenation reaction may be considered to prove that isopropenylcyclobutane, unlike isopropenylcyclopropane, does not have the properties of a conjugated system, that in this case no analogy exists between three—and four—membered carbon rings.

EXPERIMENTAL

Hydrogenolysis of Isopropylcyclobutane

The isopropylcyclobutane used had the following properties: b.p. 92.5° (760 mm); n_D^{20} 1.4082; d_4^{20} 0.7380; found MR 32.81; calc. for C_7H_{14} MR 32.33. The catalyst (platinized charcoal), apparatus, and experimental procedure were the same as those described previously [1,2,7]. Passage of 7.8 g of isopropylcyclobutane over the

catalyst at 250° at a space velocity of 0.2 hour $^{-1}$ gave 7.6 g of catalyzate, b.p. 89–90°; n_D^{20} 1.3897; d_4^{20} 0.6900. A further passage of the catalyzate over the platinized charcoal under the same conditions did not affect the constants.

Raman spectrum of the catalyzate *: 308 (3,b), 324 (1,b background), 386 (0), 412 (0), 424 (2), 432 (2), 463 (2,b), 480 (1,b), 499 (2,b), 556 (2,b), 712 (4), 741 (4), 751 (4), 762 (1,background), 785 (3,b), 798 (2,b,background), 823 (3,b), 848 (3,b), 873 (3,b), 895 (3,b), 917 (4,b), 956 (3,b), 969 (4,b), 986 (4), 1021 (2, b, background), 1040 (4,b), 1062 (2,b, background), 1105 (2,b), 1144 (4), 1167 (5,b), 1193 (4,b), 1222 (0), 1253 (1,b), 1284 (4,b), 1304 (5,b), 1338 (4,b), 1355 (4,b), 1382 (3,b), 1445 (8,b,background), 1464 (9,b, background).

Analysis of the Raman spectrum shows that the catalyzate was a binary mixture of 2–methylhexane and 2,3–dimethylpentane. The composition of the mixture was calculated on the basis of additivity of refractive indices and specific volumes. The mixture consisted of about 30% of 2–methylhexane and about 70% of 2,3–dimethylpentane.

Catalytic Hydrogenation of Isopropenylcyclobutane

The isopropenylcyclobutane we used had the following constants: b.p. 98.7°; n_D^{20} 1.4347; d_4^{20} 0.7743; found MR 32.36; calc. on C_7H_{12} with one double bond MR 31.86.

a) Hydrogenation at Room Temperature. This has been described previously [6]. Hydrogen adds at the double bond with formation of isopropylcyclobutane.

b) Hydrogenation at 120°. Passage of 2.1 g of isopropenylcyclobutane over the catalyst at 120° and at a space velocity of 0.2 hour^{-1} gave 2.0 g of catalyzate, b.p. 92–93°; n_D^{20} 1.4073; d_4^{20} 0.7361. These constants are close to those of isopropylcyclobutane. The lowering of the constants is due to the presence of the paraffin formed by hydrogenolysis.

c) Hydrogenation at 250°. Passage of 2.6 g of isopropenylcyclobutane over the catalyst at 250° and at a space velocity of 0.2 hour^{-1} gave 2.4 g of catalyzate, b.p. 89–90°; n_D^{20} 1.3897; d_4^{20} 0.6899. It therefore had the same composition as the product of the catalytic hydrogenation of isopropylcyclobutane at the same temperature.

SUMMARY

1. It was shown that the hydrogenolysis of isopropylcyclobutane occurs to a greater extent at the bond more remote from the substituent.

2. It was shown that in catalytic hydrogenation isopropenylcyclobutane, unlike isopropenylcyclopropane, shows none of the properties of a conjugated system.

SYNTHESIS OF ALIPHATIC AMINO DICARBOXYLIC ACIDS FROM THIOPHENE

Ya. L. Goldfarb, B. P. Fabrichny, and I. F. Shalavina

Goldfarb and Fabrichny [1] have previously described a new method for preparation of aliphatic amino acids based on the reductive desulfurization (hydrogenolysis) of corresponding thiophene derivatives with the aid of Raney nickel. Later, a short paper by Buu-Hoi and Sy [2] appeared in which the authors described what they regarded as a new method of preparing amino acids, although it was in fact based on the principle that we had proposed previously. We have recently applied the method of reductive desulfurization of thiophene derivatives to the preparation of amino dicarboxylic acids. This part of the work is not yet complete, but the appearance of the paper of Buu-Hoi and Sy—who are apparently not acquainted with our experiments—made it necessary for us to publish the incomplete results obtained up to the present time.

We prepared α-amino dicarboxylic acids in accordance with the following scheme:

In this way we prepared 2-aminodecanedioic acid (VI, n = 2) and 2-aminoundecanedioic acid (VI, n = 3).

We have previously demonstrated the possibility of preparing aliphatic amino acids by the hydrogenolysis of oximes of keto acids of the thiophene series, the example taken being the oxime of α-oxo-2-thiopheneacetic acid [3]. We decided to make use of this method for the synthesis of 5-aminotridecanedioic acid. The route to this acid was as follows:

Hydrogenolysis of the oxime (IX) gave a mixture of 5-aminotridecanedioic acid (X) and its lactam:

By boiling this mixture with concentrated hydrochloric acid we obtained the hydrochloride of 5-aminotridecanedioic acid which we converted into the free amino acid.

EXPERIMENTAL

Methyl γ-Oxo-2-thiophenebutyrate (I, n = 2), described previously, and Methyl δ-Oxo-2-thiophenevalerate (I, n = 3) were prepared in 74-80 % yield by condensation of thiophene with methyl 3-(chloroformyl) propionate and with 4-(chloroformyl) butyrate, respectively, in benzene in presence of stannic chloride [5].

2-Thiophenebutyric Acid (II, n = 2) and 2-Thiophenevaleric Acid (II, n = 3), which have been described previously [4, 6-8], were prepared in 90% yield by reduction of the methyl esters of γ-oxo-2-thiophenebutyric and δ-oxo-2-thiophenevaleric acids by the Kizhner method, as modified by Huang-Minlon [9]. Treatment of 2-thiophenebutyric and 2-thiophenevaleric acids with ethanol saturated with hydrogen chloride at the boil gave 89-92% yields of the Ethyl Esters of 2-Thiophenebutyric (III, n = 2) [10] and 2-Thiophenevaleric (III, n = 3) Acids respectively.

Ethyl 5-Formyl-2-thiophenebutyrate (IV, n = 2) and Ethyl 5-Formyl-2-thiophenevalerate (IV, n = 3) were prepared in 75-83% yield by formylation of the ethyl esters of 2-thiophenebutyric and 2-thiophenevaleric acids with the aid of N-methylformanilide and phosphoryl chloride. From these compounds the hydrochlorides of the corresponding α-amino dicarboxylic acids containing a thiophene nucleus were prepared by the amino-nitrile reaction, as already described [1], in 20-30% yield. These hydrochlorides are very unstable and lose hydrogen chloride when dried in a vacuum desiccator.

5-[Amino (carboxy) methyl]-2-thiophenebutyric Acid (V, n = 2) was prepared by elimination of HCl from its hydrochloride; m.p. 191° (with decomposition).

Found %: C 49.44; H 5.34; S 13.15; N 5.66; $C_{10}H_{13}NO_4S$. Calculated %: C 49.41; H 5.39; S 13.18; N 5.76.

Its p-toluenesulfonyl derivative melts at 132-133°.

5-[Amino (carboxy) methyl]-2-thiophenevaleric Acid (V, n = 3) was prepared by elimination of HCl from its hydrochloride; m.p. 175° (with decomposition)

Found %: C 51.29; H 5.87; S 12.49; N 5.50; $C_{11}H_{15}NO_4S$. Calculated %: C 51.34; H 5.88; S 12.46; N 5.44.

Its p-toluensesulfonyl derivative melts at 127-128°.

2-Aminodecanedioic Acid (VI, n = 2) was prepared by hydrogenolysis under previously described conditions [1] of the corresponding α-amino dicarboxylic acid of the thiophene series (V, n = 2) in 83% yield; m.p. 233-234° (with decomposition). The literature [11] gives m.p. 228° (with decomposition).

Found % C 54.96; H 8.77; N 6.33; $C_{16}H_{19}NO_4$. Calculated % C 55.27; H 8.81; N 6.45.

The p-toluenesulfonyl derivative melts at 94–95°. The hydrochloride melts at 156–158°; when dried in a vacuum it loses HCl.

2-Aminoundecanedioic Acid (VI, n = 3) was prepared in 78% yield by the hydrogenolysis of 5-[amino (carboxy) methyl]-2-thiophenevaleric acid (V, n = 3); m.p. 226–228° (with decomposition).

Found % C 57.23; H 9.21; N 5.87; $C_{11}H_{21}NO_4$. Calculated % C 57.11; H 9.11; N 6.06.

Its hydrochloride melts at 149–151°.

Acylation of ethyl 2-thiophenebutyrate (VII) with methyl 4-(chloroformyl) butyrate in the usual way (in benzene in presence of stannic chloride with cooling) gave a 93% yield of Methyl δ Oxo-5-[3-(ethoxycarbonyl) propyl]-2-thiophenevalerate (VIII) and treatment of this with excess of hydroxylamine hydrochloride and alkali gave the oxime 5-(3-Carboxypropyl) - δ- (hydroxyimino)-2-thiophenevaleric Acid (IX). In the preparation of this oxime from (VIII) it is preferable first to hydrolyze this ester to δ Oxo-5-[3-(ethoxycarbonyl) propyl]-2-thiophenevaleric Acid (93% yield) and then form the oxime. In this way the oxime (IX) is obtained in an appreciably purer form; yield 95%.

The hydrogenolysis of the oxime (IX) was carried out under the previously described conditions [1]. A mixture of a solution of 8.2 g of (IX) in 250 ml of aqueous ammonia (about 5%) with 30 g of Raney nickel was stirred for two hours at 75–80°. Nickel was filtered off, and the filtrate was vacuum-evaporated to dryness. Drying of the residue in a vacuum desiccator gave 6.5 g of a mixture of 5-aminotridecanedioic acid and its lactam 6-Oxo-2-piperidineoctanoic Acid (XI), which was obtained in a pure state after several recrystallizations of the mixture from aqueous alcohol and reprecipitations from alkaline solution with acetic acid; m. p. 141–141.5°.

Found % C 64.80; H 9.68; N 5.97; $C_{13}H_{23}NO_3$. Calculated % C 64.70; H 9.61; N 5.80.

The Hydrochloride of 5-Aminotridecanedioic Acid was prepared by boiling the mixture of 5-aminotridecanedioic acid and its lactam, formed by hydrogenolysis of (IX), with concentrated hydrochloric acid. From 5.6 g of the mixture, 5.0 g of the hydrochloride of the amino acid, m.p. 143–145°, was obtained.

5-Aminotridecanedioic Acid (X) was isolated in 89% yield from a solution of its hydrochloride by addition of aqueous ammonia; m. p. 139.5–140°.

Found % C 59.92; H 9.86; N 5.43; $C_{13}H_{25}NO_4$. Calculated % C 60.20; H 9.72; N 5.40.

Its p-toluenesulfonyl derivative melted at 114–115°.

Found % C 58.15; H 7.76; S 7.42; $C_{20}H_{31}NO_6S$. Calculated % C 58.09; H 7.56; S 7.75.

SUMMARY

By hydrogenolysis of the corresponding thiophene derivatives, the following aliphatic amino dicarboxylic acids were prepared: 2-aminodecanedioic, 2-aminoundecanedioic, and 5-aminotridecanedioic acids.

CURRENT EVENTS

ALL-UNION CONFERENCE ON THE APPLICATION OF ISOTOPES IN CATALYSIS

An All-Union conference on the application of isotopes in catalysis was held from March 31 to April 5, 1956, in Moscow. The conference was organized by the Institute of Physical Chemistry of the Academy of Sciences of the USSR. There were more than four hundred participants working on catalysis in the research institutes of the Academies of Sciences of the USSR and of the individual republics, of the ministries of the chemical and petroleum industries, of industrial organizations, and of teaching establishments; this number includes also scientists from the People's Democracies: China, Rumania, Hungary, Czechoslovakia, Poland, and the German Democratic Republic. Forty-four papers were read. The conference operated in two sections: Theory, and Experimental Methods.

The conference was opened by V. I. Spitsyn, Corr. Member Acad. Sci. USSR, director of the Institute of Physical Chemistry of the Academy of Sciences of the USSR. He stated that much work had been carried out in the Soviet Union in recent years on the peaceful uses of atomic energy, and one of the important fields in this work was the application of radioactive and stable isotopes in chemical investigation. Academician M. M. Dubinin gave an address of welcome on behalf of the Division of Chemical Sciences of the Academy of Sciences of the USSR.

In an introductory address, S. Z. Roginsky, Corr. Member Acad. Sci. USSR, said that this conference was the first, not only in the Soviet Union, but also in the world. The task of the conference was to make a critical examination of the results of the application of radioactive and stable isotopes to the investigation of catalysts and catalytic processes and to plan the further development of this line of work.

Greetings to the conference were conveyed by Professor Yan Chen Tsun, leader of the delegation from the Chinese People's Democratic Republic, by R. Ripan, Active Member of the Academy of Sciences of the Rumanian People's Democratic Republic and leader of the Rumanian delegation, by Professor W. Langenbeck from the German Democratic Republic, and Professor Imre Lajos from the Hungarian People's Democratic Republic.

S. Z. Roginsky's paper "Isotopes in Catalysis" indicated the wide possibilities of applying isotope methods in the investigation of catalysts and catalytic processes. The author paid particular attention to existing isotope methods for the study of active surface, and he proposed several new methods. The material obtained up to the present indicated that the active surface of catalysts is very frequently heterogeneous. The application of isotopes in the study of the microchemistry of surfaces is of immense importance, for the microchemistry frequently determines the properties of the catalyst.

The second part of this paper was devoted to an investigation of the mechanism of catalytic processes. In several cases the application of isotopes has enabled us to make great progress in the establishment of the mechanism of complex catalytic processes of great importance to the national economy and has enabled us to envisage possible ways of controlling these processes. The author stated that in the near future the mechanisms of all the main types of catalytic processes must be examined by isotope methods.

There followed a group of papers on the catalytic reactions of hydrogen. A paper by V. V. Voevodsky (Institute of Chemical Physics of the Academy of Sciences of the USSR) presented some views on the mechanism of homogeneous deuterium exchange that leads to far-reaching exchange via the deuterium exchange of free radicals in which the free valency can migrate over the radical. It is considered that the same mechanism may explain also far-reaching deuterium exchange observed under catalysis conditions. The regularities observed in deuterium-hydrogen exchange over palladium favor a mechanism of exchange through the interaction of adsorbed

hydrogen and deuterium atoms.

M. A. Avdeenko, G. K. Boreskov, and M. G. Slinko (L. Ya. Karpov Physicochemical Institute) reported an investigation on isotopic hydrogen exchange over metals differing in electronic structure, in particular over iron, cobalt, nickel, and copper, which differ in the extent to which the d levels are filled with electrons. In Group VIII specific catalytic activity at high temperatures increases with increase in the atomic number of the element and sharply diminishes as we pass to the metals of Group I, copper sub-group. For gold-platinum alloys, in which the extent to which the d levels are filled changes, the specific activity varies in a complicated way with composition. The reaction mechanism is not the same at low and at high temperatures. At low temperatures, at which the activation energy is low, an exchange mechanism via the charged intermediate complex D_3H^+ [Catalyst] is probable. Exchange at low temperatures is less specific; for example, the specific catalytic activities of platinum and gold are of the same order. The specific catalytic activities of metal catalysts of constant chemical composition but prepared by different methods are approximately constant, except in the case of platinum supported by silica gel.

In an investigation by a team of workers—A. A. Balandin, M.B. Neiman, O. K. Bogdanova, G. V. Isagulyants, A. K. Shcheglova, and E.I. Popova (Institutes of Organic Chemistry and Chemical Physics of the Academy of Sciences of the USSR)—the mechanism of the dehydrogenation of butane and butene has been studied with the aid of Neiman's kinetic isotopic method applied to the catalytic process. It was shown that butadiene is formed preferentially from butene. The rates at which butane and butene are transformed were established, and a stepwise dehydrogenation mechanism was given; the course of some side reactions was examined.

A separate session was devoted to the study of the mechanisms of reactions of catalytic oxidation of organic and inorganic compounds with the aid of the method of labeled atoms. A paper by A. B. Nalbandyan, M. B. Neiman, R. I. Mokshina, G. I. Feklisov, and A. N. Antonova (Institute of Chemical Physics of the Academy of Sciences of the USSR) described the results of an investigation on the mechanism of the thermal oxidation of methane with the aid of the kinetic isotopic method. It was shown that oxidation proceeds through the intermediate formation of formaldehyde, which is then oxidized to carbon monoxide.

An investigation of the mechanism of the oxidation of ethylene to ethylene oxide over a silver catalyst, described by L. Ya. Margolis and S. Z. Roginsky (Institute of Physical Chemistry of the Academy of Sciences of the USSR), showed that neither acetaldehyde nor formaldehyde is an intermediary in this reaction. Oxidation of olefins proceeds through non-isolated labile forms, which are tentatively considered to be charged peroxide complexes and adsorbed oxygen in the form O_2^- and O^-. The oxidation of ethylene to carbon dioxide proceeds by two independent routes via unidentified labile intermediate products. The study of oxygen exchange over V_2O_5 and Cu_2O indicated the low mobility of oxygen in the lattices of these oxides under the given conditions of reaction. Introduction of small amounts of acceptor substances into the silver catalyst alters its activity and selectivity.

A paper by G. N. Maklukhin (now deceased) and A. F. Rekasheva (Institute of Physical Chemistry of the Academy of Sciences of the Ukrainian SSR) discussed the mechanism of various oxidation–reduction reactions that have been studied in the liquid phase both by these authors and by others. It was established that in Meerwein–Ponndorf, Cannizzaro, and similar reactions hydrogen is transferred to a carbon atom of the compound being reduced from a covalent CH, PH, or NH of the reducing agent, and not from a hydroxyl. The transferable hydrogen does not enter into isotope–exchange reactions with the readily exchangeable hydrogen of polar solvents. It is considered that the transfer of hydrogen in these reactions proceeds intramolecularly in six- or four-membered cyclic complexes formed by the reactants. This mechanism is in accord with the low isotope effects observed for hydrogen transfer in these reactions.

A paper by Professor Wolf Langenbeck (German Democratic Republic) was devoted to a study of the mechanism of the oxidation of aliphatic hydrocarbons. It was found that, for normal hydrocarbons, combination with oxygen is equally probable for all secondary carbon atoms. The author pointed out that decisive results on the mechanism of the oxidation can be obtained only with the aid of labeled atoms—a method which he had not used.

G. K. Boreskov and L. A. Kasatkina (L. Ya. Karpov Physicochemical Institute) gave a paper on the mechanism of the oxidation of sulfur dioxide over vanadium pentoxide, investigated with the aid of O^{18} as tracer element. The heavy oxygen was introduced into the vanadium pentoxide. It was shown that the sulfur trioxide formed contained heavy oxygen in an amount corresponding to the addition of one atom of labeled oxygen per molecule.

This indicates that the primary step in the oxidation is the transfer of oxygen from the oxide catalyst to the substance being oxidized with subsequent oxidation of the catalyst by oxygen. It was possible to follow this process because of the rapidity with which oxygen diffused from the middle to the surface. S. M. Karpacheva and A. M. Rozen reported the results of a study of oxygen exchange between cupric oxide, manganese dioxide, and alumina, on the one hand, and O^{18}- labeled water, on the other. It was shown that an unequivocal interpretation of the results is impossible without special experiments, because different physical assumptions lead to identical kinetic equations.

These papers were followed by a discussion of the mechanism of catalytic oxidation, the part played by oxygen of the catalyst in the process, and also the possibility of making use of the isotopic exchange of oxygen with calcium carbonate as a geological thermometer.

In the course of the discussions, short reports of experimental results were made by B. B. Vartanyan—on the mechanism of photosynthesis, investigated by the method of labeled atoms—and by G. D. Lyubarsky—on the conductivity and catalytic activity of silver films.

A group of papers was devoted to the application of the method of labeled atoms to the determination of the mechanism of important industrial processes: synthesis of butadiene by S. V. Lebedev's method, cracking of hydrocarbons, the synthine process, etc.

O. M. Vinogradova, N. P. Keier, and S. Z. Roginsky reported the results of an investigation of the mechanism of the synthesis of butadiene. The intermediaries formed in the synthesis of butadiene from ethanol and their mutual transformations were investigated with the aid of ethanol, diethyl, ether, acetaldehyde, crotonaldehyde, and ethylene labeled with radioactive carbon. In general, the investigation confirmed the correctness of the scheme of transformations in this reaction proposed by Yu. A. Gorin, and by M. Ya. Kagan and coworkers. The behavior observed in the redistribution of hydrogen between acetaldehyde and ethanol indicates that the mechanism proposed by American workers—Quattlebaum and others—for the formation of butadiene from alcohol–aldehyde mixtures via deoxygenation of rotonaldhyde must be rejected.

In an investigationof the processes of coke formation and the polymerization of butadiene over the Lebedev catalyst, which was reported by G. M. Zhabrova and B. M. Kadenatsy (Institute of Physical Chemistry of the Academy of Sciences of the USSR), it was shown that, in presence of the Lebedev catalyst, butadiene undergoes considerable transformation, with coke formation, polymerization and hydrogenation to 2—butene. It was shown that these processes are accelerated by traces of water vapor and retarded by the introduction of alkali into the catalyst. By the use of C^{14}- labeled ethanol and butadiene, it was shown that coke is formed mainly from ethanol and polymers from butadiene.

The work of G. P. Panchenkov, Z. V. Gryaznov, V. M. Emelyanov, and L. G. Ganichenko (Moscow State University) shows that in catalytic cracking, deuterium exchange proceeds independently of the catalytic process and includes exchange between cracking products and acid centers of the catalyst. The isomerization of cyclohexane, which is considered to have an acidic mechanism, is also independent of exchange. These results are in conflict with the existing simplified concept of the mechanism of acid catalysis in cracking and isomerization. A paper by T. I. Andrianova and S. Z. Roginsky (Institute of Physical Chemistry of the Academy of Sciences of the USSR) gave the results of a study of the mechanism of the cracking of octane and hexadecane. The kinetic data indicate that the primary act consists in simultaneous breaking of the molecule into several fragments of various lengths, which then undergo secondary transformations. By the use of C^{14}- labeled ethylene and other hydrocarbons, the process of redistribution of hydrogen between ethylene and ethane, butane, and octane was investigated. In the main, redistribution of hydrogen proceeds by hydrogenation of olefins by the hydrogen of coke. The coke is formed mainly from olefins. Cracking is accelerated by the introduction of substances that decompose with formation of radicals or other active forms. Olefins, alcohols, esters, and alkyl iodides have an accelerating effect on the process.

A. Z. Dorogochinsky, N. I. Melnikov, and I. A. Shakhzadov (Grozny Petroleum Research Institute) reported results on the study of exchange between various hexane isomers and deuterium oxide adsorbed on an aluminosilicate catalyst. The exchange of n-hexane was slow, but the presence of a tertiary atom greatly accelerated exchange. The presence of a quaternary carbon atom in the molecule did not result in rapid exchange. Comparative experiments showed that the catalyst accelerated hydrogen exchange to the same degree as sulfuric acid does.

An investigation reported by O. A. Golovina, S. Z. Roginsky, M. M. Sakharov, and Ya. T. Eidus (Institute of Physical Chemistry and Institute of Organic Chemistry of the Academy of Sciences of the USSR) was concerned with the mechanism of the synthesis of hydrocarbons from a mixture of carbon monoxide and hydrogen by the Orlov–Fischer–Tropsch method. The dehydration–condensation mechanism for this process was confirmed for the first time over a typical synthine cobalt–thorium catalyst. C^{14}-labeled ethanol and acetaldehyde were used, and it was shown that, under the conditions of the reaction, acetaldehyde is hydrogenated to ethanol and that acetaldehyde gives similar results to ethanol. When labeled ethanol is present in the reaction mixture, hydrocarbon fractions of C_6 and higher are characterized by constancy of molar radioactivity, irrespective of molecular weight. It was shown that, whether ethanol is present or not, the product does not vary in composition, which is evidence in favor of the participation of ethanol in the initiation of hydrocarbon chains, but not in their rupture.

Problems of isotopic exchange, as also the theory of these processes, were given much attention at the conference, for they are continually being encountered in the investigation of catalysts and catalytic processes by isotope methods.

A. I. Shatenshtein, E. I. Zvyagintseva, E. Ya. Yakovleva, E. A. Izrailevich, Ya. M. Lozhkina, and E. V. Vedeneev (L. Ya. Karpov Institute of Physical Chemistry) studied the dependence of hydrogen exchange between hydrocarbons and solvents on the acid–base characteristics of the system investigated. It was shown that Bronsted's theory of acid–base equilibrium and catalysis gives only an approximate description of the acid-base processes investigated because these are not associated with simple proton transfer, but depend also on the charge and structural peculiarities of the substance undergoing exchange.

In the investigations of V. N. Setkina, D. N. Kursanov, and E. V. Bykov (Institute of Heteroorganic Compounds of the Academy of Sciences of the USSR) it was shown that exchange with saturated hydrocarbons of various structures in sulfuric acid proceeds by an ion-chain mechanism with intermediate formation of carbonium ions. By study of the hydrogen exchange of carbonium ions of various structures it was shown that the carbonium carbon confers exchangeability on hydrogen atoms on a carbon atom attached to the carbonium center. The carbonium center may be able to move along a carbon chain with the result that far-reaching exchange occurs, but when a hydroxyl-group is present the displacement of the carbonium center does not occur and far-reaching exchange is absent. The presence of a positively-charged oxygen or nitrogen atom in an organic molecule, unlike that of a carbonium ion, does not confer mobility on hydrogen atoms on a neighboring carbon; this difference in properties is probably associated with the incompleted, sextet structure of the electron shell of the carbonium ion, as distinct from the oxygen and nitrogen ions, which have completed octets.

In a paper by A. I. Brodsky and N. A. Vysotskaya (Institute of Chemical Physics of the Academy of Sciences of the USSR), on the basis of much experimental material on the exchange of the oxygen of acids and of salts of various structures with the oxygen of water, a mechanism is proposed, according to which exchange passes through the intermediate stage of addition of water with formation of the ortho acid, which then decomposes either by reversal of the process or by hydrolysis, depending on the properties of the central atom; in both cases oxygen exchange will occur.

In a paper entitled "Isotopic Exchange of Oxygen between Free Hydroxyl Radicals and Water" by I. A. Kazarnovsky, N. P. Lipikhin, and M. V. Tikhomirov (L. Ya. Karpov Institute of Physical Chemistry) it was reported that observations on oxygen exchange indicate interaction between free hydroxyl radicals and water.

These papers were followed by a lively discussion.

In the discussion on papers on the mechanism of isotopic exchange it was pointed out that important advances had been made in this field in the Soviet Union and that the work described in the papers was of high standard.

In the application of labeled atoms in the field of catalysis, an important line of work is the study of the active surface of catalysts and their microchemistry. At the session devoted to this question, Imre Lajos (Hungary) gave his views on the possibility of characterizing the catalytic activities of solids by their ability to participate in isotopic exchange between their own ions and the same ions in the solution. The author showed that there is generally no parallelism because the phenomenon of exchange is complicated by recrystallization and other secondary effects. In the investigations of G. I. Korneichuk, V. A. Roiter, N. A. Stukanovskaya, B. P. Rzaeva, and Ya. V. Zhigali (Institute of Physical Chemistry of the Academy of Sciences of the Ukrainian SSR) it was shown with

the aid of S^{35} that in the course of the catalytic oxidation of SO_2 to SO_3 the barium-aluminum-vanadium catalyst undergoes considerable chemical change, which has a slight effect on its activity. The stability of zinc and cadmium sulfides under the conditions of the catalytic decomposition of isopropyl alcohol was studied by O. V. Krylov and E. A. Fokina (Institute of Physical Chemistry of the Academy of Sciences of the USSR). By the use of radioactive S^{35} it was shown that there is a partial conversion of sulfates into sulfides during the catalytic process. On pure sulfides dehydrogenation of the alcohol predominates, but on sulfates dehydration occurs as well as dehydrogenation. A paper by I. I. Tverdovsky and I. F. Tupitsyn (State Institute of Applied Chemistry) described the application of deuterium in the determination of the hydrogen content of a nickel catalyst. A. P. Murin and B. G. Lurye (V. G. Khlopin Radium Institute of the Academy of Sciences of the USSR) applied radioactive indicators for the investigation of the diffusion of native and foreign ions in silver halide lattices. The investigations showed that the diffusion of all these ions is determined by the general process of decompacting of the lattice. Plastic deformation produces defects, which result in an increase in the self-diffusion coefficient of the silver ion and also in the electrical conductivity. A paper by N. P. Keier (Institute of Physical Chemistry of the Academy of Sciences) was devoted to an investigation by isotope methods of the relative effects of biographical heterogeneity of the active surface and of interaction between adsorbed molecules on the laws of chemical adsorption. It was shown by direct experiments with new isotope methods that the effect of interaction or so-called "induced heterogeneity" associated with the electronic processes accompanying chemical adsorption is small and is not able to explain the departure from Langmuir adsorption observed for the activated adsorption of acetylene on nickelous oxide. In an investigation of the kinetic laws of the exchange of adsorbed C^{14}-labeled acetylene with acetylene in the gas phase which did not contain C^{14}, it was proved that the active surfaces of catalysts are extensively heterogeneous, in particular those of nickelous oxide, alumina, copper, and nickel

In the theoretical section, papers were read on the theory of isotopic effects—an important question for the application of isotope methods in any field of investigation. A paper by V. M. Tatevsky (Moscow State University) "Methods for the Statistical Calculation of Equilibrium Isotopic Exchange in the Gas Phase" contained a review of work by the author and others on this question. I. M. Lifshits and G. I. Stepanova (Kharkov Physicotechnical Institute) described their new method for determining the thermodynamic functions of a solid solution of isotopes and the laws they had found for the equilibrium of solid solutions with the gas phase.

A paper by L. S. Mayants (Institute of Heteroorganic Compounds of the Academy of Sciences of the USSR) gave several methods for the calculation of the zero vibration energy and the frequency shift when some of the atoms of a molecule are replaced by their isotopes. These data are indispensible for the calculation of equilibrium constants of reactions in which labeled molecules take part, including isotope—exchange reactions. It was shown that, in the calculation of the shifts of characteristic frequencies of isotopically substituted molecules, the vibrations must not be attributed to individual bonds, since this leads to considerable errors. It was shown that, as a rule, the characteristic frequencies correspond to vibrations in which a whole group of bonds and angles takes part. Ya. M. Varshavsky (L. Ya. Karpov Physicochemical Institute) showed that the thermodynamic isotopic effect on the kinetics of exchange reactions is appreciable only in reactions with light isotopes, e. g. hydrogen, carbon and oxygen. The kinetics of isotopic exchange show the greater departure from a first-order law, the greater the distribution coefficient differs from unity; the greatest departure should be observed for exchange of hydrogen with deuterium and tritium. It was shown that, in the investigation of the kinetic laws of exchange reactions, the specificity of these processes must be taken into account—in particular, the equilibrium distribution of isotopes. In the discussion on these matters, it was pointed out that work on kinetic isotopic effects has not been adequately developed in the Soviet Union.

Another paper read in the theoretical section was that of M. B. Neiman (Institute of Chemical Physics of the Academy of Sciences of the USSR). The author expounded his theory of the application of the method of labeled atoms in the investigation of complex chemical processes. The application of this method was illustrated by several examples. In their paper "Isotopic Exchange between Gaseous Oxygen and the Sulfates of some Alkali Metals at High Temperature", V. I. Spitsyn and V. G. Finikov (Institute of Physical Chemistry of the Academy of Sciences) showed that the rate of isotopic exchange depends on the state of a solid reactant, in particular, on its dispersity. In a group of alkali—metal sulfates, the specific rate of exchange depends on the nature of the alkali metal as well as the particular properties of the central atom of the anion. A paper by S. N. Oziraner (Institute of Physical Chemistry of the Academy of Sciences) was devoted to a study of the kinetic laws of exchange between iodine and the iodides of lithium, sodium, potassium, and calcium. The paper gives a

theoretical interpretation of these results and an equation that satisfactorily described the laws is found.

A. N. Frumkin expounded the theory of the mechanism of the electroreduction of multi-charged anions at a metal electrode and the part played by direct electron transitions in ionic isotope–exchange reactions.

In the section on Method, a session was devoted to methods of synthesizing labeled compounds. Papers were read by S. Z. Roginsky on the general principles of introducing isotopes into organic and inorganic molecules by isotopic exchange, catalytic synthesis, biosynthesis, and the use of hot atoms (atoms of high energy); by A. I. Shatenshtein and E. A. Izrailevich on methods of synthesizing molecules containing deuterium in predetermined positions and of introducing deuterium by isotopic exchange; and by L. I. Kyukhtenko (Pisarzhevsky Institute of Physical Chemistry of the Ukrainian SSR) on the author's method of preparing certain organic compounds labeled with hydrogen, oxygen, and nitrogen isotopes.

In a second session of this section, O. V. Krylov and E. A. Fokina read a paper on the study of the acid-base surface of catalysts by a differential isotope method; they showed that the active surfaces of some oxides are homogeneous with respect to acid-base properties, for which purpose they used C^{14}-labeled cresol and aniline. D. S. Kapustin, V. A. Nogotkov-Ryutin, and M. I. Yanovsky described a method for the analysis of the specific radioactivities of the individual components of a gas mixture, which are separated chromatographically and examined by means of scintillation counter with a thin mica window in a flow-type radiometric cell in which the activity of the air-gas mixture leaving the chromatographic column is measured continuously. R. V. Kalinenko and K. P. Lavrovsky described a simple, exact method of separating a complex mixture of cracking gases by the use of chromatographic columns containing different fillings. V. A. Protashchik (Institute of Chemistry of the Academy of Sciences of the Belorussian SSR) showed that it is possible to measure the surface area of magnesia by determining its radioactivity after saturation of the surface with radioactive carbon dioxide. Two papers were concerned with the mass-spectrometric method of isotope analysis. I. P. Gragerov (Institute of Physical Chemistry of the Academy of Sciences of the USSR) showed that the isotopic composition of oxygen in various organic compounds can be determined from the isotopic composition of carbon dioxide after it has been allowed to undergo exchange with the substance under investigation. G. M. Panchenkov, I. A. Akishina, and N. N. Vasilyev (Moscow State University) described a method of investigating the emission properties of aluminosilicate catalysts.

In conclusion, the work of the conference was reviewed and a resolution was passed.

In the resolution reference is made to the progress made in the Soviet Union in the application of isotope methods for the investigation of catalysts and catalytic processes. It is pointed out, however, that the application of isotopes is mainly concentrated in the larger scientific centers (Moscow, Kiev, Leningrad) and that the amount of experimental and theoretical work is still not adequate. The extension of the use of stable isotopes is hindered by the short supply and high price of mass spectrometers and ancillary apparatus.

The conference drew the attention of the Presidia of the Academies of Sciences of the USSR and of the individual Republics, and also of the various ministries, to the necessity for a greater measure of coordination in work on the application of isotopes in catalysis and for attracting the participation of workers from branch institutes and works laboratories in this work.

The desire was generally expressed for the holding of further conferences at suitable intervals for the purpose of discussing theoretical and experimental work on the application of isotopes in catalysis.

N. Keiner

CATHODE PROCESSES OCCURRING IN THE ELECTRODEPOSITION OF THORIUM FROM FUSED ELECTROLYTES

M. V. Smirnov and L. D. Yushina

Cathode processes occurring in the electrolysis of fused salts have received far from adequate study. Many of the investigations reported were concerned with the determination of the deposition potentials of individual metals from fused electrolytes, and only a few were directly concerned with the kinetics of cathode processes.

For most fused electrolytes one of the characteristic features of their electrolysis is the high temperature of the process, which leads to the alleviation, or even complete disappearance, of kinetic difficulties in the discharge of ions at the cathode. This was shown experimentally by Karpachev and Rempel [1] for the electrolysis of fused lead and cadmium chlorides. Liquid metals separate at the cathode from the fused lead and cadmium chlorides. Liquid metals separate at the cathode from the fused chlorides without appreciable polarization. In the deposition of solid metals, polarization must again be absent when the electrolysis temperature is notably higher than the temperature at which they recrystallize. As stated by Gorbunov [2], under these conditions the atoms of the metals being deposited are so mobile that they can move quite unhindered into a position of minimum free energy on the surface of large crystals of the cathodic deposit.

The electrolysis of fused salt mixtures, unlike that of fused individual salts, is accompanied by polarization. As various workers have shown [3-8], polarization is associated with changes in concentration in layers of electrolyte in the vicinity of the electrode and is analogous to concentration polarization in aqueous solutions. When the metals being deposited are present in low concentration, limiting diffusion currents may be attained, so that the polarographic method of analysis may be extended to fused electrolytes [9-13].

At high temperatures many metals may react with higher chlorides with formation of subchlorides. This can result in the dissolution of a metal in a salt melt. The electrolysis of melts is therefore often accompanied by partial discharging of ions, which precedes the liberation of metal at the cathode and reduces current efficiency. Thus, Karpachev and Poltoratsky [14] showed that, in the electrolysis of fused lead chloride at low current density at a carbon cathode, univalent lead ions are formed:

$$Pb^{2+} + e \rightarrow Pb^{+}.$$

The cathode potential then depends on the ratio of the concentrations of Pb^{2+} and Pb^{+} ions in the electrolyte layer in contact with the electrode. This ratio is itself determined by the current density and the relative rates of diffusion of these ions in the melt. The possibility of the partial discharging of ions at the cathode has been mentioned by other authors [15-19].

It is known [20-23] that at high temperatures thorium may form lower halides. Investigations carried out in our laboratory showed that thorium dissolves in chloride melts containing Th^{4+} ions with ultimate formation of Th^{3+} ions. Laboratory experiments showed that, in the electrolysis, metal does not begin to separate immediately, but separates only on the attainment of a limiting value of the current density determined by the thorium content of the electrolyte, the temperature, the distance between the electrodes, and the accessibility of atmospheric oxygen to the melt. In an open bath, electrolysis with a current density of less than this limiting value may proceed for a long time without the separation of thorium at the cathode. At high current densities,

however, not only thorium but also alkali metal separates from mixed-salt melts.

With the object of determining what processes occur at the cathode in the electrolysis of chloride and fluoride-chloride melts containing quadrivalent thorium and alkali-metal ions, we have measured the cathodic polarization over a wide range of current densities (10^{-3} to 4 amp/sq. cm). The $ThCl_4$ concentration in the melts was varied from 0.18 to 27.8% by weight, and the temperature was varied from 600° to 800°.

EXPERIMENTAL

Thorium tetrachloride was prepared by heating briquets, formed by compressing an intimate mixture of the oxide and carbon, at 900-1000° in a stream of pure chlorine. The product was purified by two sublimations at a pressure of about 10^{-2} mm. Pure thorium tetrachloride was melted in the required proportion by weight with a eutectic mixture of lithium and potassium chlorides in an atmosphere of dry hydrogen chloride, which was blown through the melt in order to remove any possible decomposition products formed by the action of atmospheric oxygen and moisture. The salt mixtures so prepared were preserved in sealed tubes.

The measurements of cathodic polarization were made in a hermetically closed quartz cell, which is shown diagrammatically in Fig. 1. Salt mixtures of the compositions indicated above were melted in the cell under a protective atmosphere of hydrogen chloride and were then maintained under reduced pressure (about 0.1 mm) until bubbles of dissolved gases ceased to be given off. Before the measurements the cell was filled with argon, which was carefully purified from traces of oxygen and moisture.

Fig. 1. Cell: 1) thermocouple; 2) tube for passage of argon; 3) cathode; 4) chlorine electrode (anode); 5) quartz test tube; 6) asbestos diaphragm.

Preliminary investigations showed that at 600-800° thorium separating at the cathode does not react appreciably with molybdenum. The polarization measurements were therefore carried out on a molybdenum wire whose surface had been freed from oxide film. The wire was immersed to a definite depth in the electrolyte, the correct depth being established by a special locator which closed a control-lamp circuit on coming into contact with the surface.

The cathode potential was measured against a chlorine electrode. This consisted of a tube of spectrographically pure carbon through which chlorine prepared by the electrolysis of fused lead chloride [24] was passed continuously. This electrode served simultaneously as anode. In order to prevent chlorine coming into contact with the cathode, the subsidiary electrode was placed in a quartz test tube having a small side tube packed with asbestos, which acted as a diaphragm. The cell was placed in a massive metal block heated in an electric resistance furnace. The temperature of the cell was controlled automatically and maintained at the desired value within not more than ±2°.

Measurements of potential difference between cathode and chlorine electrode were carried out by means of an electromagnetic oscillograph at the moment when the polarizing current was switched off. At the given current density, the cathode was polarized within 5-6 seconds. As preliminary experiments showed, this period was sufficient for the establishment of a stationary cathode potential. Breaking of the electrolysis current with simultaneous switching-in of the electromagnetic oscillograph was effected by means of a special time relay. In each experiment the cathode potential was measured for 30-40 values of current density. However, the total amount of electricity passing through the cell did not exceed 0.001 amp·hr, so that the change in the thorium tetrachloride content of the electrolyte was of no importance.

Results of Measurements and Discussion of Results

The results of our measurements are given in Figures 2, 3 and 4. The graphs are plots of relative current densities calculated for the original geometric surface of the molybdenum cathode. The polarization curves may be divided into three sections which correspond to different electrode processes determining the value of the cathode potential and the way in which it depends on current density. The first section, at low current density, corresponds to partial discharge of thorium ions without separation of metallic thorium on the cathode.

The second section characterizes deposition of metal, and the third is associated with simultaneous separation of thorium and alkali metal at the cathode.

Fig. 2. Polarization of a molybdenum cathode in a chloride melt containing 0.18% by weight $ThCl_4$ (0.0133 mole % Th^{4+}) at 600° (lower curve), 700° (middle curve), and 800° (upper curve).

Fig. 3. Polarization of a molybdenum cathode in a chloride melt containing 2.6% by weight $ThCl_4$ (0.195 mole % Th^{4+}) at 600° (Curve 1), 700° (Curve 2), and 800° (Curve 3).

Partial Discharge of Thorium Ions at Low Cathode Current Densities. Depending on the thorium concentration and the temperature, in the current-density range 10^{-3}—10^{-2} amp/sq. cm the cathode potential lies at 0.95-1.25 v more negative than the potential of the chlorine electrode and 1.10-1.25 v more positive than the thorium electrode. With increase in current density, the potential increases very slightly in accordance with the empirical equation: $\varphi = \text{const} - b \log i$, in which, within the limits of possible errors in measurements, the coefficient before the logarithm is approximately of the value $2.3\frac{RT}{2F}$. Further increase in current density from 10^{-2} to 10^{-1} amp/sq. cm is accompanied by fairly rapid increase in cathode potential to values at which metallic thorium begins to separate.

Such a course of the polarization curve at low current density may be explained by the partial discharge of thorium ions. If we consider that the reaction of reduction of Th^{4+} ions to Th^{2+} ions occurs with intermediate formation of Th^{3+}, then with establishment of the stationary cathode potential a definite relationship between the mole-fraction concentrations of these ions will be attained in the layer adjacent to the electrode, the relationship being expressed by the thermodynamic equation:

$$\ln \frac{[Th^{4+}]_s [Th^{2+}]_s}{[Th^{3+}]_s^2} = \frac{F}{RT}(E_2^0 - E_1^0),$$

in which E_1^0 and E_2^0 are constants in the thermodynamic equations for the corresponding oxidation-reduction potentials:

$$E_1 = E_1^0 + \frac{RT}{F} \ln \frac{[Th^{4+}]_s}{[Th^{3+}]_s} \text{ and } E_2 = E_2^0 + \frac{RT}{F} \ln \frac{[Th^{3+}]_s}{[Th^{2+}]_s}.$$

In the case of electrolysis of fused salts at high temperatures it may be considered that the partial discharge of ions proceeds without particular difficulty, as a result of which there are always equilibrium proportions of thorium ions in the electrolyte layer adjacent to the electrode. The cathode potential may, therfore, be expressed by the equation:

Fig. 4. Polarization of a molybdenum cathode in a chloride melt containing 27.8% by weight $ThCl_4$ (2.49 mole % Th^{4+}) at 600° (Curve 1), 700° (Curve 2), and 800° (Curve 3).

$$\varphi = \frac{E_1^0 + E_2^0}{2} + \frac{RT}{2F} \ln \frac{[Th^{4+}]_s}{[Th^{3+}]}.$$

When a stationary state is attained at the cathode for a given current density i, the concentrations of thorium ions in the cathode layer of electrolyte are determined by the relationships:

$$[Th^{4+}]_s = [Th^{4+}] - \frac{\delta}{2FD_{Th^{4+}}} i \text{ and } [Th^{3+}]_s = \frac{\delta}{2FD_{Th^{3+}}} i,$$

in which $[Th^{4+}]$ is the mole fraction of Th^{4+} ions in the electrolyte, δ is the thickness of the cathode diffusion layer, and $D_{Th^{4+}}$ and $D_{Th^{3+}}$ are the diffusion coefficients of the ions Th^{4+} and Th^{3+} in the melt.

For the stationary cathode potential we then obtain:

$$\varphi = \frac{E_1^0 + E_2^0}{2} + \frac{RT}{2F} \ln \left\{ \frac{[Th^{4+}] - \delta/2FD_{Th^{4+}} i}{\frac{\delta}{2FD_{Th^{3+}}} i} \right\}$$

or

$$\varphi = \frac{E_1^0 + E_2^0}{2} + \frac{RT}{2F} \ln \left\{ \frac{2FD_{Th^{3+}}[Th^{4+}]}{i} - \frac{D_{Th^{3+}}}{D_{Th^{4+}}} \right\}.$$

At low current density, $i \ll 2FD_{Th^{3+}}[Th^{4+}]$, and the term $D_{Th^{3+}}/D_{Th^{4+}}$ in the expression subjected to the logarithm operator may be neglected without great error. We then have:

$$\varphi = \text{const} - \frac{2.3\,RT}{2F} \log i,$$

where

$$\text{const} = \frac{E_1^0 + E_2^0}{2} + \frac{RT}{2F} \ln 2FD_{Th^{3+}}[Th^{4+}].$$

It is indeed found that such a relationship is observed experimentally at current densities of $i < 10^{-2}$ amp/sq. cm.

With increase in current density the first member of the expression under the logarithm operator diminishes and finally becomes comparable in magnitude with the second ($D_{Th^{3+}}/D_{Th^{4+}}$). The cathode potential begins to increase more and more as the difference between the terms becomes closer to zero. It is clear that increase in the concentration of Th^{4+} ions in the electrolyte, and also rise of temperature, must lead to increase in the limiting current density for partial discharge of thorium ions at the cathode.

In the above considerations we have taken account only of the diffusion of Th^{3+} ions from the cathode layer to the bulk of the electrolyte and have been able to explain the courses of the polarization curves. The diffusion of Th^{3+} ions probably has no appreciable effect on the cathode potential. In all probability it is not the simple ions Th^{4+}, Th^{3+} and Th^{2+} that diffuse through the melt, but complex groupings with the anions. With increase in the charge and reduction in the radius of an ion, the number of anions that become bound to a cation in a complex must increase, so that its mobility is reduced. It may, therefore, be expected that the least mobile ions in the melt are Th^{4+} ions, and the most mobile ions are Th^{2+} ions. Tervalent thorium ions occupy an intermediate position. As a result, the ions diffusing from the cathode layer into the bulk of the electrolyte must be mainly Th^{2+} ions, even when their concentration is lower than that of Th^{3+} ions. In the bulk of the electrolyte, Th^{2+} ions may react with Th^{4+} ions and give Th^{3+} ions, i. e., the final result will be the same as in the direct diffusion of Th^{3+} ions.

Deposition of Metallic Thorium on the Cathode. When $D_k = 0.02$-0.20 amp/sq. cm (depending on the temperature and the concentration of Th^{4+} ions in the electrolyte), a second clearly marked section of the polarization curve is found: the cathode potential almost ceases to change with further increase in the electrolysis current. A deposit of metallic thorium appears on the cathode.

Investigations carried out in our laboratory showed that the potential of an indifferent (molybdenum) electrode becomes equal to that of a thorium electrode when, at the given temperature, the relative mole fractions of Th^{2+} and Th^{4+} ions in the layer of electrolyte in contact with the electrode attain the values given by the empirical equation:

$$\log \frac{[Th^{3+}]_s}{[Th^{4+}]_s} = -10.50431 + \frac{13367}{T}.$$

With rise in temperature from 600 to 800°, the ratio $\frac{[Th^{3+}]_s}{[Th^{4+}]_s}$ changes approximately from 10^5 to 10^3. In this temperature range, therefore, thorium begins to separate on the molybdenum cathode only when the great majority of the Th^{4+} ions have been reduced to Th^{2+}. As Th^{3+} ions are formed by reduction of Th^{4+} ions from the bulk of the electrolyte, the above equation may be written as follows:

$$\log \frac{[Th^{4+}]}{[Th^{4+}]_s} = -10.50431 + \frac{13367}{T},$$

in which $[Th^{4+}]$ is the Th^{4+} concentration in the bulk of the electrolyte and $[Th^{4+}]_s$ is its concentration in the layer in contact with the cathode.

In one of our investigations it was found that the equilibrium potential of the thorium electrode with respect to Th^{4+} ions in chloride melts containing not more than 25% by weight of $ThCl_4$ varies with temperature and concentration in accordance with an empirical equation (with respect to a chlorine reference electrode):

$$E_{Th/Th^{4+}} = -2.568 + 4.742 \cdot 10^{-4} T + 0.496 \cdot 10^{-4} T \log [Th^{4+}].$$

If it is assumed that the cathode potential for the separation of metallic thorium has the equilibrium value,

i. e., is determined by the mole fraction of Th^{4+} ions in the electrolyte layer in contact with the cathode $\varphi = E^0 + \frac{RT}{4F} \ln [Th^{4+}]_s$, then it can be expressed by the equation:

$$\varphi = -3.231 + 9.952 \cdot 10^{-4} T + 0.496 \cdot 10^{-4} T \log [Th^{4+}].$$

In the table we give values of the cathode potential calculated from this equation for the temperatures and Th^{4+} concentrations that we investigated. A correction was made for the thermoelectromotive force of opposite sign between the molybdenum and carbon electrodes.

TABLE

Temperature °C	Thermo-emf	0.18 wt. % $ThCl_4$ $[Th^{4+}] = 1.33 \cdot 10^{-4}$	2.6 wt. % $ThCl_4$ $[Th^{4+}] = 1.96 \cdot 10^{-3}$	27.8 wt. % $ThCl_4$ $[Th^{4+}] = 2.49 \cdot 10^{-2}$
600	0.008	−2.52	−2.47	−2.42
700	0.009	−2.44	−2.38	−2.33
800	0.011	−2.36	−2.30	−2.24

As will be seen, the potentials corresponding to the beginning of the separation of metallic thorium on the molybdenum cathode lie on the polarization curves in positions somewhat more positive than those of the calculated values of the equilibrium potentials of the thorium electrode, particularly in melts of low thorium content. This is due to rapid depolarization by the current (of the order of 1 ma) taken from the cell by the electromagnetic oscillograph after the breaking of the polarizing current. However, when a sufficient amount of metallic thorium has collected on the cathode, the depolarization effect becomes insignificant and the cathode potential becomes identical with the equilibrium potential of the thorium electrode within the limits of experimental error (± 0.02 v). This implies that the electrocrystallization of thorium from melts is not accompanied by any appreciable polarization. In fact, its recrystallization temperature — calculated from the empirical formula $\underline{t} = \alpha \frac{t_m}{a}$, in which t_m is the melting point of the metal (1800°), $\underline{a}$ is its highest lattice parameter (5.075 A), and α is a coefficient that is assumed to be unity [25] — is 355° and considerably lower than the temperature of electrolysis.

The potential for the separation of metallic thorium is attained at current densities close to the limiting diffusion current for the discharge of Th^{4+} ions to Th^{3+} ions. If, during the deposition of thorium, the actual cathode surface remained unchanged, the limiting diffusion current for the discharge of Th^{4+} to metal should be about twice the limiting current for the partial discharge of the ions. This, however, is not observed. The cathode potential varies very little over considerably wider ranges of nominal current density (calculated on the geometric surface of the molybdenum cathode), particularly in melts of high thorium concentration. This appears to be due to the fact that, with the separation of a crystalline deposit of thorium, the active surface of the cathode changes and the nominal value of current density is no longer the actual one. As shown by the investigations of Vagramyan [26] and of Gorbunova and Dankov [27], the current density calculated for a growing (active) surface of crystalline metal deposited on the cathode from aqueous solutions remains constant during the whole electrolysis process. With increase in electrolysis current, the active surface of the deposit becomes greater in such a way that the true current density remains unchanged. An analogous phenomenon can clearly occur also in the case of the electrocrystallization of metals from fused electrolytes.

Simultaneous Separation of Thorium and Alkali Metal on the Cathode. With increase in electrolysis current, the true current density remains constant only until the transfer of Th^{4+} ions from the bulk of the electrolyte to the growing parts of the crystals of the cathode deposit of metal is assured. In other words, the development of the active surface of the cathode deposit must freely follow the growth in the electrolysis current. When it begins to lag, the cathode potential rapidly rises to −3.3-3.4 v with respect to the chlorine electrode and then remains almost constant with further rise in the current. Alkali metal appears at the cathode.

It is quite obvious that transference of Th^{4+} ions is encouraged by rise of temperature and particularly by increase in the thorium concentration of the electrolyte, as can be readily seen from the polarization curves. In a melt containing 27.8% by weight of $ThCl_4$, the cathode potential, and, therefore, the true current density, vary little for a wide range of change (more than by 50 times) in the electrolysis current. As the concentration is lowered, this range becomes narrower. We must here take acccount of the relative character of polarization curves in the region of thorium deposition. According to Vagramyan's observations [26], the measured value of the cathode potential, which rose sharrply after increase in the electrolysis current, gradually fell until a "self-adjusting" current density was established.

Various authors, including Andrieux [28] and Drossbach [19], consider that, in the electrolysis of fused mixtures containing salts of alkali or alkaline-earth metals, in the first place alkali or alkaline-earth metal separates at the cathode and this then reduces other components of the melt. Our investigations do not support an electrolysis mechanism of this sort.

Polarization of a Molybdenum Cathode in the Electrolysis of Mixed Fluoride-Chloride Melts containing Thorium. We also studied the polarization of a molybdenum cathode in a fused eutectic mixture of lithium and potassium chloride with an addition of 2.2 and 20% by weight of ThF_4. The thorium tetrafluoride was not prepared specially, but the corresponding amount of an alkali-metal fluoride was added to the chloride melt containing an equivalent amount of the tetrachloride. The results of some of the measurements are shown graphically in Fig. 5.

Fig. 5. Polarization of a molybdenum cathode in a mixed fluoride-chloride melt containing 2.2% by weight of ThF_4. The broken lines represent polarization in a straight chloride melt containing an equivalent amount of $ThCl_4$.

The introduction of fluoride ions into the melt in amounts equivalent to the thorium tetrachloride has no appreciable effect on the character of the cathode polarization at low current density, when partial discharge of ions occurs at the cathode. A difference appears at higher current density, particularly in the region of discharge of Th^{4+} to metal: in fluoride-chloride melts the cathode potential is displaced in the direction of more negative values and alkali metal begins to separate at lower values of the electrolysis current.

This phenomenon is probably to be attributed to the fact that, in fluoride-chloride melts, Th^{4+} ions are less mobile than in straight chloride melts. Owing to the lower radius of fluoride ions, fluoride complexes are more stable than chloride complexes; they are, therefore, formed during electrolysis as fluoride ions accumulate in the cathode layer of electrolyte, in this way rendering the subsequent discharge of Th^{4+} ions difficult. It is quite to be expected that the deposition potential of alkali metal will not change appreciably when we pass from a chloride to a mixed fluoride-chloride melt. This is to be explained by the fact that alkali metals do not form complex groupings with anions in melts.

SUMMARY

1. The polarization of a molybdenum cathode was studied at 600, 700, and 800° in a fused eutectic mixture of lithium and potassium chlorides containing 0.18, 2.6 and 27.8% by weight of $ThCl_4$ or 2.2 and 20% by weight of ThF_4 at current densities ranging from 10^{-3} to 4 amp/sq. cm.

2. It was shown that at relatively low current density (below 0.01 amp/sq. cm) reduction of Th^{4+} ions to Th^{3+} proceeds at the cathode. The cathode potential then varies with current density according to the law of

concentrational polarization. The potential for the deposition of metallic thorium is attained as the limiting diffusion current for the discharge of Th^{4+} ions to Th^{3+} is approached. During the formation of the metal deposit the true current density remains constant. When there is a low concentration of metal ions in the electrolyte, increase in the electrolysis current may result in simultaneous separation of alkali metal.

3. It was shown that introduction of fluoride ions into the melt in amounts equivalent to ThF_4 increases the potential at which metallic thorium separates at the cathode, but has no appreciable effect on the partial discharge of thorium ions at low current density and on the potential at which alkali metal separates.

APPLICATION OF THE DYNAMIC METHOD OF MEASURING ADSORPTION OF VAPORS TO THE DETERMINATION OF THE SURFACE AREAS OF CATALYSTS

A. M. Rubinshtein and V. A. Afanasyev

The methods now in use for the determination of the surface area of solids from adsorption isotherms obtained with nitrogen, argon, or hydrocarbon vapors (butane, benzene, etc.) require the use of a high-vacuum, special optical apparatus, large amounts of mercury, and a continuous supply of liquid nitrogen; in many laboratories, particularly those in outlying districts, these requirements cannot be met. In the study of catalysts, however, a knowledge of the surface area and the character of the porous structure is very important because they largely determine catalytic activity. These are the properties which can be derived from an analysis of adsorption isotherms. The determination of such catalyst characteristics is becoming more and more necessary in every individual investigation on catalysis for the elucidation of the changes occurring during thermal treatment, aging, poisoning, and regeneration, and also, in particular, for the purpose of generalizing information on catalysts of given chemical characteristics in connection with the development of work on the scientific principles underlying the selection and preparation of catalysts. There is therefore an urgent need for experimental methods for the determination of surface area and porosity which, from the point of view of apparatus and technical considerations, are accessible for any chemical laboratory. In this connection, great possibilities are shown by the dynamic method of investigating the adsorption of organic vapors, which was developed during World War I. This method, in which the adsorption of a gas or vapor from a stream of carrier gas (air, nitrogen) at atmospheric pressure is followed gravimetrically, was one of the first to be used and was applied with great success in Zelinsky's work [1] on the development of the charcoal gas mask; we must refer also to the investigations of Alekseevsky [2], Okatov [3], Dubinin [4] and, among foreign workers, Berl and coworkers [5], and others [6, 7, 8].

In spite of the fact that the dynamic method has been widely used for the study of dynamic activity (duration of the protective action of the adsorbent with respect to the given gas or vapor) and of the adsorptive power of porous substances with respect to vapors at various partial pressures, and in spite of the fact that this method enables us to determine adsorption isotherms, it has received no application at all, until recently, for the determination of the surface area of catalysts. Not until 1951 did work of this sort appear: Fricke and Jokers [9], working with alumina, and Davis [10], working with active carbons, made use of adsorption isotherms of benzene vapor determined by the dynamic method. However, in the first of these papers [9] no comparison is made between the results presented and data obtained by other methods. Hence, owing to the paucity of experimental data, the question of the possibility of applying this method to the determination of surface areas considerably less than those of active carbons and, in even greater measure, the question of the lower limit of areas measurable with sufficient accuracy by the dynamic method remain open, as also do questions concerning purely experimental details of the method in its application to catalysts. Moreover, it is necessary to determine the extent to which a correlation exists for various values of specific surfaces between results obtained by the dynamic method and those obtained by classical adsorption methods. It is to the elucidation of all these questions that we devoted the investigation described in this paper, which has the object of drawing the attention of investigators to a convenient, simple method for determining surface area.

EXPERIMENTAL

As it was desirable to carry out the adsorption measurements by the dynamic method at ordinary temperature and pressure, the most convenient adsorbates were substances having a fairly high vapor pressure under these conditions, as high a molecular weight as possible, and a great tendency to be adsorbed. These requirements are satisfied by substances such as benzene (p_s 74.7 mm at 20°, M 78.1) and carbon tetrachloride (p_s 91.3 mm at 20°, M 153.8).

Fig. 1.

The details of the method, which are given below, were worked out in the course of the determination of the surface areas of more than fifty catalysts having specific surfaces ranging from 4 to 550 sq. m/g (determined mainly from the adsorption of benzene vapor with nitrogen as carrier); some adsorption isotherms were determined also for carbon tetrachloride.

Apparatus. The apparatus constructed for surface-area determinations by the adsorption of vapors from a gas stream was not greatly different from that generally used for the investigation of the dynamic activity and adsorptive power of solids; the apparatus is shown diagrammatically in Fig. 1. A stream of nitrogen enters a large buffer reservoir a intended for the maintenance of a steady feed, and it is dried and purified in the columns b, c, c', and d, which are filled, respectively, with active charcoal, indicator silica gel (blue), and soda lime. Preliminary crude regulation of the stream is effected by means of the tap e, which rejects excess of nitrogen into the atmosphere. Beyond the tap e the stream divides into two, which are regulated by the pinchcocks f' and f'' and measured by the flowmeters g' and g''. They pass through the protecting towers of blue silica gel h' and h'' (which trap water vapor evaporating from the flowmeters) and on to the copper coils i' and i'', in which they take up the temperature of the thermostat. One stream then passes into the evaporators j, which are filled with liquid benzene or other adsorbate; it is here saturated with the vapor and is mixed in the mixer k with the second stream, which is of pure nitrogen. By variation of the relative rates of the two nitrogen streams, the relative pressure p/p_s of adsorbate in the system can be varied from 0 to 1. From the mixer, the combined stream, which contains adsorbate vapor at a definite concentration which does not vary with time, passes to the adsorption part of the apparatus, in which there is a tube containing a weighed sample of catalyst (0.5-3 g in our experiments). The parts of the apparatus i, j, k, l are thermostated (water thermostat; ±0.1°). The velocities of the nitrogen streams were varied from 0 to 30-35 ml/min, the flowmeters being designed for this range of velocity.

Experimental Procedure and Calculations. Except when used immediately after preparation, the catalyst sample was first heated for 5-6 hours at a moderate temperature which would not cause any irreversible structural changes — preferably the temperature at which it is used in catalysis experiments or the temperature of the last stage in its preparation — for example, 400-420° for magnesia. In this process water and organic substances adsorbed during storage or in an experiment were removed. An exact amount of the sample was then weighed on an analytical balance into a previously weighed adsorption tube, which was attached through a joint to the extension piece n (Fig. 1) and lowered into the adsorber l. As will be shown below, a preliminary adsorption-desorption cycle, as recommended in the paper [10] for activated charcoals, is generally not necessary.

The tracing of the isotherm may proceed from low relative pressures, following the adsorption branch, or from high relative pressures along the desorption branch. For this purpose the nitrogen stream is turned on and regulated by means of the pinchcocks f' and f" so that the readings of the flowmeters are in accord with the required value of p/p_s, previously tabulated as a function of the relative velocities of the streams with the aid of Equation 1. After a certain time (30-60 minutes), the adsorption tube is taken out, stoppered, and weighed. For each value of p/p_s this operation is repeated until constant weight is attained. In this way the amount adsorbed is determined in grams for the given weight of sample at the given vapor pressure, so that a point on the adsorption isotherm is obtained. This procedure is repeated for a series of increasing relative pressures so as to give the whole of the adsorption isotherm. The desorption branch of the isotherm is determined by varying p/p_s in the opposite direction: for each successive point the flow of nitrogen through j is reduced and the flow of pure nitrogen is increased until p/p_s is reduced to zero.

The pressure of adsorbate vapor depends on the rate of flow of the pure nitrogen which dilutes the stream saturated with vapor at the temperature of the experiment. This relationship is expressed by the following equation [10]:

$$p/p_s = \frac{v_1}{v_1 + v_2 - v_2 \cdot p_s/p_A}, \qquad (1)$$

in which p/p_s is the relative pressure of adsorbate vapor, v_1 is the velocity of the nitrogen stream saturated with adsorbate vapor, v_2 is the velocity of the stream of pure nitrogen, p_s is the saturated vapor pressure of the adsorbate, and p_A is the atmospheric pressure (mm) (more exactly, the sum of the atmospheric pressure and the hydraulic resistance of the system (expressed in mm of mercury), which, as is shown below, may be neglected).

The isotherm is constructed in the usual coordinates: relative pressures p/p_s as abscissas, and amount adsorbed (mmole/g) as ordinates. The surface area is determined from the isotherms either graphically from the point B corresponding to the completion of a monolayer (the beginning of the linear section of the isotherm), or from the BET equation [11]; it is calculated from the equation $S = a_m \cdot \omega_0 \cdot N$, in which a_m is the amount adsorbed as a monolayer (mole/g), ω_0 is the area occupied by one adsorbed molecule on the surface, and N is Avogadro's number.

It is to be noted that of 59 isotherms which we measured by this method, 55 had the normal S-form and only 4, which were determined without prior heat treatment of samples that had been kept for a considerable time, had a concave initial portion and were unsuitable for the usual graphical calculation of the surface area. In the calculations we took the value of ω_0 for benzene to be 39 A^2 (cf. [12]). As a typical example of the isotherms obtained we give the isotherm for the catalyst MgO · NiO of specific surface 96 sq. m/g (Fig. 2); the corresponding experimental data are given in Table 1.

Fig. 2

Preliminary Treatment of Samples. In view of the impossibility of vacuum activation of catalysts in apparatus for the dynamic method, experiments were carried out on the cleaning of catalyst surfaces by heating and washing with adsorbate. A preliminary heating in the air greatly alters the form of isotherms obtained from catalysts that have been kept for some time after preparation and causes the isotherms to approach those obtained in a vacuum apparatus. Typical examples of the effect of a preliminary thermal treatment are shown in Fig. 3: the isotherms I are obtained with MgO catalysts that have been first heated at 420°, and isotherms II are obtained on untreated catalysts. In Fig. 3c, the triangles denote points on the isotherm determined for the catalyst MgO-7 for the adsorption of benzene vapor in a vacuum apparatus at 20°. Fig. 3c shows that, as a result of the preliminary heat treatment, the catalyst surface is adequately cleaned, this being evidenced by the almost exact coincidence of the results obtained in the vacuum apparatus and by the dynamic method. Without preliminary heat treatment the samples give isotherms that are not S-shaped; on these isotherms (Fig. 3a and 3b, isotherms II) it is impossible to distinguish the point B

and so determine the surface area graphically. Fig. 3a also shows the change in the form of the isotherm due to preliminary heating of the sample. Calculation of the specific surface of MgO-7 from the point B gave 113 sq. m/g for the dynamic method and 114 sq. m/g for the vacuum method. However, calculation from isotherm II for MgO-7 in accordance with the BET equation gave the considerably lower value of 85 sq. m/g, which indicated that part of the surface of the unheated catalyst was occupied by adsorbed substances, probably mainly

Fig. 3.

water vapor. Similar results were obtained with various other samples. These experiments show that, if a catalyst is not used immediately after its preparation for the measurement of isotherms, then a preliminary thermal treatment is essential for reliable results.

"Washing" the sample with adsorbate vapor can also clean the surface from physically adsorbed substances. This treatment can be carried out either by means of a preliminary adsorption-desorption cycle [10], or by keeping the sample in saturated adsorbate vapor in a desiccator and desorbing the adsorbate in a stream of pure nitrogen before measurement of the isotherm. Our experiments showed that this treatment is by no means essential: for samples of not very high specific surface (up to about 100 sq. m/g) it sometimes gives satisfactory results, but it has no advantage over thermal pretreatment. For catalysts of high specific surface (in our experiments, silica gel with a specific surface of 550 sq. m/g) preliminary "washing" or an adsorption-desorption cycle does not completely remove discrepancies between successively determined isotherms, which is apparently associated with the low accessibility of the fine pores to the adsorbate. The absence of irreversible hysteresis at low p/p_s for catalysts having a moderate specific surface indicates that cleaning of the surface from adsorbed gases proceeds to an appreciable extent even in the actual adsorption process.

Time Required for the Establishment of Adsorption Equilibrium. The time required for the establishment

of adsorption equilibrium not only determines the rate at which isotherms or individual points can be measured, but must be taken into account for the obtaining of reliable results. Experiments showed that the time for the establishment of equilibrium increases with increase in the specific surface of the catalyst. This is illustrated by the kinetic curves in Fig. 4. Figure 4a shows the kinetic curve for the adsorption of carbon tetrachloride

vapor on a catalyst having S = 124 sq. m/g at $p/p_s = 0.036$; adsorption equilibrium was established in 40 minutes. For a catalyst having S = 204 sq. m/g (absorbate benzene) at the same relative pressure, equilibrium was attained in 3 hours; for S = 550 sq. m/g it was attained only after 7 hours (Fig. 4b). Hence, for the determination of a single point on the isotherm, 1-7 hours may be required, depending on the specific surface and character of the porosity of the sample. It should be noted that for the determination of specific surface we may confine our measurements to the section of the isotherm up to $p/p_s = 0.5$-0.6, thus considerably shortening the time spent on the determination.

Fig. 4.

Reproducibility of Results. The data given below show that the reproducibility of results obtained by the dynamic method of measuring adsorption isotherms is quite satisfactory: in repeat determinations on various samples of the same catalyst, values of the specific surface were 176 and 195 sq. m/g for MgO-32, 113 and 108 sq. m/g for MgO-12, and 113, 124 and 129 sq. m/g for MgO-6. It will be seen that the variation in the results obtained on various samples of the sample catalyst does not exceed 10-12%, which may be regarded as quite allowable in view of the differing amounts taken and the possibility of the samples' not being completely identical.

Verification of the Results Obtained in the Present Investigation by the Dynamic Method, and the Degree of Correlation with Results Obtained by Other Methods. As will be clear from the above discussion, the results obtained by the dynamic method were verified by measuring the adsorption isotherm of benzene vapor at 20° in a standard vacuum apparatus with a quartz spring balance.*

* These isotherms were determined by B. A. Zakharov in the course of our joint work [13, 14], which was carried out simultaneously with the present investigation.

In both cases the adsorption and desorption branches of the isotherm were determined. The agreement between the results is indicated in Fig. 5, in which the circles denote points obtained by the dynamic method and triangles denote points obtained by the vacuum method (the solid points indicate the desorption branch).

As the measurements were carried out on a large number of catalysts based on magnesia (various magnesia preparations and mixed catalysts containing 10 mole % of other oxides), for the verification of the results obtained by the dynamic method we made use also of a new convenient method developed by Zettlemoyer and

Fig. 5

Walker [15] for pure magnesium oxide – determination of the specific surface by adsorption of iodine from nonaqueous solution. It must be emphasized that, in our experiments, this method was extended to mixed magnesia catalysts, as will be seen from the tabular results given below.

All the principal experimental material is presented in Tables 2-4. These show the compositions of the catalysts, the specific surfaces determined by the dynamic (S_d), vacuum (S_v), and iodimetric (S_i) methods, and also the degree of correspondence between the results, expressed as ratios of S_d to S_v and to S_i. For convenience, the catalysts are divided into groups according to the value of the specific surface: 150 sq. m/g and

TABLE 2

higher (Table 2), 150-100 sq. m/g (Table 3), and 100-20 sq. m/g (Table 4).

Figure 5 shows that isotherms determined by the dynamic method for a wide range of p/p_s are in close accord with isotherms determined by the vacuum method; cases were found in which the "dynamic" isotherms lay somewhat higher than the "vacuum" isotherms, though were of identical form. Already from this identity or close accordance of the isotherms it follows that the two methods should give closely agreeing results. The data in Tables 2-4 show that this is in fact so: S_d/S_v is very close to unity. These results are in close accord also with results of determinations of the adsorption of iodine from carbon tetrachloride solution: S_d/S_i again

differs very little from unity. We therefore find very close agreement of results obtained by the three independent methods for catalysts having a specific surface of more than 20 sq. m/g, and we may consider that the dynamic method provides a sufficiently accurate means for the determination of the specific surface of catalysts that are unaffected, of course, by contact with air, which is almost unavoidable owing to the peculiar characteristics of the method itself (weighing of the adsorption tube, which must be taken from and replaced

in the apparatus, with removal and replacement of stoppers). The worst results were obtained with catalysts having a specific surface of about 20 sq. m/g, as will be seen from Table 4, Nos. 10-12; moreover, for four samples with specific surfaces of up to 20 sq. m/g, values of S_d/S_v of about 0.6 were obtained. The causes of this are not altogether clear to us; we may only suppose that in these latter cases the preliminary treatment

TABLE 4

did not result in adequate cleansing or that some of the pores were inaccessible to the large benzene molecules. It is possible that for catalysts of low specific surface these small pores may be satisfactorily determined by the dynamic method when supplementary methods of preliminary treatment are employed; this matter is being investigated further.

Simultaneous Measurement of Several Adsorption Isotherms. In the interests of economy in time and greater productivity from the apparatus, we carried out a series of experiments in which benzene vapor adsorption isotherms were determined simultaneously on six catalyst samples. For this purpose the adsorption part of

the apparatus was constructed as shown in Fig. 6. Experiments showed that, in this apparatus, adsorption equilibrium is attained considerably more slowly than when a single tube and sample is employed; the results, however, are just as accurate as those described above. Steps can be taken to combat the retardation of the establishment of adsorption equilibrium when several isotherms are determined simultaneously by diminishing the dead space in the adsorption part of the apparatus and somewhat increasing the linear velocity of the nitrogen stream containing benzene vapor, i. e., the combined stream leaving the mixer k (Fig. 1). The use of an apparatus containing several adsorption tubes can be recommended for catalysts having low or moderate specific surface: in this case a considerable economy in time can indeed be obtained.

Fig. 6

Sources of Possible Error. For a given weight of catalyst and a given adsorbate, the accuracy of the results depends mainly on the accuracy with which the required pressure of vapor is established in the stream (i. e., on the accuracy of the flowmeters and of the maintenance of a constant rate of flow), on the accuracy of weighing, and, to a much lower degree, on the accuracy of thermostating and the variation in atmospheric pressure. Simple calculations that we have made for $p/p_s = 0.525$ show that, for a change in atmospheric pressure from 730 to 760 mm, the value of p/p_s calculated from Equation 1 changes by only 0.0015. For this reason we may make a preliminary calculation of the ratio of the velocities of the nitrogen streams necessary for the establishment of a given value of p/p_s. These results show that the hydraulic resistance of the system, which amounts to 10-20 mm, can be neglected and p_A can be assumed to be equal to atmospheric pressure without appreciable distortion of the results. For thermostating we used an ultrathermostat, and we considered that the temperature was constant to within 0.1°; a somewhat greater variation in temperature is permissible and very simple thermostats can be used. The errors due to the two causes examined are less than those of the measurement of rates of flow of nitrogen with the flowmeters; in our experiments these measurements were accurate within 0.08-0.1 ml/minute, so that for medium values of p/p_s this error in the measurement of rates leads to an error of 0.005 in the value of p/p_s, and for low values of p/p_s it leads to an error of up to 0.01. It is therefore necessary to select an calibrate the flowmeters with the greatest care, and it is most important to regulate the nitrogen stream very accurately and to maintain the liquid levels constant for each value of p/p_s.

When the usual analytical balance (accurate within $2 \cdot 10^{-4}$ g) is used, then for 1 g of adsorbent with benzene as adsorbate the sensitivity of the method is $2 \cdot 10^{-4}$ mmole/g, which corresponds to an error in the determination of the surface of about 0.05 sq. m/g, which may be completely neglected.

All these determination errors, which are peculiar to the method itself, are negligibly small in comparison with the error introduced in the choice of the value of the molecular area ω_0 (for example, for benzene ω_0 is taken to be 39 A^2 in some papers, but 32.3 and even 23 A^2 in others), as will be clear from the formula $S = a_m \cdot \cdot \omega_0 \cdot N$. However, if it is not required to determine the "absolute" value of the surface area, then for a series of determinations it is quite allowable to use any well-founded value of ω_0.

In conclusion, we must point out that, as comparisons of surface area and its effect on activity have meaning only for catalysts of identical chemical nature — of the same type with respect to composition — for catalysis the greatest interest is presented not by the absolute value of the surface area, but the relative specific surfaces within a series of catalyst samples. The accuracy of determinations made by the dynamic method is therefore quite adequate for the evaluation of catalysts on the basis of specific surface.

SUMMARY

1. It was shown that adsorption isotherms for benzene vapor can be determined at ordinary temperature and pressure by a method which, from the point of view of apparatus, is accessible to any chemical laboratory and which can be successfully applied to the determination of the surface area of catalysts with results that are in close accord with those obtained with the aid of high-vacuum apparatus.

2. For specific surfaces ranging from 20 sq. mμg upwards, the discrepancies between the results obtained by these two methods do not exceed 10%. The same degree of correlation is observed both for pure and mixed magnesia catalysts investigated by these two methods and also by the method [15].

3. It was shown that method [15] can be applied to mixed catalysts based on magnesium oxide.

4. The sources of possible error and methods of preparing samples for the determination are discussed.

HEAT OF ADSORPTION OF BENZENE VAPOR ON CARBON BLACKS
THERMODYNAMICS OF THE PROCESS AND THE ADSORPTION FORCES

N. N. Avgul, G. I. Berezin, A. V. Kiselev and I. A. Lygina

In a previous investigation on the heats of adsorption of hydrocarbons, the heats of adsorption of hexane on oxidized and graphitized carbon blacks were determined [1]. The present paper is concerned with the adsorption of benzene vapor on the same carbons. The molecules of the two hydrocarbons contain equal numbers of carbon atoms, but they differ greatly in structure, so that the determination and comparison of the heats of adsorption of these hydrocarbons and the theoretical calculations of the adsorption energies are of great interest for the study of the nature of adsorption; they are also of practical importance for the understanding of the chromatographic separation of hydrocarbons. For convenience of comparison, the scheme adopted for the discussion and calculations is the same in this paper as in the previous one [1].

EXPERIMENTAL

The same carbon samples were used as in the previous investigation [1]. The original material was the carbon black "Sferon-6," which was evacuated for 12 hours at about 900°. This sample was considerably oxidized at the surface. The graphitized sample was prepared as follows: the same Sferon-6 was evacuated for 6 hours at about 950° and then heated further at 1700° in a stream of hydrogen in a Tamman furnace for 90 minutes. The sample was cooled in a stream of hydrogen. In the course of this treatment there was an increase

Fig. 1. Adsorption isotherms for benzene vapor (1) and hexane (2) on graphitized Sferon-6 at 20°. The solid points refer to desorption.

in the size of the crystallites forming the particles of the carbon, the surface of which became more homogeneous.

After the investigation of these samples in experiments on the heats of adsorption of hexane vapor [1], they were again evacuated in the thimble of the calorimeter at 280°, after which the adsorption of benzene vapor was measured. The experiments were carried out at 20°. The heats of adsorption were measured with the aid of an automatic constant heat-exchange calorimeter (1953 model) – an improved model of the calorimeter described in [2]. The adsorption was measured by the volumetric liquid method with the aid of vacuum

Fig. 2. Relation of the differential heats of adsorption of benzene (1) and hexane (2) vapors to the amounts adsorbed on graphitized carbon.

microburet similar to that described in [3].

The isotherm for the adsorption of benzene vapor on graphitized carbon is given in Fig. 1 (curves with points); plots against three different p/p_s scales are shown. As the surface area of the sample is known [1], not only the relative values a (mmole/g) are given, but also the absolute adsorption α (μmole/sq. m). Three agreeing series of measurements were made; the different markings of the points correspond to the different series. The adsorption isotherm has an S shape. The desorption isotherm coincides with the adsorption isotherm right down to very low relative pressures.

The relation of the differential heat of adsorption Q_a to the amount adsorbed is shown for benzene vapor in Fig. 2 (Curve 1). The amount adsorbed is again shown on two scales – relative and absolute. The denotation of the points is the same as in Fig. 1. The vertical broken line corresponds to the covering of the surface by a compact unimolecular layer. It will be seen from Fig. 2 that, with the filling of the first 25% of the surface, the heat of adsorption falls sharply; with the filling of the next 50% of the surface it remains constant; and on transition to the adsorption of the second layer of benzene molecules the heat of adsorption falls steeply. It does not attain the level of the heat of condensation L (the horizontal broken line); the true heat of adsorption of the second layer of molecules $Q_a - L$ is about 0.5 kcal/mole. In the adsorption of the third layer of benzene molecules there occurs a further lowering of the heat of adsorption to values close to the heat of condensation of benzene.

In order that the adsorption properties of benzene and hexane may be compared, Figures 1 and 2 show also the adsorption and heat of adsorption isotherms for hexane on the same graphitized carbon [1] (Curves 2, without points). In Fig. 2 there is a corresponding vertical broken line indicating filling of the surface with a compact unimolecular film of hexane, and a corresponding horizontal broken line indicating the level of the heat of condensation of the vapor. It will be seen from Fig. 1 that at low relative pressures the adsorption isotherm of hexane lies considerably higher than that of benzene. In the vicinity of $p/p_s = 0.05$ the isotherms intersect and the adsorption of benzene becomes greater than that of hexane. Above $p/p_s = 0.2$ the isotherms are approximately affine.

The cause of the great difference in the adsorbabilities of benzene and hexane in the initial part is readily seen when the heats of adsorption are compared. It will be seen from Fig. 2 that in the the middle part of the

section concerned with the filling of a unimolecular layer, which characterizes the homogeneous part of the surface, the heat of adsorption of hexane is 2.1 kcal/mole greater than that of benzene. The value Q_a is here 12.1 kcal/mole for hexane and 10.0 kcal/mole for benzene. The true heats of adsorption $Q_a - L$ differ still more: the difference is almost 2.5 times as much. The intersection of the adsorption isotherms in the region of the completion of a unimolecular layer above $p/p_s = 0.05$ is to be explained by the fact that the area occupied by a molecule in a compact monolayer is less for benzene than for hexane. In the region of multimolecular adsorption the isotherms are affine and the ratio of the amounts adsorbed by the two substances is close to the ratio of the values of ω_0 for these hydrocarbons (see below).

Fig. 3. Absolute adsorption isotherm for benzene vapor on the graphitized carbon Sferon-6 in the coordinates of the Langmuir equation (above) and in the coordinates of the BET equation (below).

Thermodynamics of Adsorption in the System Benzene — Graphitized Carbon

1. Equation of the Absolute Adsorption Isotherm. As in the case of the system hexane — graphitized carbon [1], for the system benzene — graphitized carbon we used the theoretical equations of Langmuir and BET and also Halsey's equation. Figure 3 shows the absolute adsorption isotherm of benzene vapor on graphitized carbon in the coordinates of the linear forms of the first two equations. It was found that Halsey's equation was not applicable in this case. It will be seen from the upper part of Fig. 3 that Langmuir's equation is obeyed in the range of p/p_s from 0.01 to 0.06, which corresponds to a change in the amount adsorbed from 1.4 to 3.5 μmoles/sq. m. Figure 2 shows that in this range the heat of adsorption remains constant, which is a theoretical prerequisite for the validity of this equation. The Langmuir graph gives the adsorption equilibrium constant K_1 as 51 and the density of the unimolecular layer as $\alpha_m = 4.60$ μmoles/sq. m.

The BET equation is valid over a wider range of relative pressures, extending in the direction of higher p/p_s (p/p_s values ranging from 0.01 to 0.20, the amounts adsorbed ranging from 1.4 to 4.5 μmoles/sq. m). The BET graph gives values of the constants of $C = 56$ and $\alpha_m = 4.12$ μmoles/sq. m. Hence, in meaning, the constants K_1 and C are the same quantity [1], and the values of the constant α_m determined from the two equations are very similar, the difference being less than 10%.

Comparison of Fig. 3 with the corresponding graph for the system hexane — graphitized carbon [1] shows that both equations are obeyed by benzene, but over a shorter range than for hexane. This may be due to the following two causes. First, owing to their compactness, benzene molecules are more sensitive to residual surface heterogeneity, which narrows the range of applicability of the equations in the low p/p_s region. Second, in the case of the BET equation the range of high relative pressures is narrowed because the value of the true heat of adsorption $Q - L$ is considerably less for the first layer of benzene molecules than for the first layer of hexane molecules, but the heat of adsorption Q_a of the second layer is considerably higher as a percentage of the heat of adsorption of the first. Hence, in the case of hexane the prerequisite of the validity of the BET equation — the equality of the heat of adsorption of a second or subsequent layer with the latent heat of condensation L — is more closely fulfilled than in the case of benzene.

On the basis of the BET equation we estimated the area occupied by a benzene molecule on graphitized carbon to be 40.3 A^2. This value is closely in accord with that given in the paper [4] on the carbon "Graphon" (41 A^2). Hence, in the adsorption layer the benzene molecule is oriented parallel to the carbon surface. The area ω_0 for a benzene molecule adsorbed on ungraphitized carbon black was determined in the investigations [5] and [6]. In the first of these investigations the value $\omega_0 = 46.5$ A^2 was obtained, and in the second $\omega_0 = 44.5$ A^2. We determined the adsorption isotherm for benzene vapor on the original sample of carbon by a more exact method than had been used in the investigations [5] and [6]. The adsorption isotherm on this sample

is represented in Fig. 4 in the usual coordinates and also in the coordinates of the BET equation. The adsorption isotherm is in accord with the BET equation in the p/p_s range 0.02-0.3 and in the adsorption range 0.2-0.55 mmole/g. From the BET graph we obtain values of constants of $C = 35$ and $a_m = 0.408$ mmole/g. As the specific surface of this sample of carbon is known [1], it was possible to calculate ω_0 for benzene, the value obtained being 44.0 A^2. This value is close to that obtained in the investigations [5] and [6] and appears to be the most accurate value. From the cited values of ω_0 for these samples of carbon black it will be seen that as we pass from ungraphitized carbon to graphitized carbon there is an increase in the energy constant C and a reduction in the area occupied by one molecule, i. e., ω_0 is a function of adsorption energy, as pointed out in the paper [7].

Fig. 4. Adsorption isotherm for benzene vapor on the original Sferon-6 (above) and the same isotherm in the coordinates of the BET equation (below).

2. Work, Heat and Entropy of Adsorption. Knowing the differential heats of adsorption, we were able to calculate and compare changes in thermodynamic functions in the system graphitized carbon–benzene. The changes in total energy $\partial\Delta U/\partial a$, free energy $\partial\Delta F/\partial a$, and entropy $\partial\Delta S/\partial a$ were calculated as in the paper [1] and are given in Fig. 5. As the adsorption increases, the state of the adsorbed benzene approaches its state in the free liquid. The course of the curve for the internal energy has already been examined above (Fig. 2). The free energy of adsorption changes in a regular fashion. The curve for the the differential of the entropy of adsorption has a complex wave-like form. At the start of the formation of the first surface layer the entropy is positive. In this region the entropy passes through a maximum and then falls and passes over to the negative side as the surface fills. This fall continues until the formation of a compact monolayer is complete. In the region of transition to adsorption in the second layer the entropy curve rises, after which as the second layer gradually fills a reduction in entropy is again observed.

The results indicate that the mobility of benzene molecules at the start of the formation of the first layer is greater than in the free liquid. As the surface becomes filled the mobility of benzene molecules diminishes sharply, and as the formation of a compact monolayer is approached it becomes less than in the free liquid. Molecules adsorbed in the rarefied second layer are again more mobile than in the liquid. With further adsorption the state of the benzene becomes close to its state in the free liquid. The early maximum on the curve is probably to be associated with residual heterogeneity of surface, which reduces the mobility of benzene molecules somewhat.

Fig. 5. Relation of changes in thermodynamic functions in the adsorption of benzene vapor on graphitized carbon to the absolute value of the adsorption.
Curves 1 and 2: $\frac{\partial\Delta U}{\partial a}$ and $\frac{\partial\Delta F}{\partial a}$ (scale on left);
Curve 3: $\frac{\partial\Delta S}{\partial a}$ (scale on right).

Comparison of the adsorption entropy curve of benzene on graphitized carbon with the corresponding curve for hexane [1] shows that their courses are extremely similar, but the curve for benzene is considerably displaced toward the positive region, as compared with the hexane curve. This indicates the greater mobility of benzene molecules in the adsorbed layer, which is in keeping with the lower heat of adsorption. This will be seen clearly from a comparison of the values of the mean molar change of entropy in the adsorption of the first layer of adsorbate. This is – 2.6 cal/mole degree for hexane and + 1.6 cal/mole·degree for benzene, which is greater, therefore, by 4.2 entropy units.

3. Standard Values of Free Energy, Total Energy, and Entropy of Adsorption. For comparison with other adsorbates in investigation [1], the values of the thermodynamic functions at a given surface coverage (θ) were examined. A coverage of 50% was taken as the standard state. The standard values of the functions ($\theta = 0.5$) are then:

$$\left(\frac{\partial \Delta U}{\partial a}\right)_{\theta=0.5} = \Delta U^0, \left(\frac{\partial \Delta F}{\partial a}\right)_{\theta=0.5} = \Delta F^0, \left(\frac{\partial \Delta S}{\partial a}\right)_{\theta=0.5} = \Delta S^0.$$

For the system benzene – graphitized carbon: $Q_a = 10.0$ kcal/mole; $\Delta U^\circ = -(Q^\circ_a - L) = 1.85$ kcal/mole; $\Delta F^\circ = -2.40$ kcal/mole; $\Delta S^\circ = +1.9$ cal/mole·degree. The corresponding values for hexane are $Q^\circ_a = 12.1$ kcal / mole, $\Delta U^\circ = -4.5$ kcal/mole, $\Delta F^\circ = -3.65$ kcal/mole, $\Delta S^\circ = -2.90$ cal/mole·degree.

4. Work, Heat and Entropy of Wetting. With the aid of the total energy and free energy curves (Fig. 5), we calculated the work, heat and entropy of wetting [1]:

$$\frac{A_w}{s} = -\int_0^{a_s} \frac{\partial \Delta F}{\partial a} da + \sigma, \qquad (1)$$

in which σ is the surface tension of benzene (28.1 ergs/sq. cm). Graphical integration gives 86.2 ergs/sq. cm for the work of wetting:

$$\frac{Q_w}{s} = -\int_0^{a_s} \frac{\partial \Delta U}{\partial a} da + \varepsilon, \qquad (2)$$

in which ϵ is the total surface energy of benzene (65.9 ergs/sq. cm).

Graphical intergration gives $\frac{Q_w}{s} = 118$ ergs/sq. cm. This value is, in graphites, 114 and 117 ergs/sq. cm [8]. At 20° the work of wetting is 73% of the heat of wetting. The entropy of wetting is −0.109 ergs/sq. cm·degree.

Fig. 6. Relation between the differential heat of adsorption of benzene vapor and the amount adsorbed on the original Sferon-6 carbon. The broken line is the heat of condensation.

We measured also the differential heat of adsorption of benzene vapor on the original sample of oxidized carbon (Fig. 6). It falls continuously as the surface coverage increases, this being due to the heterogeneity of the surface of ungraphitized carbon. Graphical integration gives 125 ergs/sq. cm as the heat of wetting of this carbon. From this it is clear that although the courses of the curves for differential heat of adsorption are quite different for graphitized and ungraphitized carbons, the integral effect is not very sensitive to the difference between these samples. In the investigation [9] the value 300 ergs/sq. cm was found for the heat of wetting of an oxidized sample of the same Sferon-6 carbon; this value is more than double the value found by us and in the investigation [8]. It is probable that the value obtained in [9] in incorrect.

Theoretical Calculation of the Energy of Adsorption of Benzene on Graphite

It might be expected that the adsorption of benzene, like that of hexane, is due solely to dispersional interactions. We carried out a theoretical calculation of the energy of interaction of benzene with graphite by the same method as before [1]. The interaction energy of an isolated benzene molecule adsorbed on a plane having a graphite lattice was calculated from the equation:

$$\Phi = -C\left[\sum\left(\frac{1}{r^6} - \frac{r_0^6}{2r^{12}}\right) + \frac{\pi\nu}{6(r')^3}\right] = -Cf(r, r_0), \qquad (3)$$

in which C is the dispersional-interaction constant. The first term under the summation $\frac{1}{r^6}$ takes account of the energy of interaction between a CH of the benzene molecule and a carbon atom of the graphite lattice, placed at a distance r; the second term $\frac{r_0^6}{2r^{12}}$ takes account of the corresponding repulsion energy; r_0 is the equilibrium distance of the benzene molecule from the graphite surface, i. e., 3.55 A, the sum of the interplane distance in the graphite lattice (1.7 A) and the half-thickness of the benzene molecule (1.85 A) [10].

The summation was made for the 100 nearest atoms in the adsorbent. The last term of Equation 3 takes account of the interaction of the benzene molecule with all the remaining adsorbent atoms in accordance with London's integral formula [11] (ν is the number of carbon atoms in 1 cc and r' is 8.5 A); this last member forms only about 4% of the total value of $f(r, r_0)$.

The constant C was calculated from Kirkwood's equation [12]:

$$C = -6mc^2 \frac{\alpha\alpha_1}{\alpha/\chi + \alpha_1/\chi_1}, \qquad (4)$$

in which m is the mass of an electron, c is the velocity of light, and α and χ are the polarizabilities and diamagnetic susceptibilities of graphite and benzene, equal respectively to $0.937 \cdot 10^{-24}$ cc, $10.54 \cdot 10^{-30}$ cc; $10.32 \cdot 10^{-24}$ cc, $92.0 \cdot 10^{-30}$ cc. The value of $\sum\left(\frac{1}{r^6} - \frac{r_0^6}{2r^{12}}\right)$ depends on the position of the molecule over the graphite lattice. As the molecule is displaced it varies over a range of 15% [13]. As benzene molecules are mobile on a graphite surface at ordinary temperatures, we used the mean value of this summation in our calculations.

In the calculation of the interaction energy of benzene the value of $f(r, r_0)$ was found to be $3.20 \cdot 10^{65}$ cm^{-6}, which is considerably greater than the corresponding value for hexane, $2.86 \cdot 10^{65}$ cm^{-6} [1]. However, owing to the lower values of mean polarizability and diamagnetic susceptibility for benzene, the value of the constant C was found to be considerably less for benzene than for hexane, its value being $3.37 \cdot 10^{-65}$ kcal·cm^6/mole, which, for the energy of interaction between benzene and a graphite surface, gives $-\Phi = 10.8$ kcal/mole. For hexane $-\Phi = 12.0$ kcal/mole. The calculated value of $-\Phi$ for benzene agrees satisfactorily with the heat of adsorption that we found, namely 10.0 kcal/mole. In the investigation [1] we obtained 12.0 and 11.8 kcal/mole, respectively, for hexane. The change observed when we pass from the theoretical value for hexane to that for benzene is in close accord with the corresponding change in the experimental heats of adsorption.

As we pass from hexane to benzene, theoretical calculation shows a fall in adsorption energy from 12.0 to 10.8 kcal/mole, and experiment shows a fall in heat of adsorption from 11.8 to 10.0 kcal/mole.*

Hence, the heats of adsorption of these hydrocarbons on graphite are satisfactorily described theoretically by the energy of dispersional interaction with the graphite lattice.

The authors thank M. M. Dubinin for his interest and support in this work and A. P. Arkhipova for help in the measurements.

SUMMARY

1. With the aid of an automatic calorimeter having constant heat exchange and an adsorption apparatus with a capillary microburet, determinations were made of differential heats of adsorption and the adsorption isotherms for benzene vapor on carbon black, both graphitized and in its original oxidized state. Much of the surface of graphitized carbon is homogeneous and is filled at a constant heat of adsorption. The adsorption isotherm is satisfactorily described by the Langmuir and BET equations.

2. The relation of the free energy, total energy, and entropy of adsorption to the surface coverage was investigated. The respective standard values for adsorption of vapor and for wetting were determined.

3. A theoretical calculation of the adsorption energy of benzene was carried out by means of a summation of the dispersional interactions with the 100 nearest atoms of the graphite lattice, account being taken of interactions with the remaining atoms with the aid of an integral formula. The calculated value of the adsorption energy is very close to the measured heat of adsorption.

4. Comparisons are made between the isotherms and heats of adsorption of benzene and hexane vapors. As required by theoretical calculation, in the unimolecular region the heat of adsorption of benzene is considerably less than that of hexane.

HYDROGENATION OF CYCLOPENTADIENE IN BINARY MIXTURES WITH OTHER UNSATURATED HYDROCARBONS IN PRESENCE OF RANEY NICKEL

L. Kh. Freidlin and B. D. Polkovnikov

The selective hydrogenation of cyclic hydrocarbons having a system of conjugated double bonds in admixture with olefins has received little investigation. We recently [1] studied the hydrogenation of cyclopentadiene in presence of Raney nickel at 25°. The reaction proceeds in two stages: the cyclopentadiene is first hydrogenated as far as cyclopentene, after which the latter begins to combine with hydrogen with formation of cyclopentane. The rate of the process is greatly dependent on the nature of the solvent. In a methanol or ethanol medium both stages are rapid. In hydrocarbon solvents such as cyclohexane or benzene the second stage is slow and the stepwise character of the process is clearly evident on the kinetic curve. It may be supposed that the stepwise character of the hydrogenation of the unsaturated bonds of cyclopentadiene is to be attributed to adsorptional displacement, the cyclopentene formed being displaced by cyclopentadiene from the catalyst surface, whereas neither an alcohol nor cyclohexane can displace an olefin [2]. In this connection we have now studied the hydrogenation of cyclopentadiene in admixture with cyclopentene and other unsaturated hydrocarbons.

EXPERIMENTAL

Procedure. Experimental Conditions. The hydrogenation was carried out at 25° at ordinary pressure in a shaking glass hydrogenation flask (length 180 mm, diameter 30 mm), agitation being at a rate of 900 shakes per minute with a sweep of 12.7 cm. Special experiments showed that such agitation completely ensures reaction in the kinetic region. The solvents used were cyclohexane and 96% ethanol. For the reaction, freshly prepared cyclopentadiene (b.p. 41-42°, n_D^{20} 1.4442-1.4446) was used; it was prepared by depolymerization of the dimer. The olefins had the following constants: cyclopentene [fraction of b.p. 43.5-43.8° (756 mm); n_D^{20} 1.4252], cyclohexene [fraction of b.p. 82-83° (754 mm); n_D^{20} 1.4467], tolan [diphenylacetylene] [m.p. 60-61° (750 mm)], 1 octene [fraction of b.p. 121.2-122.6° (742 mm); n_D^{20} 1.4130].

The Raney nickel catalyst was prepared by leaching a 50% nickel-aluminum alloy with 20% sodium hydroxide solution for two hours at 100°. For each experiment a new portion (0.42 g) of the same sample of catalyst was taken. The hydrogen used was electrolytic and was freed from traces of oxygen.

In the experiments carried out in cyclohexane, the catalyst was washed from a spoon into the flask with 10 ml of ethanol, which was then poured off; the catalyst was then washed twice with cyclohexane (10 ml portions). Before the reaction the catalyst was saturated with hydrogen under the same conditions (temperature, solvent, rate of agitation) as those used for the hydrogenation. The sample of substance (or mixture of substances) to be hydrogenated was then introduced in 10 ml of cyclohexane and the hydrogenation was begun. All such operations were carried out in a stream of hydrogen. We estimated the rate of hydrogenation and the activity of the catalyst from the rate of absorption of hydrogen.

Hydrogenation of Cyclopentadiene in Binary Mixtures with Cyclopentene, Cyclohexene, 1-Octene, and Tolan. Figure 1 shows the kinetic curves for the hydrogenation of olefins in ethanol and in cyclohexane. It will be seen from Fig. 1 and Table 1 that, in an alcoholic medium, the compounds investigated are hydrogenated at a considerably higher rate than in cyclohexane. Thus, the half-period for the hydrogenation of a

sample of cyclopentene is 9 times as long, and of a sample of tolan is 16 times as long, in cyclohexane as in ethanol (Fig. 1, b and d). The half-period for the hydrogenation of 1-octene or cyclohexene in alcoholic solution is 3-5 minutes, but these compounds are hydrogenated very slowly in cyclohexane (Fig. 1, e and c).

Fig. 1. Hydrogenation: a) cyclopentadiene; b) cyclopentene; c) cyclohexene; d) tolan; e) 1-octene. In ethanol (△) and in cyclohexane (○).

The same sort of difference is found when initial rates of hydrogenation are compared: in alcohol the rates for cyclohexene and tolan are respectively 12 and 19 times as high as in cyclohexane. The difference in the rates of hydrogenation of cyclopentadiene to cyclopentene in these solvents is not great (Fig. 1, a).

It will be seen from Fig. 2 that the kinetic curves for the hydrogenation of binary mixtures of cyclopentadiene with olefins in cyclohexane are, in general, repeats of the kinetic curve for the hydrogenation of cyclopentadiene alone in cyclohexane (Fig. 1, a). It may be supposed that in the hydrogenation of the mixture the steeply falling section of the curve again represents hydrogenation of cyclopentadiene to cyclopentene. The horizontal part of the curve represents the hydrogenation of cyclopentene and the second unsaturated component of the mixture. It is, in fact, found that the volume of hydrogen absorbed from the beginning of the reaction to the point of inflection on the kinetic curve is 24-25 ml on the average, which corresponds to 50% of the hydrogen necessary for the conversion of the cyclopentadiene into cyclopentane. Moreover, qualitative tests with hydroquinone in parallel experiments showed that at the time corresponding to the bend cyclopentadiene was absent from the mixture. This indicates the selectivity of the hydrogenation of cyclopentadiene (to cyclopentene) and confirms the correctness of our interpretation of the character of the kinetic curves of the hydrogenation of binary mixtures in cyclohexane. The character of the kinetic curves for the hydrogenation of binary mixtures in ethanol is such that it is impossible to infer that addition of hydrogen to the individual components of the mixture occurs in a stepwise manner (Fig. 2). It was shown by the hydroquinone reaction that, in alcoholic solution also, cyclopentadiene is absent from the solution after 50% of the hydrogen theoretically necessary for the conversion of cyclopentadiene into cyclopentane has been consumed.

In another series of experiments the second unsaturated component was at first hydrogenated in cyclohexane or alcohol and, after a few minutes, 0.00095 mole of cyclopentadiene was introduced into the flask in the appropriate solvent (5 ml) and hydrogenation was continued. It will be seen from Fig. 3 that, in both solvents, the rate of absorption of hydrogen rises sharply after the addition of cyclopentadiene. In ethanolic solution the

* Counted from moment of introducing cyclopentadiene.

initial rate of addition of hydrogen (maximum point on kinetic curve) after the introduction of cyclopentadiene greatly exceeds the initial rate of hydrogenation of the second unsaturated component of the mixture. In cyclohexane the initial rate of addition of hydrogen after the introduction of cyclopentadiene is close to the initial rate of hydrogenation of cyclopentadiene in this solvent. During hydrogenation in cyclohexane the consumption of hydrogen from the moment of introducing cyclopentadiene to the bend on the kinetic curve (about 25 ml) represents about 50% of the hydrogen necessary for the hydrogenation of cyclopentadiene to cyclopentane. Hence, from the moment at which cyclopentadiene is introduced into the reaction mixture hydrogenation of the second unsaturated hydrocarbon comes to a stop until the whole of the cyclopentadiene has been converted into cyclopentene.

Fig. 4. Hydrogenation: a) cyclopentadiene; b) piperylene; c) styrene; d) heptyne.

The results show that, both in cyclohexane and in alcohol, cyclopentadiene displaces cyclopentene, cyclohexene, 1-octene, and tolan from the surface of a nickel catalyst. In the binary mixtures that we have studied, at first cyclopentadiene is selectively hydrogenated to cyclopentene, and only when this process is complete does hydrogen begin to add to other unsaturated hydrocarbons.

Hydrogenation of Cyclopentadiene in Binary Mixtures with Piperylene, 1-Heptyne and Styrene. The experimental conditions are shown in Table 2. Figure 4 gives the kinetic curves for the time-dependence of the rate of absorption of hydrogen in the hydrogenation of single unsaturated components; Figure 5 gives the curves for mixtures of these with cyclopentadiene in cyclohexane. It will be seen from Fig. 4 and Table 2 that, unlike the previously investigated unsaturated hydrocarbons (above), piperylene, styrene, and 1-heptyne are rapidly hydrogenated, even in a cyclohexane medium. The half-periods for complete hydrogenation of these compounds are 3, 3.5, and 8 minutes, respectively.

In its general features, the curve for the hydrogenation of piperylene (Fig. 4, b) repeats the curve for the hydrogenation of cyclopentadiene (Fig. 4, a). It also has a bend corresponding to the addition of about 50% of the hydrogen necessary for the complete saturation of the piperylene. The bend on the kinetic curve for the hydrogenation of 1-heptyne is less clearly marked. The rate of absorption of hydrogen in the hydrogenation of a mixture is less than the rate of addition of hydrogen to cyclopentadiene and greater than the rate of hydrogenation of the second component of the binary mixture taken.

The character of the kinetic curves for the hydrogenation of binary mixtures of cyclopentadiene with 1-heptyne (Fig. 5, c) and with styrene (Fig. 5, b) in cyclohexane does not enable us to infer that the addition of hydrogen to the individual components of the mixture proceeds in stepwise fashion. Experiments were, therefore, carried out in which test samples were taken at the moment when hydrogen had been consumed in an amount equivalent to that required to convert the cyclopentadiene present into cyclopentene and were tested for the presence of cyclopentadiene with hydroquinone. It was first established by special experiments that the other unsaturated hydrocarbons under investigation did not interfere in the detection of cyclopentadiene by this method. It was found that, at the stated moment of hydrogenation in cyclohexane, cyclopentadiene was still present in all three mixtures; in the mixtures with styrene, piperylene, and 1-heptyne it was detected after the consumption of 114.6, 134.2 and 135% of the hydrogen required for the conversion of cyclopentadiene into cyclopentene. These results show that, in binary mixtures, hydrogenation of cyclopentadiene is accompanied

by simultaneous hydrogenation of styrene, piperylene and 1-heptyne.

Fig. 5. Hydrogenation of binary mixtures of cyclopentadiene: a) with piperylene; b) with styrene; c) with 1-heptyne.

Figure 6 represents the results of experiments in which cyclopentadiene (0.00095 mole) was introduced into the flask 5-10 minutes after the beginning of the hydrogenation of the second component (styrene, piperylene, or 1-heptyne). These experiments were undertaken on the view that, if the unsaturated hydrocarbon of the binary mixture in cyclohexane was hydrogenated simultaneously with cyclopentadiene, then the consumption of hydrogen between the point of addition of cyclopentadiene and the bend should be appreciably higher

Fig. 6. Hydrogenation with addition of cyclopentadiene: a) piperylene; b) styrene; c) 1-heptyne.

than that which corresponds to the selective hydrogenation of cyclopentadiene alone (to cyclopentene).

It will be seen from Fig. 6 and Table 2 that the hydrogen consumption between the point of addition of cyclopentadiene and the bend is indeed appreciably higher than the amount necessary for the hydrogenation of cyclopentadiene to cyclopentene. In the experiment with 1-heptyne, cyclopentadiene was added after the consumption of about 50% of the hydrogen required to convert it into 1-heptene. In this case the consumption of hydrogen between the moment of introducing cyclopentadiene and the bend corresponds almost exactly to the amount necessary for the hydrogenation of cyclopentadiene to cyclopentene. Hence, in binary mixtures with piperylene, 1-heptyne, and styrene in a cyclohexane medium, cyclopentadiene is hydrogenated nonselectively in presence of Raney nickel.

SUMMARY

1. An investigation was made into the hydrogenation of cyclopentadiene in binary mixtures with other unsaturated hydrocarbons in presence of a Raney nickel catalyst.

2. It was shown that, in an alcohol medium, all the investigated unsaturated hydrocarbons combine with hydrogen considerably more rapidly than in a cyclohexane medium. Cyclohexene, cyclopentene, 1-octene, and tolan are hydrogenated particularly slowly in a hydrocarbon medium.

3. It was found that, both in alcohol and in cyclohexane, in mixtures of cyclopentadiene with cyclopentene, cyclohexene, 1-octene, and tolan, only the cyclopentadiene is hydrogenated at first (to cyclopentene); only when this process is complete does hydrogen begin to add to the second component of the binary mixture. This selectivity of hydrogenation may be explained by adsorptional displacement of unsaturated hydrocarbons from the catalyst surface by cyclopentadiene.

4. In its binary mixtures with piperylene, 1-heptyne, and styrene, cyclopentadiene is hydrogenated nonselectively, i. e., cyclopentadiene itself suffers partial adsorptional displacement.

DETERMINATION OF FLUORINE IN SILICATES

Yu. V. Morachevsky and E. N. Egorova

There is extensive literature on the determination of fluorine. We shall consider briefly the principal ways in which the problem of determining fluorine in silicates has been solved.

Fusion with sodium carbonate or other alkaline fusion agent is a widely used method for the digestion of the sample – it may, in fact, be the only method for silicates that are not decomposed by acids, irrespective of the analytical procedure selected for the final determination of fluorine. The melt is leached with water, and fluorine passes into solution in the form of sodium fluoride. The further treatment of the solution depends on the method selected for the determination of fluorine. The oldest method, which was developed by Berzelius [1] and by Rose [2] and was for a long time the only method for the determination of fluorine in silicates, requires a cycle of operations aiming at the complete removal of silicic acid and aluminum from alkaline and neutral solutions, fluorine then being isolated and weighed in the form of calcium fluoride.

The method is well known and is described in several treatises [3-6]. We must point out that the method is complicated and lengthy and, according to several investigators [7-11] and also according to our own observations, it gives somewhat low results; at low fluorine contents the results are not very reliable.

Another gravimetric method for the determination of fluorine – precipitation in the form of lead "fluorochloride" – was proposed by Starck [12]. The conditions of separating the precipitate were studied and more accurately defined by many investigators [10, 13-16]. It was established that lead fluorochloride is a compound of definite composition [17, 18]. Determination of the fluorine content can be carried out also by an indirect volumetric method – titration of the chlorine present in the precipitate [10].

Hoffmann and Lundell [9] proposed the use of this method for the determination of fluorine in silicates. They investigated the effect of silicic acid, aluminum, boron, alkali and ammonium salts, and other compounds on the completeness of the precipitation of lead fluorochloride. For the simultaneous determination of silica and fluorine it is recommended that silicic acid and aluminum be removed completely by precipitation with a zinc salt and ammoniacal zinc oxide. However, for the determination of fluorine only (without simultaneous determination of silica) the authors confine themselves to the separation of components interfering in the determination of fluorine by treatment with a solution of a zinc salt in sodium carbonate solution. This treatment does not ensure the complete removal of silicic acid and aluminum. Some variants of this procedure for the treatment of the solution before precipitation of lead fluorochloride do not generally require the separation of silicic acid and aluminum [10, 19]. These variants provide considerably simpler procedures for the determination of fluorine in silicates; it was important to determine the extent to which this simplification affects the accuracy of the estimation.

The determination of fluorine by separation in the form of PbFCl is applicable only when the fluorine content of the material to be analyzed is relatively high. Various variants of the indirect colorimetric determination of fluorine in silicates have been proposed for low fluorine contents. However the colorimetric determination of fluorine in silicates may be carried out, it is necessary to perform several preparatory operations, beginning generally with fusion of the silicate with sodium carbonate and aqueous extraction of the melt. It is recommended that interfering components should then be removed. For the separation of most of the silicic acid and aluminum the procedure proposed by Berzelius – treatment of the alkaline extract with ammonium carbonate – may be used. As applied to preparation of a sample for colorimetric determination of fluorine,

this method is described by Babko and Pilipenko [20]. One method for the colorimetric determination of fluorine is based on the change in the red color of the zirconium lake of alizarin in presence of fluorine. There are no references in the literature to the effect of the silicic acid remaining in the solution on the results of the colorimetric determination of fluorine with the aid of the zirconium lake of alizarin.

The various advantages of the colorimetric method of determining fluorine when the fluorine content is low prompted us to make a more detailed investigation of the conditions of applying this method to silicates.

A special group of methods is based on removal of fluorine by distillation in the form of volatile compounds – silicon tetrafluoride [21] and hydrofluosilicic acid [22]. The distillation method was first proposed for the determination of fluorine in fluorides; it is of limited application in the analysis of silicates, since most natural and synthetic silicates are not decomposed by acids or are decomposed incompletely. For silicates that are not decomposed by acids preliminary digestion with an alkaline fusion agent is necessary. In both cases colloidal silicic acid is bound to be formed when the solution is acidified. However, investigation of the elimination of the fluorine as hydrofluosilicic acid showed that the presence of a gel of silicic acid and alumina makes the elimination of fluorine incomplete [23-25].

For the determination of fluorine in silicates various methods have been proposed recently in which the silicate sample is prepared for analysis by fusion and separation of most of the silicic acid and aluminum before driving off the fluorine. This is attained either by fusion of the silicate with zinc oxide and sodium carbonate and leaching of the melt with water [25, 26] or fusion with sodium peroxide, dissolution of the melt in water and precipiatation of most of the silicic acid and aluminum with the aid of a zinc salt [27]. The authors consider that the precipitate contains a negligible amount of fluorine [25] or contains none at all [26, 27].

In the distillation method various methods for the determination of the fluorine in the distillate may be used; it is very usual to titrate the fluorine in the solution with thorium nitrate solution, as proposed by Willard and Winter [28] – the zirconium lake of alizarin is used as indicator, the titration being carried out in aqueous-alcoholic solution. Armstrong showed [29] that the presence of zirconium is not essential in titration with thorium nitrate, for the end point can be established also by the formation of the thorium lake of alizarin. The method has been investigated by several workers; particular attention has been paid to the question of the pH of the medium in which the titration is carried out [30-34].

In the present paper we give the results of experiments designed to define more closely the conditions for the colorimetric determination of low concentrations of fluorine in silicates with the aid of the zirconium lake of alizarin – and of large amounts of fluorine by the method of precipitation in the form of lead fluorochloride.

EXPERIMENTAL

Colorimetric Determination of Fluorine in Silicates with the aid of the Zirconium Lake of Alizarin

A weighed amount of the material is fused with four times this amount of a mixture of sodium and potassium carbonates, and the melt is leached with water [20]. Solid ammonium carbonate (2-4 g) is added, and the solution is heated and then evaporated on a water bath until the ammonium carbonate is completely decomposed. The precipitate contains most of the silicic acid and aluminum hydroxide; it is filtered off and washed with water. Fluorine is determined colorimetrically in an aliquot of the acidified filtrate with the aid of the zirconium lake of alizarin.

When ammonium carbonate is added, the pH of the sodium carbonate solution is lowered to 9-9.3. Under these conditions polymerization of silicic acid proceeds at an appreciable rate. With heating, the rate of polymerization increases and a gel of silicic acid finally separates. With further heating until the ammonium carbonate is completely decomposed, the pH of the solution rises somewhat and partial dissolution of the gel occurs; the amount of silicic acid remaining in the solution may therefore be considerable. Our experiments showed that for a 0.38 g sample of silica, the amount remaining in solution after separation of silicic acid by the method described is generally equivalent to 20-30 mg of silica.

The rate at which the color of the zirconium lake of alizarin changes in presence of fluorine increases with increase in the concentration of acid in the solution. It was shown that the maximum color is attained in one hour in 2 N HCl. The colorimetric determination was carried out on 50 ml of solution by the method of standard series. For low fluorine contents – 50γ – standards having a low content of the zirconia-alizarin lake

(5 ml) were used,* and for fluorine contents of greater than 50γ comparison was made with a series of standards having a higher content of the lake (10 ml). In the first series, the standards were at intervals of 5γ, and in the second series — 25γ.

Experiments were carried out with the object of determining the effect of the presence of silicic acid in the solution on the results of the colorimetric determination of fluorine in the solution. We took into account the fact that, as we had shown previously, the silicic acid content may attain 20-30 mg. Various amounts of standard silicic acid solution were introduced into 50 ml standard flasks, each containing 10 ml of sodium carbonate solution (0.6 g of sodium carbonate). The solution was neutralized with dilute hydrochloric acid (1 : 10), 8 ml of concentrated hydrochloric acid (sp. gr. 1.18) was added, and this was followed by 5 ml of the zirconia-alizarin solution. The solution was made up to the mark with distilled water, well mixed, and set aside for one hour. The change in color caused by the presence of silicic acid was compared with a series of standard solutions containing fluorine together with all the other reagents at the same concentrations. The experiments showed that, like fluorine, silicic acid breaks down the zirconia-alizarin lake, probably owing to

Fig. 1.

Fig. 2

the formation of zirconium silicates (Fig. 1). The change in color of the zirconia-alizarin lake in presence of silicic acid may result in high results for fluorine when silicic acid is incompletely removed; fluorine can, however, be determined colorimetrically.

Experiments on the determination of fluorine in solutions containing silicic acid gave the results shown in Fig. 2. When the fluorine content is 5γ, the change in the color of the zirconia-alizarin lake is almost equal to the sum of the effects of the fluorine and the silicic acid; with increase in the fluorine content, the observed color change is less than the summation value, but the amount of fluorine found (for an absolute content of up to 50γ) is nevertheless considerably greater than the actual amount. In the determination of fluorine, therefore, it is necessary to determine silicic acid colorimetrically in an aliquot of the solution and introduce the same amount of silicic acid into the standard solutions.

As already indicated, the determination of fluorine in silicates requires fusion of the sample with sodium carbonate and a series of operations for the removal of silicic acid and alumina. Many investigators [7-10] have shown that, for complete transfer of the fluorine to the aqueous extract of the alkali melt, it is necessary that the silica content of the material to be fused should be sufficiently high; in the analysis of materials poor in silica it is recommended that silica should be added during fusion. However, the relation of the completeness of leaching of fluorine to the contents of silica and alumina — the main components of the silicate — has not been completely determined.

* Preparation of a solution of the zirconia-alizarin lake: 0.87 g of zirconium nitrate is dissolved in 100 ml of water and 0.17 g of sodium alizarinsulfonate is dissolved in 100 ml of water; the zirconium nitrate solution is slowly added with shaking to the alizarinsulfonate solution, and the solution is set aside overnight. For the colorimetric determination the solution is diluted ten times with water.

In the cycle of operations for the removal of silicic acid and alumina, fluorine may be lost. This matter also is insufficiently clear. We carried out special experiments on these two questions: the results are given below.

The first series of experiments established the distribution of fluorine between solution and insoluble residue in the leaching of the melt $Na_2CO_3-CaF_2$ with water; the effect of the amount of sodium carbonate was determined. Calcium fluoride (200 mg) was fused with sodium carbonate, the melt was leached with hot water, and the insoluble residue was filtered off and washed with 0.5% sodium carbonate solution. The volume of the filtrate was made up to 250 ml with distilled water. Fluorine was determined colorimetrically in an aliquot of the solution.

The second series of experiments established the distribution of fluorine between solution and insoluble residue in the leaching of the melt $Na_2CO_3-CaF_2-SiO_2$; the effect of the amount of SiO_2 taken was determined. Special experiments were carried out to determine the distribution of fluorine between the solution and insoluble residue in the leaching of the melt $Na_2CO_3-CaF_2-SiO_2-Al_2O_3$. In these experiments the insoluble residue was further treated by boiling with 50 ml of 2% sodium carbonate solution. When the synthetic mixture contained silica, before the fluorine determination silicic acid was determined colorimetrically and the amounts found were introduced into the standard fluoride solutions. For high fluorine content the colorimetric determination of fluorine is not sufficiently accurate, but the results nevertheless give a clear picture of the distribution of fluorine between solution and residue in its relation to the composition of the material to be analyzed. The results are given in Table 1.

TABLE 1

Experiment	Amount taken				Amount of F Found (mg)		Relative amounts by weight		
	Na_2CO_3 (g)	SiO_2 (mg)	Al_2O_3 (mg)	F (mg) (as CaF_2)	in the solution	in the insoluble residue	$Na_2CO_3 : CaF_2$	$SiO_2 : Al_2O_3$	$SiO_2 : CaF_2$
1	1	—	—	97.4	58.2	39.5	5 : 1	—	—

* The melt was leached with water, and the insoluble residue was treated for ten minutes at the boil with 50 ml of 2% sodium carbonate solution. Fluorine was determined in the combined filtrates.

** The insoluble residue was treated twice with 2% sodium carbonate solution under the same conditions.

In the fusion of calcium fluoride with sodium carbonate and the leaching of the melt with water, the equilibrium $CaF_2 + Na_2CO_3 \rightleftharpoons CaCO_3 + 2NaF$ was established. As Experiments 1-3 showed, fusion even with a large excess of sodium carbonate (30 : 1) does not result in complete transfer of fluorine into the solution during the leaching of the melt. Increase in the completeness of the extraction of fluorine may be attained by repeated treatment of the insoluble residue with sodium carbonate solution (Experiments 4 and 5). It is known that

introduction of silica during fusion results in complete transfer of fluorine to the solution in the leaching of the melt; it is generally recommended that the weight of silica be 2.5-3 times that of calcium fluoride. Our results showed that the amount of silica can be considerably less: when the insoluble residue is given a supplementary treatment with sodium carbonate solution, a ratio of $SiO_2 : CaF_2$ of 1 : 20 by weight ensures complete passage of fluorine into solution. In presence of alumina, even a large excess of silica and supplementary treatment of the insoluble residue are insufficient to ensure complete transfer of fluorine to the solution (Experiments 11 and 13). As our results show, the amount of silica ensuring complete transfer of fluorine to the solution in the fusion of samples containing alumina is determined by the weight ratio $SiO_2 : Al_2O_3$. Almost complete transfer of fluorine to the solution is attained when the silica content is equal to or greater than the alumina content; the insoluble residue from the aqueous extraction must be treated with sodium carbonate solution (Experiments 12 and 14).

Special experiments were devoted to the study of the behavior of fluorine in the process of separating silicic acid and alumina by means of ammonium carbonate, the weight ratio $SiO_2 : Al_2O_3$ being varied in the material to be analyzed. The results are given in Table 2.

TABLE 2

Experiment	Amount taken (mg)			Weight ratio $SiO_2 : Al_2O_3$	F found (mg)
	F as CaF_2	SiO_2	Al_2O_3		
1	9.74	450	50	9 : 1	9.75

17	9.0	30	470	1 : 16	6.9
18	9.0	—	500	—	6.9

It will be seen from these results that the precipitates contain almost no fluorine when the silica content of the material to be analyzed is higher than the alumina content. For the inverse proportions, part of the fluorine is retained by the precipitate: the higher the alumina content, the worse the results. As the silica content of most natural silicate minerals and rocks is higher than the alumina content, addition of silica during fusion is unnecessary. Moreover, the high silicic acid content of the solution would complicate the colorimetric determination of fluorine.

Our proposed variant of the procedure for determining fluorine, in which silicic acid is first determined colorimetrically, enables us not only to determine the fluorine content more accurately, but also to determine the silica content simultaneously. Silica is determined by the usual methods in the precipitates, and to the silica content found is added the silica content of the solution, which is determined colorimetrically.

Determination of Fluorine by Precipitation as Lead Fluorochloride

In the separation of PbFCl, the solution must not contain aluminum. There are no direct references in the literature to the effect of silicic acid on the precipitation of lead fluorochloride: it is stated only that, in the volumetric method, small amounts of silica have no effect, but the precipitate is difficult to filter when the silica content is higher than 50 mg.

Experiments on synthetic solutions enabled us to reach the following conclusions: 1) presence of silicic acid retards the separation of the lead fluorochloride precipitate, and at a silica content of more than 50 mg complete separation is not attained even after 15 hours of settling; 2) presence of alumina in an amount of 3-4 mg results in the nonprecipitation of about 1 mg of fluorine.

Experiment showed, therefore, that the solution prepared for the precipitation of lead fluorochloride must be free from aluminum, whereas silicic acid may be present in an amount not exceeding 50 mg of SiO_2. By Berzelius's method, complete removal of alumina and silicic acid is attained by two precipitations from the solution obtained by leaching the alkali melt. The first precipitation of the bulk of the silicic acid and alumina is effected by means of ammonium carbonate from a sodium carbonate solution, and the second is effected by means of ammoniacal zinc oxide. When the fluorine content is high, it is recommended that it should be further extracted from all the precipitates separated.

With the object of shortening the operation of preparing the solution, we carried out experiments on the separation of the alumina and the bulk of the silicic acid with the aid of ammonium carbonate from an alkaline extract of the melt, which was first neutralized to Methyl orange with nitric acid. The filtrate was investigated for completeness of separation of alumina: in all experiments 6-8 mg of aluminum was found in it. It must be pointed out that, in the preparation of the solution in the way recommended by Berzelius, and also by Hoffmann and Lundell, complete separation of the aluminum is again not attained. Thus, in the analysis of a mixture of aluminosilicates and calcium fluoride (present in large amount), the aluminum content of the solution was 3-4 mg of Al_2O_3.

In other experiments on material of high fluorine content we investigated the distribution of fluorine between solution and precipitate, the latter being formed by the above-described simplified method. Fluorine was determined in the solution by precipitation of lead fluorochloride; an aliquot of the solution was taken, the volume being chosen so that the aluminum content was not greater than 3 mg of Al_2O_3. As indicated above, such an aluminum content is associated with some incompleteness of precipitation of fluorine, but when the total content is high the error is relatively small. Fluorine was determined in the combined precipitates by the colorimetric method. The results of these experiments are give in Table 3.

TABLE 3

Experiment	Amount taken (mg)			Amount found (mg)			Error of determination (mg)
	SiO_2	Al_2O_3	F as CaF_2	in soln. (volumetric)	in ppts. (colorimetric)	total	
1	250	250	97.4	20.9	—	—	—
2	650	350	97.4	76.5	—	—	—
3	350	150	97.4	90.7	6.1	96.8	—0.6
				91.2	6.1	97.3	—0.1
4	437	190	97.4	88.6	7.35	95.95	1.45
				89.8	6.1	95.90	—1.5

				39.07	7.35	46.42	—2.28
9	500	160	97.4	89.4	7.35	96.75	—0.65
				88.2	8.2	96.4	—1.0
10	1150	350	97.4	89.4	7.5	96.9	—0.5
				89.4	7.5	96.9	—0.5

As will be seen from the data in Table 3, in the rapid variant for the preparation of the solution which we have proposed, the precipitates entrain more fluorine than under the generally recommended conditions. The entrainment of fluorine by the precipitates diminishes as the weight ratio $SiO_2:Al_2O_3$ increases. When this ratio becomes greater than 2:1, the amount of fluorine entrained by the precipitate becomes constant and does not change substantially with further increase in the silica content.

The fluorine content of the precipitates lies within the limits within which colorimetric determination is possible. The total content of fluorine, as established by volumetric determination (PbFCl) in the solution and by colorimetric determination in the precipitates, can be regarded as sufficiently accurate at high fluorine contents. The results are somewhat low, which can be readily explained by slight incompleteness of the precipitation of lead fluorochloride owing to incomplete separation of alumina. We consider that the proposed simplified variant of the procedure, which considerably reduces the time required for the analysis, can be recommended for the routine analysis of silicate materials rich in fluorides.

SUMMARY

1. It was shown that silicic acid interferes in the colorimetric determination of fluorine by the zirconia-alizarin method by combining with zirconium and reducing the red component of the color. In order to avoid error it is proposed to determine silicic acid colorimetrically in an aliquot of the solution and introduce the amount so found into the standard fluoride solutions.

2. A study was made of the conditions under which fluorine passes into solution in the process of fusing the material with sodium carbonate and then leaching the melt with water. It was shown that, in absence of silica and alumina in the material to be analyzed (e. g., CaF_2), complete extraction of fluorine can be attained by addition of a very small amount of silica — very much less than is usually recommended.

3. The conditions for the separation of fluorine in the form of lead fluorochloride were investigated. It was shown that the separation of the precipitate is retarded by the presence of silicic acid in the solution, and the precipitation of fluorine is incomplete when the silica content is high.

4. A variant of the procedure for the determination of high fluorine contents in silicate materials is proposed: the preparation of the solution is simplified, and fluorine is determined as the sum of the amount found volumetrically in the solution and the amount found colorimetrically in the precipitates.

PHYSICAL BASIS OF THE REACTIVITY OF CARBONYL COMPOUNDS

M. I. Batuev

1. Butlerov, as also Markovnikov, imagined a molecule as an actually existing dynamic spatial system of atoms which are in constant motion and are bound together by affinity forces. According to the ideas of Butlerov and Markovnikov, in a molecule, "we always have a certain state of dynamic equilibrium" [1] established as a result of "the combined effects of all the chemical and physical influences" [2], which, in principle, cannot be isolated from one another. However, Butlerov and Markovnikov saw that the physics of that time was not sufficiently advanced to participate with chemistry in the development of a unified physicochemical theory of the structure and reactivity of a molecule; they regarded this as a problem of "the future dynamic theory of chemistry" [3]. With regard to the chemical theory of their time they wrote that, in its creation and development, " we may as yet discuss only chemical effects, as being best known to us" [4]. Being compelled to accept this temporary isolation of the chemical aspect of his theory from the physical aspect, Butlerov, in the creation and development of this theory, consciously tried to reflect this fact even in his terminology [5]; he spoke of the theory of chemical structure, having as its object the establishment of "the distribution of the chemical bond between atoms" [6] and the determination of "the order of a chemical bond existing between atoms in a 'particle' " [7] and its representation in a single structural formula for a given molecule under given conditions [8], and so on.

In physics, great advances have now been made in our knowledge of the structure of the individual molecule as a dynamic spatial system of interacting atoms which is in a definite state of dynamic equilibrium under given conditions. However, the development (particularly during the twenties and thirties) of the physicochemical theory of the structure and reactivity of a molecule — which has proceeded in various directions associated in various degrees with sound theoretical and experimental foundations — is still far from attaining a generally recognized state of finality as regards the basic underlying principles. This position is partly attributable to substantial experimental difficulties, which still exist, in the detailed examination of an individual molecule with all the specific characteristics of the physical states of the individual bonds.

Actually, experimental determinations of quantitites of such great importance for the theory as dipole moment (polarity), polarizability (displaceability of the electronic envelope), and others refer to the molecule as a whole, and not to its individual bonds. Such important quantitites as bond energy and interatomic distances, especially for bonds containing a hydrogen atom, have been determined insufficiently accurately for the purpose of the theory and generally for conditions removed from the specific conditions in individual molecules; the values obtained have then been assigned to bonds of the same sort (e. g., C—H) in molecules that vary greatly in composition and structure.

This substantial gap in our knowledge of the individual molecule forces the theorist to have recourse to hypothetic assumptions and calculations regarding the polarity of individual bonds in a given individual molecule, the character and degree of their polarizability in the form of various "mechanisms" of electron displacement, the variation in the electron density of bonds,* bond energies, interatomic distances, etc., and moreover,

* The distribution of electron density in a molecule may be extremely nonuniform; for example, in a shortened (under the influence of neighboring atoms and other structural factors) C—H bond, the binding electrons of the outer electron shells of these atoms, which are in constant orbital motion, carry out their motions in a smaller volume and have a higher effective density than in a lengthened C—H bond, etc.

these suppositions are often arbitrary and without experimental foundation.

There naturally arises a question of great importance: from the arsenal of experimentally determined physical parameters of a molecule to select those which can directly characterize with adequate accuracy the specific physical state of individual bonds in the individual molecule as a dynamic self-equilibrating spatial nucleus-electron system; for it is just this sort of experimental data that is now necessary for the further development of the theory of structure and the understanding of the principles underlying the reactivities of individual substances.

Taking a clear example, in which we shall make comparisons of relevant physical and chemical data for a given bond, we shall first show the dependence of the chemical nature of this bond on its physical condition as expressed by experimentally determined parameters.

2. One of the clearest examples of the manifestation of physical, and the associated chemical, interaction between atoms in a molecule is found in the great variation in the chemical and physical nature of a hydrogen atom according as it occurs in a hydroxyl such as is found in a strong acid, e. g., oxalic acid, or in a hydroxyl such as the OH^- ion. In the first case the interatomic distance $\underline{r}$ in the O—H bond is much greater than normal, the proton of the hydrogen atom being almost freed from the dynamic orbital-electron system of the hydroxyl, i.e., the hydrogen atom is almost completely "protonized." In this sense we may speak also of the protonization of the O—H bond as a particular case of very marked polarity of a bond containing a hydrogen atom. The electron density of such a bond is greatly reduced.* The initiation of various reactions in which the hydroxyl group participates arises, in the case under examination, mainly from this protonized or almost protonized hydrogen atom $(R\dot{\ddot{O}}\dot{x})\overset{\cdot\cdot}{\rceil}H^+$. Furthermore, for such a hydroxyl, the bond energy E and the vibrational frequency ν are much below normal. In the second case, on the other hand, the interatomic distance $\underline{r}$ is much less than normal: the proton of the hydrogen atom is, as it were, deeply drawn into the dynamic electron system of the hydroxyl ion $(\dot{x}\ \ddot{O}H\dot{x})^-$, the electron orbits overlap greatly. In this sense we may speak of the electronization of the O—H bond; in the given case this bond has enhanced electron density. The initiation of various reactions with the hydroxyl now arises mainly from electrons of the outer electron shell of the hydroxyl ion. Also, the bond energy E and the vibrational frequency ν of such a hydroxyl are much higher than normal.

The concept of the protonization of a bond, as is not difficult to see, is one of the limiting cases of its electronization when this is greatly depressed in bonds of the type X—H (X = O, F, etc).

The range of variation of the above-mentioned three physical parameters of the hydroxyl group is very considerable, particularly for ν and E (Table 1) [9].

TABLE 1

Vibrational Frequencies ν, Bond Energies E, and Interatomic Distances $\underline{r}$ for the Hydroxyl Groups of Various Compounds.

Compound	ν (cm^{-1})	E (kcal/mole)	r (A)
Oxalic acid (β form, crystalline)	2500	51	1.147
OH radical	3480	100	0.971
Methanol (gas)	3683	112	0.960
OH^- ion	4200	145	0.906

* With regard to this concept see the preceding footnote.

As will be seen, a definite change in the chemical nature of the O—H bond from strongly acidic (RO^-H^+) to strongly ionic (OH^-) stands in strict relationship with change in its physical state, as characterized by the three selected physical parameters; the directions of the changes correspond strictly. This correlation in the directions of changes in ν, E, and r for bonds having characteristic frequencies (O—H, C—H, etc.) is confirmed without exception by extensive experimental material. In this connection it should be noted that, as the range of change of vibrational frequencies is greater than for the other two parameters and as vibrational frequencies can be more readily and accurately determined experimentally (optically) than bond energies and interatomic distances, for bonds having characteristic vibrational frequencies (it is essential not to lose sight of this condition) the direction and magnitude of changes in all three parameters can be assessed from the direction and magnitude of the change in vibrational frequency.

From this discussion it will be seen that the parameters ν, E, and r must not be regarded as being primary physical factors determining the chemical nature of a molecule and its reactivity. The primary physical factors are electron-neucleus interactions in the molecule, as a nucleus-electron system in a state of dynamic equilibrium. It is this interaction that is suitably expressed and manifested in our selected bond parameters — mechanical ν, energetic E, and geometric r — so that by the strictly interrelated changes in these parameters in characteristic bonds we may form an idea of the physical state of the latter — of the electron-nucleus interaction in them, of change in their electron density,* etc. The concept of the electronization of a characteristic bond determined through its parameters ν, E, r in their strict interrelationship is an exact characterization, far-reaching in its concreteness, of the physical state of a bond as an element of a dynamic self-equilibrating nucleus-electron system; moreover, in this way it is possible to learn fine details concerning the physical state of individual bonds,** which are generally inaccessible*** for other methods.

3. We have now discussed the interrelationship between the physical parameters ν, E, and r and the chemical nature of the O—H bond. However, if the partner of hydrogen in the bond is an atom other than oxygen, then the phenomena of protonization and electronization may proceed somewhat differently.

Owing to the extremely high Gordy electronegativity of the oxygen atom (3.45) as compared with that of the hydrogen atom (2.13), in no known compound does the oxygen atom give electrons to the hydrogen atom under normal conditions, i. e., no compounds are known in which the limiting distribution of electrons in the O—H bond is of the form RO^+/H^-. Owing to this relationship of electronegativities, the oxygen atom, in drawing the dynamic orbital-electron system of the hydroxyl bond to itself, either in some measure frees the hydrogen atom from the system as a proton (since the latter together with electrons cannot approach closely to an oxygen atom owing to the repulsive forces that arise and rapidly increase at short interatomic distances), or, in another type of compounds, separates from the residue of the molecule together with a hydrogen atom in the form of an OH radical or OH^- ion.

In compounds in which hydrogen is attached to other atoms, the range of variation of the parameters of the X—H bonds (X = C, N, halogen, etc.) in the direction of the protonization or electronization of the hydrogen atom is substantially different from that found in the O—H bond. The extreme limits of the dynamic change in the orbital-electron system may be different. In the C—H bond, for example, this range is considerably narrower than in the O—H bond. Under the usual conditions we are not concerned with the formation of the $(CH)^-$ ion in RCH (R is the residue of the molecule) because of the smaller difference between the electronegativities of C (2.55) and H (2.13), as compared with the difference between O (3.43) and H (2.13), and also the firmness of the binding of the C atom to the residue of the molecule by three valencies, and not one as in the

---

* See Preceding footnotes.

** For example: data on symmetrical and antisymmetrical vibrations of C—H bonds. A relevant matter in this connection is the question of the correlation between the limits of electronization of a bond and its physical nature; we shall not discuss this in detail in this paper.

*** For example: for the topographical aspect of the determination of electron density in the x-ray structure analysis of crystals by the Fourier method, which is limited in scope and can provide comparatively little information on the properties of individual characteristic bonds of the X—H type (X = C, O, etc.) and on their reactivity in individual molecules.

case of the oxygen of the hydroxyl group, etc. In the C—H and Si—H bonds (owing to the fact that the electronegativity of the carbon atom is only slightly greater than that of the hydrogen atom, and the electronegativity of the silicon atom (1.8) is even less than that of carbon), no "creeping" of the electron shell from the hydrogen atom, due to the effect of neighboring strongly electronegative atoms in themolecule, etc., occurs; it is attracted together with the proton, and this occurs all the more because the "reserves" of interatomic distance (unlike those in O—H and F—H bonds, which are greatly shortened) are considerable in C—H and Si—H bonds, i. e., repulsive forces do not hinder the attraction of the proton.

An illuminating example is to be found in the growing protonization of the O—H bond and growing electronization of the C—H bonds in the series acetic, monochloroacetic, dichloroacetic and trichloroacetic acids. As is well known, in this series the acid dissociation constant of the O—H bond increases sharply (i. e., the vibrational frequency and bond energy fall, and the interatomic distance increases); on the other hand, the C—H bond is electronized, as indicated by rise in vibrational frequency (and consequently rise in bond energy and reduction in the interatomic distance) (Table 2 [10]).

TABLE 2

Vibrational Frequencies of Acetic and Chloroacetic Acids and Other Compounds (cm^{-1})

C—H of CH_3				C—H of CH_2			Methylidyne C—H	
Compound	ν			Compound	ν		Compound	ν

CH_3 of n-paraffins	2879s	2938a	2967a	CH_2 of n-paraffins	2853	2908a	Methylidyne of hydrocarbons	2870
Rise	+21	+3	+23	Rise	+107	+94	Rise	+148

* s— symmetrical vibration; ** a— antisymmetrical vibration.

4. It is natural to extend the concept of greater or lesser electronization — determined by the relative values of the parameters ν, E, and r as characterized above — to the characteristic bond C = O, as also the multiple CC bonds, etc. Increase in the electronization of these bonds is expressed, as in OH, CH and other bonds, in rise in vibrational frequencies and energies, and reduction in interatomic distances; reduction in electronization is expressed in the opposite changes in these parameters, as will be seen from Tables 3 and 4.

TABLE 3

Parameters ν, E, and r in Single and Multiple CC Bonds

Bond	Compound	ν (cm^{-1}) [10a]	E* (kcal/mole [11])	r (A)
C—C	C_2H_6	992	83	1.543
C=C	C_2H_4	1621	110	1.353
C≡C	C_2H_2	1974	145	1.207

* The heat of sublimation of carbon is taken as 138 kcal/mole [11].

Although change in the multiplicity of the bond causes a sudden change in the state of electronization of the bond and its neighbors (see Tables 3 and 4), the mutual effects of atoms in the molecule smooth out these sudden transitions in the sense that, as a result of these interactions, a double bond may, in its parameters, pass

through all intermediate stages and approach the region of the triple bond; in the course of these changes the chemical nature of the bond changes correspondingly.

All the above discussion indicates that the concept of the electronization of a bond, determined through the parameters ν, E, and $\underline{r}$, permits experimental investigation of electron-nucleus interactions occurring in characteristic bonds and changes of electron density in these bonds due to mutual effects of atoms in the molecule and the structure of the molecule, etc., and it thus enables us to reveal experimentally the physical states in which the molecule reacts in various reactions, showing various reactivities; it enables us to determine whether various hypotheses regarding the displacements of electrons in bonds are in accordance with actuality.

There are two points that we wish to emphasize: 1) increase in bond energy due to increased electronization of the bond implies strengthening of the bond against rupture, but it may be accompanied (on attainment of a certain limit of electronization) by increased reactivity of atoms of this bond, i.e., by chemical instability; 2) it is, of course, impossible to consider the phenomena of electronization and protonization of bonds as factors in reactivity divorced from other factors (chemical structure of other reactants, geometry of the molecule, reaction conditions, etc.), but only in their mutual relationship with these factors.

TABLE 4

Parameters ν, E, and $\underline{r}$ of C = O Bonds in Various Compounds

No.	Substance	Formula	ν (cm^{-1}) [12]	E (kcal/mole) [13]	r (A) [13]
I	Carbon monoxide (for comparison)	CO*	2155	211	1,128
II 1	Ketene	$H_2C{=}C{=}O$	2049	(206)	1.17
II 2	Phosgene	$Cl_2C{=}O$	1808	(192)	1.18
II 3	Formaldehyde	$H_2C{=}O$	1744	190	1.21
II 4	Acetaldehyde	CH_3-CHO	1720	184	1.22
II 5	Acetone	$CH_3-CO-CH_3$	1707	(183)	—
II 6	Oxoctenol***	$(H_3C)_3C-C(=O)-CH(-O-H)-C(CH_3)_3$	1692	(182)	—
II 7	Acetic acid (dimer)	$H_3CC(=O)-O\cdots H-O-C(=O)CH_3$	1668	(180)	1.25
III	C–O bond in CH_3-OH (for comparison)	CH_3-OH	1033	86.5	1.44

* Langmuir, Herzberg and other authors speak of an approach to a triple bond in carbon monoxide [14, 15].

** The heat of sublimation of carbon is taken as 190 kcal/mole [13]. The figures in parentheses are estimates made from the curve for the relation of vibration frequency to bond energy.

*** 4-Hydroxy-2,2,4-trimethyl-3-pentanone.

5. The hypothesis of electron displacement in a carbonyl group as the physical basis of the reactivity of the group in carbonyl compounds [16] is very widely adopted at present: "Addition reactions in this group of substances are controlled by the electron shift $C\overset{\curvearrowright}{=}O$, and the displacement determines the orientation of the adding molecule unequivocally," for example, [17]:

Such a displacement of electrons in a carbonyl group is explained in two ways on a hypothetical basis: 1) on the basis of the hypothesis of a possible inductional shift of valency electrons in the C = O bonds in the direction of the oxygen atom because of its higher positive charge (+6), as compared with the charge of the carbon atom (+4), i.e., on the basis of the hypothesis of the existence of a —I effect on the oxygen atom [18]; 2) on the hypothesis of the presence of a tautomeric effect —T in the carbonyl group, i.e., a tendency for the doubly bonded oxygen atom to reduce its valence, a process which, if it went to completion, would result in the formation of a semipolar bond $\overset{+}{C}—\overline{O}$ in the carbonyl group [19].*

Even the authors of this hypothesis speak of the inseparability of the actions of these two supposed effects in the carbonyl group [21], confining themselves to a graphical representation of the electron shift in the C = O bond in the form $>C\overset{\frown}{=}O$, $>\overset{+\delta}{C}—\overset{-\delta}{O}$, $>\overset{+}{C}—\overline{O}$ etc. and referring to partial polarization of the C = O group [22] and so on. The authors of the hypothesis do not cite any direct physical experiment in support of the described hypothetical electron shift in the carbonyl group (by the —I or —T mechanism); until quite recently they have regarded the physical side of the matter on a purely hypothetical plane.

However, in the light of our discussion above, direct verification of the hypothesis is quite possible, and we shall now discuss this question.

6. According to the hypothesis under examination, the oxygen atom of a carbonyl group to a certain extent plays the same part in relation to the carbon atom as it plays in the hydroxyl group in relation to the hydrogen atom, i.e., it again draws electrons from its partner along the bond and makes this partner (C) in some degree positive. The characteristic bond C = O, being on this hypothesis more polar on account of the —I effect (or less covalent on account of the —T effect) than is indiciated by its simple classical formula with two valence lines, must naturally have substantially different dynamic characteristics, expressed by the parameters ν, E, and r from those which it would possess if it remained a simple double bond C = O; i.e., its interatomic distance should be greater, its bond energy and vibrational frequency lower, and its electron density greatly reduced. The double bond, therefore, should be characterized by lower ν and E and greater r (i.e., should be less electronized and have a lower electron density) in $\begin{matrix}H\\H\end{matrix}\!\!>\!C=O$, for example, as compared with $\begin{matrix}H\\H\end{matrix}\!\!>\!C=CH_2$ (the bonds C—H, C = C, and C = O are characteristic); moreover, this should be so not only because of the supposed lowering of the double-bond character in C = O, as compared with C = C (in which there is no basis for such lowering to occur, owing to the symmetry of charges), but also because of the greater mass of the oxygen atom as compared with the mass of the carbon atom. However, in spite of this last fact, the actual picture observed is quite the opposite to that portrayed above:**

	ν(cm^{-1})	E(kcal/mole)	r (A)
$H_2C=CH_2$	1621	110	1.353
$H_2C=O$	1744	149	1.210

* Whereas, according to this hypothesis, the induction effect —I represents a state of permanent electronic strain (an electronic shift), the tautomeric effect —T, when taken to completion, represents the transfer of an electron pair from the C-octet to the O-octet [20].

** See Tables 3 and 4. In the determination of E, the heat of sublimation of carbon was taken to be 138 kcal/mole [11] in both cases. We do not cite the other numerous examples that indicate that, as compared with the C=C bond, the C=O bond is characterized by higher ν and E and lower r.

The rise in μ and E for C = O, as compared with C = C, is very great, as also is the shortening of the interatomic distance: the latter is 11%, i.e., considerably higher (by about 2%) than would have been expected if account were taken only of the somewhat smaller covalent radius of the O atom as compared with that of the carbon atom in single bonds.

These data quite unequivocally indicate that a hypothetical shift of the type $\overset{+}{C}-\overset{-}{O}.\ C=\overset{+\delta}{O}.\ C=\overset{-\delta}{O}$, etc., does not take place in the carbonyl group. The electron-nucleus interactions in the C = O bond resemble not those observed in the O—H bond, but rather those occurring in the C—H bond: under the influence of the difference in electronegativities, the oxygen atom of the carbonyl group does not draw electrons from the C atom (as if by the action of the −I and −T effects of the hypothesis discussed above). In the struggle between C and O for binding electrons there is a compacting of the whole carbonyl bond — the nuclei approach one another and the electron density and electronization of the bond increase. This is possible 1) because of the "reserves" of interatomic distance in the C = O bond of carbonyl compounds* (this can be seen by a comparison with the interatomic distance in carbon monoxide,** see Table 4); 2) because of the inadequate, even though considerable, difference in the electronegativities of C and O; and for other reasons.

Actually, the relative electronegativities of the atoms are:

$$\frac{O}{K} = 4.37; \quad \frac{O}{H} = 1.64; \quad \frac{O}{C} = 1.37; \quad \frac{C}{H} = 1.20.$$

With such ratios of electronegativities, the drawing of the electron shell from the K atom in K^+OH^- is quite understandable. But already in the alcohols the drawing of the electron shell from the hydrogen atom proceeds to an insignificant extent: the acid dissociation constants of alcohols are very small. As is well known, this constant increases greatly in chloro acetic acids, in which the otherwise inadequate ratio of electronegativities $\frac{O}{H} = 1.64$ is increased by a supplementary factor corresponding to the effect of a chlorine atom, which is observed in concrete form in the sharp increase in dissociation constant as we pass from acetic acid to mono-, di-, and trichloroacetic acids. The still lower electronegativity ratio $\frac{O}{C} = 1.37$ in association with the above-mentioned "reserve" in interatomic distance leads not to drawing of electrons from the C atom, but, as in the case of the C—H bond, to compacting of the bond owing to the mutual approach of the nuclei and increase in electron density with, of course, the formation of a certain asymmetry of distribution of the electron density between the C and O atoms (this will arise if only from the fact that the electron shell of the oxygen atom is considerably larger than that of the carbon atom; the electron shell of the oxygen atom, unlike that of the carbon atom, contains electrons that are not concerned in interatomic bonds).

7. We will turn to an examination of the second thesis of the hypothesis under examination. According to this, allegedly owing to the positive character of the carbon atom of the carbonyl group, "the power to add to a carbonyl group is generally possessed only by nucleophilic reagents" [16] and this power is lost together, it is suggested, with reduction in the positive character of the carbon atom of the carbonyl group, when there are corresponding electron shifts in neighboring C—X (X = H, Cl, etc.), as for example, in the series [23]:

---

* As in C—H, as distinct from O—H and F—H, see above: the "reserves" in interatomic distance in the C = O bond do not allow any sharp rise in the repulsive forces to occur.

** The CO molecule is included in Table 4 for comparison. We must point out that the reason for the association of high electronization with a fair degree of chemical inertness in the CO molecule (as in the isoelectronic molecule N_2) must be sought in the similarity of its outer electron shell to the octet of an inert gas; this matter was elucidated by Langmuir [14].

This so-called +T effect is alleged to polarize the C—Cl bond in the direction $\overset{-\delta}{C}-\overset{+\delta}{Cl}$, to protonize the hydrogens of the methyl group, and to produce a sesquipolar bond in the CO of the carboxyl ion. In other words, owing to the donating of electrons by X atoms in the direction of the carbonyl C, the bonds C—Cl and C—H_3 must in some measure become polar and, like C=O, must have lower electron density and lower electronization (owing to −I or −T effects); their dynamic characterization must be marked by lower ν and E and greater r. However, exact experimental data indicate the opposite, as will be seen from Tables 2 and 5 [10]: mutual approach of nuclei and increase in electron density occur, i.e., increased electronization takes place in these bonds. This is unequivocally indicated by the enhanced level of the vibrational frequencies of C—H bonds of methyl and methylidyne groups and of C—Cl bonds in these compounds, and also by the absence of lowered electron density in C=O bonds in acetic acids — on the contrary, the electron density is increased.*

8. Let us turn our attention to some peculiar features of the double bond in C=O, as compared with the double bond in C=C; these confirm the above statements regarding the carbonyl group (see Table 6) [25].

As we pass from No. 4 to No. 1 in a series of compounds containing a C=C bond (Table 6), as indicated in the above discussion, increase of electron density in the bond, mutual approach of nuclei, and increase in bond energy occur. The carbon atoms accumulating in the vicinity, which are equal in electronegativity, do not draw to themselves electrons of the C=C bond: together with these electrons they attract also the nuclei. However, when hydrogen atoms are replaced by atoms that are more electronegative than carbon, namely, chlorine atoms, these already find themselves in a position to draw electrons to themselves: the C=C bond becomes weak and its electrons comparatively labile.

The replacement of one carbon atom of C=C by oxygen, which has high electronegativity (in electronegativity it is exceeded only by fluorine), alters the position greatly. As we have seen, in comparison with the C=C bond the C=O bond is much strengthened and electronized. As we pass along the series of compounds from No. 7 to No. 9 (Table 6), i.e., with replacement of carbon atoms adjacent to C=O by less electronegative hydrogen atoms, the struggle of the carbonyl oxygen for electrons is made easier: together with electrons, the nuclei of C and H atoms are drawn toward it — the whole of the molecule is compacted, electronized. When, however, the hydrogen atoms are replaced by highly electronegative chlorine atoms, in their competition with the very highly electronegative oxygen atom for electrons, these chlorine atoms do not draw electrons away from the oxygen — and neither does the reverse occur: a further compacting of the whole molecule occurs with mutual approach of nuclei, increase in electron density, rise in E and ν, and shortening of r, i.e., increase in the electronization of the C=O bond.**

We must point out that in compounds such as liquid oxoctenol and acetic acid (Table 4) the electronization of the C=O bond is further weakened, as compared with this bond in ketones, owing to the effect of the hydrogen bond $>C=O\cdots H-$; the participation of the carbonyl group of an acid in a hydrogen bond reduces further its reactivity. On the other hand, in systems of the ketene type with their well known extremely high reactivity, the electronization of all the bonds increases sharply, as shown above.

9. The above discussion thows light on the mechanism of reactions of addition to carbonyl compounds, a typical example of which is the reaction mentioned previously:

* Whereas in liquid acetic acid the CO frequencies of the dimer ring and the polymeric chain (in which CO groups occur in the middle and at the end of the chain) lie in the range 1670-1740 cm^{-1} [14], in mono-, di-, and tri-acetic acids they not only do not occur in a lower range, but are in fact found in a somewhat higher range of frequencies [10].

** The described pattern of changes in the double bonds C=C and C=O in Compounds 1-6 and 7-10 (Table 6) emphasizes the characteristic nature of these bonds.

TABLE 5

1. Vibrational Frequencies of Ketene and Other Compounds (cm^{-1})

C=O	C=C	C–H group of CH_2
Ketene 2049 Acetone 1707	Ketene 1895 Ethylene 1621	Ketene 2954, 3015 n-Paraffins 2853, 2908
Increase + 342	Increase + 274	Increase + 99, + 107

2. Vibrational Frequencies of Phosgene, Formaldehyde, and Other Compounds (cm^{-1})

C=O		C–H group of CH_2*	C–Cl group of CCl_2
$Cl_2C=O$ 1808 $(CH_3)_2C=O$ 1707	$H_2C=O$ 1744 $(CH_3)_2C=O$ 1707	$H_2C=O$ 2910c, 2990a CH of n-paraffins 2858s, 2908a	$Cl_2C=O$ 883** Cl_2CH_2 762**
Increase + 101	Increase + 37	Increase + 57 + 82	Increase + 71

3. Vibrational Frequencies of Acetaldehyde, Acetone, and Other Compounds (cm^{-1})

Increase + 13	Increase + 38 + 28 + 48	Increase + 43 + 27 + 39

* s – symmetrical vibration; a – antisymmetrical vibration.

** Only the frequency of the antisymmetrical vibration is given.

The strongly electronized carbonyl bond increases the polarization of H^+/CN^- molecules, causing it to take up the ionic state. The proton, distinguished by high mobility and negligibly small dimensions, initiates reaction by attaching itself to the carbonyl oxygen, which has two unshared electron pairs. The equilibrium of the nucleus-electron system is disturbed and the carbonyl carbon at some moment becomes positive; a CN^- ion naturally attaches itself to it. Reaction, therefore, proceeds in stages in the way indicated.

In the series of compounds in Table 4, the degree of electronization of the bonds increases in the direction from the fatty acids to ketene. It is in this same direction that the reactivity of carbonyl compounds increases in addition reactions, as emphasized by the authors of the hypothesis that we are considering [16, 17]. Hence, this rise in reactivity in this series is associated with rise in the electronization of the C=O bond and adjacent bonds and is not associated in any way with the effects proposed by the authors of this hypothesis (+T in X—C bonds and –I or –T in the C=O bond of the group); not only are these effects not confirmed by direct

TABLE 6

Frequencies of C = C and C = O Bonds in Various Compounds (cm^{-1})

No.	Compound	C—C	No.	Compound	C—O	Difference of C = O and C = C frequencies
1		1676		—	—	—
2		1658	7		1707	49
3		1648	8		1720	72
4		1621	9		1744	123
5		1611	10		1808	197
6		1571		—	—	—

physical experiments, but on the contrary, experiment reveals the opposite phenomenon.

We will draw attention to one peculiar feature of addition reactions with the extreme member of the series under discussion, ketene: they proceed predominantly at the ethylene bond, not at the carbonyl [26]. This is to be related to the above-indicated higher stability of the carbonyl bond as compared with the ethylene bond and the higher lability of the electrons of the ethylene bond as compared with those of the carbonyl bond. As the C—H bonds are strongly electronized and the electron density of the C = O bond has a certain degree of asymmetry and is somewhat more highly concentrated at the oxygen atom (see above), addition reactions at the ethylene bond of ketene proceed through the same stages and by the operation of similar circumstances as in the above-described case of addition to a carbonyl group:

SUMMARY

By comparison of physical and chemical data on individual characteristic bonds it is shown that the chemical nature of these bonds is dependent on their physical state (the electron-nucleus interactions in them), which is manifested in the experimentally determined parameters of these bonds ν, E, and $\underline{r}$. Taking carbonyl compounds as an example, we have shown that from the strictly correlated changes in these parameters in characteristic bonds it is possible to make an estimate, on an experimental basis, of the electron displacements in the bonds as factors determining the reactivities of these bonds and as factors expressing the structure of the

molecule and the mutual effects of its atoms.

ATTEMPT TO SET UP A SEMIQUANTITATIVE THEORY OF MUTUAL EFFECTS OF ATOMS IN ORGANIC COMPOUNDS

COMMUNICATION 1. ELECTRONIC CHARGES OF BONDS, ELECTRONEGATIVITIES OF ATOMS, AND THE HEATS OF FORMATION OF SATURATED HYDROCARBONS

G. V. Bykov

According to the classical Butlerov-Markovnikov theory of the mutual effects of atoms, the chemical affinities of the atoms of a molecule depend on the chemical structure of the molecule, the characteristics of the chemical bonds (formed by the union of "units of affinity") depend on the chemical affinities, and the chemical and physical properties of the molecule depend on the characteristics of the bonds. Before modern experimental and theoretical physical methods of investigation were available, study of the links of this chain – chemical structure of the molecule, chemical affinities of atoms, interatomic chemical bonds, chemical and physical properties of the molecule – was confined largely to the first and last. However, although for a long time no satisfactory views existed concerning the true nature of chemical affinity and the chemical bond, chemists, by comparing the properties of molecules with their structural characteristics, were able to draw many valuable conclusions about chemical affinity and chemical bonds, and these conclusions were subsequently confirmed by physical methods of investigation.

In spite of the enormous success of theoretical chemistry based on these methods, there is at present no theory of mutual effects of atoms which would enable us to treat the mass of varied factual material in organic chemistry from a unified point of view. In the author's opinion, the creation of such a theory is hindered by an adherence to out-of-date doctrines with the associated lack of new ideas that might be used as a basis for the theory, and also by the existence of the view, tacitly accepted by most chemists and sometimes openly expressed, that the main theoretical problems of organic chemistry can be solved only by the methods of quantum mechanics. In speaking of out-of-date doctrines, above all the author has in mind the assertion – the position of which is already badly shaken in the case of π-bonds, but is still stubbornly maintained in the case of σ-bonds – that the chemical bond is formed by an electron cloud consisting of a whole number of electrons. As regards quantum methods in organic chemistry, the author is far from any underestimation of their value, but he considers that there are no grounds for a nihilistic attitude to the historically justified methods of the classical theory of chemical structure, that even now these methods can make a valuable contribution to the development of the theory of organic chemistry, and that theoretical chemistry can only lose if one set of methods is placed in opposition to the other, but will gain much if the methods are regarded as complementary and used as such.

In his attempt to set up a theory of mutual effects of atoms, the author has turned his attention to some new theoretical concepts (see below) and to some old methods – to the examination of chemical affinity and chemical bonds on the basis of the correlation of properties with the chemical structure of the molecule and to the advancing of hypotheses, the drawing of inferences from these hypotheses, and the comparison of these inferences with the facts. The object of the present investigation was to prove the correctness and fruitfulness of this new approach and the possibility of using methods of the classical theory of chemical structure in the solution of theoretical problems of organic chemistry. In this paper, therefore, only the basic ideas of the author's theory will be expounded and illustrated, and the more detailed development of these ideas will be made in a future paper. The reader will find further material on this question, including some remarks on its history, in another article by the author [1].

Concept of the Electronic Charge of a Bond, and the Basic Assumptions. By the electronic charge of a bond we mean the share of the total σ- or π-electron cloud of the molecule that is to be assigned to the given bond. In general, the electronic charge of a bond is not equal to a whole number of electrons (Fig. 1). As the chemical affinity of atoms in their valence states is now regarded as the energy of attraction of valence electrons by atom cores [2], it is clear that the electronic charge of a bond must be determined to some extent — or even predominantly — by the electronegativities of the atoms in their valence states. The characteristics of a bond (length, energy, force constant, etc.) naturally depend in one way or another on its electronic charge, but it may be assumed that the properties of a bond are determined mainly by its electronic charge and, to a first approximation, all other influences may be neglected in the consideration of this relationship.

Fig. 1. Diagrammatic representation of the distribution of electronic charges in the bonds of a molecule of the methanol type. Closer packing of the points corresponds to higher electronic charge. This representation serves also to show the polarity of the bonds.

As we shall see, both of these assumptions are justified in that they make it possible to carry out quantitative calculations. In these calculations we shall use, in the first place, some very simple semi-empirical equations, which express the relation of the electronic charge of a bond to the electronegativities of the atoms or to some of the properties of the bond. The investigation of very simple equations must be regarded as expedient from the chemist's point of view because a clear physical meaning is then retained to the greatest possible extent in the formulas, and elementary methods are developed for calculating the electronic structure and properties of the molecule; there is still always the possibility of developing a more precise and more complex form of functional relationship.

The chemical properties of organic compounds — the tendency to react and the directions in which they react — depend largely on the general distribution of valence-electron charges among the bonds of the molecule and on the electronic charges of individual bonds. Study of chemical properties from this point of view must, therefore, be preceded by the development of methods of calculating or, at least, estimating the electronic charges of the bonds from the electronegativities of the atoms and the physical characteristics of the bonds.

Relation between Electronegativities of Atoms and Electron Charges of Bonds. Let us suppose that the atoms X' and Y' (Fig. 1) contribute $n_{X'}$ and $n_{Y'}$ electrons respectively to the general valence-electron cloud of the molecule. Let us assume that the electron cloud attributable to the valence electrons of any given atom is distributed among all its bonds with other atoms in amounts directly proportional to the electronegativities of these atoms, then the share $A_{X'}$ of the electronic charge of the bond X'—Y' contributed by atom X' will be proportional to the number of its valence electrons $n_{X'}$ and the electronegativity $E_{Y'}$ of the atom Y' and will be inversely proportional to the sum of the electronegativities ΣE_Y of the atoms directly united to X'.

$$A_{X'} = \frac{n_{X'} E_{Y'}}{\Sigma E_Y} . \qquad (1)$$

An analogous formula can be written for $A_{Y'}$ — the share of the electronic charge of the bond X'—Y' contributed by the atom Y'. The total electronic charge $A_{X'Y'}$ will be expressed by the formula

$$A_{X'Y'} = A_{X'} + A_{Y'} = \frac{n_{X'} E_{Y'}}{\Sigma E_Y} + \frac{n_{Y'} E_{X'}}{\Sigma E_X} . \qquad (2)$$

If X' is a univalent atom, then it is clear from Equation 1 that in the σ-electron charge of the bond X'–Y' its share is equal to one σ-electron, but in the π-electron charge its share is zero.

It will be seen from Equation 2 that absolute electronegativities are not required for the calculations, relative values being adequate. The hydrogen scale, on which the electronegativities of the various elements are referred to that of hydrogen (unity), is particularly convenient. It will be obvious that relative electronegativity is a dimensionless quantity. Table 1 gives three electronegativity scales: Huggins' (a corrected version of Pauling's well known scale) [3], Gordy's [4], and Nekrasov's [2], which are derived from different premises.

TABLE 1

Relative Electronegativities of Various Elements ($E_H = 1.00$)

Author of scale	C	N	O	F	Cl	Br	I
Huggins*	1.18	1.39	1.59	1.77	1.43	1.34	1.20
Gordy*	1.20	1.40	1.62	1.85	1.39	1.29	1.15
Nekrasov	1.19	1.71	2.03	2.31	1.43	1.37	1.24

* The data of Huggins and Gordy were recalculated to the hydrogen scale by the author.

Nekrasov's value of the electronegativity of carbon E_C is to be preferred, since it is the arithmetic mean of the values on the other two scales, but Nekrasov's values for nitrogen, oxygen, and fluorine are considerably higher than the values given by the scales of Huggins and Gordy. Hence, when making use of Nekrasov's scale in our further calculations, we shall pay attention to the possibility of checking it and improving its accuracy.

The composition and chemical structure of a molecule affects the electronegativities of its atoms. It is possible to make an estimate of the electronegativities of carbon atoms in molecules of saturated hydrocarbons (see later). We may formulate the following rule: of the atoms of a given element, the highest electronegativity is possessed by the one that is directly united to the more highly electronegative atoms. The highest electronegativity is possessed by quaternary carbon atoms, and the lowest – by primary carbon atoms. For the simplified calculation of the electronegativities of carbon atoms in saturated hydrocarbons, the following empirical formula may be used:

$$E_C = 1.190 + \frac{\sum_{i}^{N_0} N_i^2}{3^{6-N_0} \cdot 10^2}, \qquad (3)$$

in which N_0 is the number of carbon atoms directly united with the given C atom, these directly united carbon atoms being distinguished by the numbers 1, 2, etc., =(in general) $\underline{i}$; $N_{\underline{i}}$ is the number of carbon atoms directly united to the carbon atom numbered $\underline{i}$. In the further treatment we shall employ a nomenclature which we shall illustrate by an example. We shall write the tertiary carbon of 2,2,3-trimethylbutane as C_3^{114}: the lower index is N_0, and the upper index indicates that two of the carbon atoms to which the tertiary carbon is attached are primary ($N_1 = N_2 = 1$) and one is quaternary ($N_3 = 4$). We have

$$E_{C_3^{114}} = 1.190 + \frac{1^2 + 1^2 + 4^2}{3^{3-3} \cdot 10^2} = 1.210.$$

The electronegativities given in Table 2 were calculated from Equation 3.

TABLE 2

Relative Electronegativities of Carbon Atoms in Saturated Hydrocarbons

C_1	E_C	C_2	E_C	C_3	E_C	C_4	E_C
C_1^1	1.190	C_2^{11}	1.191	C_3^{111}	1.193	C_4^{1111}	1.203
C_1^2	1.190	C_2^{12}	1.192	C_3^{112}	1.197	C_4^{1112}	1.213
C_1^3	1.191	C_2^{13}	1.194	C_3^{113}	1.202	C_4^{1113}	1.230
C_1^4	1.192	C_2^{14}	1.196	C_3^{114}	1.210	C_4^{1114}	1.253

In Table 3 a comparison is made between A'— σ-electron charges of C—C bonds of saturated hydrocarbons calculated from Equation 2 on the assumption that $E_C = 1.19$ for all carbon atoms— and A"— the charges calculated from the same equation on the assumption that the electronegativities of carbon are as in Table 2.

New Additive Scheme for the Calculation of Heats of Formation of Saturated Hydrocarbons. Let us assume that the energy of a σ-bond is directly proportional to its σ-electron charge:

$$D_{XY} = \Delta^h_{XY} A_{XY}, \qquad (4)$$

in which D_{XY} is the energy and A_{XY} is the σ-electron charge of the given X—Y bond; Δ^h_{XY} is the proportionality coefficient and is the fraction of the bond energy attributable to one σ-electron— for this reason we shall call it the specific electronic energy of the bond. For a saturated hydrocarbon C_nH_{2n+2} the following equation will hold:

$$\Delta^h_{CC}\sum A_{CC} + \Delta^h_{CH}\sum A_{CH} = \sum D_{CC} + \sum D_{CH}$$

or

$$\Delta^h_{CC}\sum A_{CC} + \Delta^h_{CH}\sum A_{CH} = (\Delta H^\circ_{298.16}\,(at))_{C_nH_{2n+2}}, \qquad (5)$$

in which $(\Delta H^\circ_{298.16}\,(at))_{C_nH_{2n+2}}$ * is the heat of atomization of the given gaseous hydrocarbon, which is equal in absolute magnitude but opposite in sign to the heat of formation of the hydrocarbon from its atoms. As is well known,

* In the further treatment we shall write $H^{at}_{C_nH_{2n+2}}$ in place of this awkward expression.

$$H^{at}_{C_nH_{2n+2}} = H^{el}_{C_nH_{2n+2}} + (2n+2)\,L_H + nL_C, \qquad (6)$$

in which $H^{el}_{C_nH_{2n+2}}$ is the heat of decomposition of the hydrocarbon into its elements, which is equal in magnitude but opposite in sign to its heat of formation from its elements, L_H is the heat of atomization of hydrogen, and L_C is the heat of atomization of carbon. In the course of atomization each carbon atom must take four σ-electrons, and therefore

$$L_C = 4\Delta^{h}_{CC}. \qquad (7)$$

TABLE 3

σ-Electron Charges of C–C bonds in Saturated Hydrocarbons (in electrons)

Bond	A'	A''	Bond	A'	A''
C_1^1–C_1^1	2.272	2.272	C_3^{113}–C_3^{113}	2.083	2.098
C_1^2–C_2^{11}	2.223	2.223	C_3^{114}–C_4^{1113}	2.042	2.078
C_1^3–C_3^{111}	2.178	2.180	C_4^{1114}–C_4^{1114}	2.000	2.076
C_1^4–C_4^{1111}	2.136	2.145	C_1^1–H	1.955	1.955
C_2^{12}–C_2^{12}	2.173(5)	2.174(4)	C_1^4–H	1.955	1.952*
C_2^{13}–C_3^{112}	2.128	2.135	C_2^{14}–H	1.913	1.908**
C_2^{14}–C_4^{1112}	2.088	2.104	C_3^{114}–H	1.875	1.867***

*In 2,2-dimethylpropane.
**In 2,2-dimethylbutane.
***In 2,2,3-trimethylbutane.

Taking Equations 6 and 7 into account we may rewrite Equation 5 as follows:

$$\Delta^{h}_{CC}\sum A_{CC} + \Delta^{h}_{CH}\sum A_{CH} = H^{el}_{C_nH_{2n+2}} + (2n+2)\,L_H + 4n\Delta^{h}_{CC}. \qquad (8)$$

For methane, taking account of the fact that there are no C–C bonds and ΣA_{CH} is equal to 8 σ-electrons, we may write the equation as

$$\Delta^{h}_{CH}\cdot 8 = H^{el}_{CH_4} + 4L_H + 4\Delta^{h}_{CC}.$$

After insertion of values of $H^{el}_{CH_4}$ (17.889 kcal/mole) and L_H (52.089 kcal/g-atom)* from tables, we obtain:

*Here and later we take values of $H^{el}_{C_nH_{2n+2}}$ and L_H from the tables of Rossini and coworkers [5] without recalculation of heats of formation from graphite into heats of formation from diamond.

$$\Delta^{h}_{CH} = 28.28 + 0.5\Delta^{h}_{CC}. \tag{9}$$

For the total σ-electron charges of C—C and C—H bonds in hydrocarbons, the following equation is valid:

$$\sum A_{CH} = N_{\sigma} - \sum A_{CC}, \tag{10}$$

in which N_{σ} is the number of σ-electrons in the molecule. In the saturated hydrocarbon C_nH_{2n+2}

$$N_{\sigma} = 4n + (2n + 2) = 6n + 2. \tag{11}$$

Let us substitute in Equation 8 the values of Δ^{h}_{CH} from Equation 9 and ΣA_{CH} from Equation 10 and rearrange the resulting equation, leaving only terms containing ΣA_{CC} on the left-hand side:

$$\sum A_{CC}(0.5 \quad \Delta^{h}_{CC} - 28.28) = H^{el}_{C_nH_{2n+2}} + (2n + 2)\, L_H - 28.28\, N_{\sigma} + \\ + (4n - 0.5N_{\sigma})\, \Delta^{h}_{CC} \tag{12}$$

For ethane $H^{el}_{C_2H_6} = 20.236$, n = 2, and $N_{\sigma} = 14$; substituting these values and also the numerical value of L_H in Equation 12, we obtain

$$A_{C_1C_1}\,(0.5\,\Delta^{h}_{CC} - 28.28) = \Delta^{h}_{CC} - 63.15. \tag{13}$$

Combining Equations 12 and 13, we may eliminate Δ^{h}_{CC}. For this purpose we shall denote the σ-electron charge of the C—C bond of ethane as

$$A_{C_1C_1} = 2 + z. \tag{14}$$

Substituting the value of $A_{C_1C_1}$ from Equation 14 into Equation 13, we obtain:

$$z\,(0.5\,\Delta^{h}_{CC} - 28.28) = -6.59. \tag{15}$$

The averaged σ-electron charge of C—C bonds in saturated hydrocarbons is

$$\overline{A}_{CC} = \frac{\Sigma A_{CC}}{n-1}, \tag{16}$$

but on analogy to Equation 14

$$\overline{A}_{CC} = 2 + \alpha z. \tag{17}$$

From Equations 17, 14 and 16 we find that

$$\alpha = \frac{\overline{A}_{CC} - 2}{A_{C_1C_1} - 2} = \frac{\frac{\Sigma A_{CC}}{n-1} - 2}{A_{C_1C_1} - 2}. \qquad (18)$$

In the further treatment we shall refer to α as the ethane coefficient of the hydrocarbon C_nH_{2n+2}.

From Equations 16 and 17 it follows that

$$\sum A_{CC} = \overline{A}_{CC} \cdot (n-1) = (2 + \alpha z)(n-1). \qquad (19)$$

Substituting this value of ΣA_{CC} in Equation 12 and rearranging, we obtain:

$$\begin{aligned}(n-1)\,\Delta^h_{CC} - 28.28\,(2n-2) + \alpha z\,(n-1)\,(0.5\,\Delta^h_{CC} - 28.28) = \\ = H^{el}_{C_nH_{2n+2}} + (2n+2)\,L_H - 28.28\,N_\sigma + (4n - 0.5\,N_\sigma)\,\Delta^h_{CC}.\end{aligned} \qquad (20)$$

Substituting the value N_σ from Equation 11 and the numerical value of L_H in Equation 20, we obtain:

$$\alpha z\,(n-1)\,(0.5\,\Delta^h_{CC} - 28.28) = H^{el}_{C_nH_{2n+2}} - 8.94\,(n+1). \qquad (21)$$

Division of Equation 21 by Equation 15 gives:

$$\alpha = \frac{8.94\,(n+1) - H^{el}_{C_nH_{2n+2}}}{6.59\,(n-1)}. \qquad (22)$$

Since ethane coefficients can be calculated from Equation 18, using electronegativity data for the calculation of A_{CC}, we have obtained an equation that relates the heats of formation of gaseous saturated hydrocarbons from their elements to the electronegativities of the carbon atoms. Calculations based on this equation will enable us to judge whether the assumptions made in its derivation are correct or not.

As will be seen from Table 4 (Nos. 1-21), there is a definite correlation between the values of ethane coefficients calculated from heats of formation and those calculated from electronegativities. The greatest discrepancy is found for hydrocarbons containing quaternary and tertiary carbon atoms (Nos. 7, 20, 21). Taking the value of the σ-electron charge of the C–C bond in ethane given in Table 3 ($A_{C_1C_1}$ = 2.272 electrons) and using the ethane coefficients calculated from heats of formation, we may calculate the total σ-electron charges in the various hydrocarbons from Equation 19. The agreement of the values of ΣA_{CC}(H) obtained by this mixed method of calculation with ΣA_{CC}(E) is quite satisfactory. The greatest discrepancies are found for Nos. 20 and 21, which contain quaternary carbon atoms.

From ΣA_{CC}(H) we can obtain – in some cases (Nos. 2, 4, 7) directly, and in others by simple calculations – values of the σ-electron charges of individual bonds. By substitution of these values in Equation 2, we may estimate the electronegativities of carbon atoms occupying structurally different places in the molecule. The results obtained in this way are generalized in Equation 3. In the three lowest lines in Table 4 (Nos. 7a, 20a, and 21a) we give total σ-electronic charges ΣA_{CC}(E), for the calculation of which we used electronegativities

TABLE 4

* n — number of carbon atoms; α_H — ethane coefficient calculated from heats of formation $H^{el}_{C_nH_{2n+2}}$ (expt); α_E — ethane coefficient calculated from data in Column 2, Table 3; $\Delta_\alpha = \alpha_E - \alpha_H$; $\Sigma A_{CC}(H)$ — total σ-electron charge of hydrocarbon calculated by substitution of α_H and z = 0.272 in Equation 19; ΣA_{CC} — total σ-electron charge of hydrocarbon calculated from data in Column 2, Table 3; $\Delta_A = \Sigma A_{CC}(E) - \Sigma A_{CC}(H)$; $H^{el}_{C_nH_{2n+2}}$ (expt) — experimental heat of formation of gaseous saturated hydrocarbon from elements [5]; $H^{el}_{C_nH_{2n+2}}$ (calc) — heat of formation calculated from Equation 22 with the use of values of α_E; $\Delta = H^{el}_{C_nH_{2n+2}}(\text{calc}) - H^{el}_{C_nH_{2n+2}}(\text{expt})$.

calculated from Equation 3. In these lines the values of ΣA_{CC} and α calculated by different methods agree very much better than in the lines Nos. 7, 20, and 21.

Of particular importance is the comparison of heats of formation $H^{el}_{C_nH_{2n+2}}$ determined experimentally with those calculated by Equation 22 with α_E substituted for α. The discrepancies between calculated and experimental values, although outside experimental error, are of the same order as the discrepancies between the values calculated by the empirical additive scheme of Tatevsky [6] and the experimental values. It must be remembered that the ratio of absolute errors

$$\frac{dH^{el}_{C_nH_{2n+2}}}{d\alpha} = -6.59(n-1)$$

is very high, so that results obtained by the use of a crude scheme for the calculation of α_E must be regarded as quite satisfactory. With improvement in the scheme of calculating α_E (three lowest lines of the table), close agreement between the calculated and experimental values of $H^{el}_{C_nH_{2n+2}}$ is obtained. Hence, the results confirm the rationality of the scheme of calculation used and, what is most important, of the theoretical postulates on which the scheme is based.

Using the values of $\Sigma A_{CC}(H)$ and $H^{el}_{C_nH_{2n+2}}$ (expt) from the relevant columns of Table 4 (Nos. 1-21), we may calculate Δ^h_{CC} from Equation 12 and then Δ^h_{CH} with aid of Equation 9. The results obtained were

$$\Delta^h_{CC} = 8.054 \pm 0.007 \text{ *and} \Delta^h_{CH} = 32.308 \pm 0.003 \text{ kcal/q} \cdot \text{electron}$$

$H^{el}_{C_nH_{2n+2}}$ may then be calculated from Equation 8. We do not give the results of this calculation because they do not differ significiantly (the mean discrepancy is 0.023 kcal/mole) from the values obtained from Equation 22. These results show that it is possible to construct an additive scheme, which is new in principle, for the calculation of heats of formation and linearly related quantities, the terms added being products of electronic charges of bonds and specific electronic energies.

SUMMARY

1. The author proposes to construct an electronic theory of the mutual effects of atoms in organic compounds on the basis of the concept of the electronic charge of a bond, which in the general case is not equal to a whole number of electrons.

2. An equation is proposed which expresses the dependence of electronic charges of bonds on the electronegativities of the atoms. An equation is derived for the calculation of heats of formation of gaseous saturated hydrocarbons from their elements with the aid of values of electronic charges of bonds calculated by the first equation. The agreement found between the experimental values of heats of formation and values calculated with these equations confirms the theoretical postulates on which they were based. In particular, confirmation is found for the postulate that the energies of the σ-bonds are, to the first approximation, directly proportional to their σ-electron charges. A new additive scheme is proposed for the calculation of heats of

*According to Equation 7 we obtain $L_C = 4\Delta^h_{CC} = 32.216$ kcal/g-atom for the heat of atomization of carbon, although this heat of atomization is most usually given values ranging from 124 to 170 kcal/g-atom. Our value must, of course, appear paradoxical. Although it would be possible to advance several more arguments in its favor, we consider it desirable to give separate consideration to the whole question of the heat of atomization of carbon which is of secondary importance for the present investigation. The author proposes to do this in the near future.

formation of saturated hydrocarbons. In this scheme the terms of the summation are products of σ-electron charges of bonds and specific electronic energies.

REACTIONS OF FLUORO OLEFINS

COMMUNICATION 6. REACTIONS OF PERFLUOROISOBUTENE AND PERFLUOROPROPENE WITH NUCLEOPHILIC REAGENTS

I. L. Knunyants, L. S. German and B. L. Dyatkin

In the study of reactions of fluoro olefins with nucleophilic reagents (alcohols, thiols, amines) the examples taken have been mainly fluoro derivatives of ethylene. Of the higher fluoro olefins, perfluoropropene has been investigated in its reactions with alcohols, thiols, and amines [1], in which it undergoes addition in accordance with the electronic interpretation of Markovnikov's rule:

$$CF_3\overset{\delta-}{C}F=\overset{\delta+}{C}F_2 + H^+X^- \longrightarrow CF_3CFHCF_2X$$

X=OAlk, SAlk, $(C_2H_5)_2N$, C_6H_5O

In the reactions with alcohols, products were isolated (in the form of dibromides) which were formed by substitution of one fluorine of the perfluoropropene molecule by an alkoxy group. It was shown that the formation of unsaturated compounds was not the result of a secondary reaction (elimination of hydrogen fluoride from the corresponding addition products).

The reactions of C_4 fluoro olefins with nucleophilic reagents have scarcely been investigated. Only the reaction of perfluoroisobutene with ethanol has been studied; this proceeds at room temperature in absence of alkaline catalysts, but only the addition product – the structure of which was not proved – was isolated [2].

In a detailed study of the reaction of perfluoroisobutene with alcohols, we found that, in addition to the main reaction products (alkyl 1,1,3,3,3-pentafluoro-2-(trifluoromethyl) propyl ethers), unsaturated compounds were formed which corresponded in composition to products formed by the replacement of one fluorine of the perfluoroisobutene molecule by an alkoxy group. For these compounds, two structures may be proposed:

(I) or (II)

R = CH_3, C_2H_5.

At first sight the structure (I) appears to be the more probably because it may be supposed that π,σ-conjugation occurs in the perfluorobutene molecule and can result in allyl rearrangement:

However, the reactions of the alkoxyisobutenes obtained correspond to the structure (II); thus, hydrolysis with concentrated sulfuric acid in presence of silica converts them into 3,3,3-trifuloro-2-(trifluoromethyl) propionic esters, and by the action of amines they are converted into the corresponding amides:

X = OH, C_5H_5NH, $(C_2H_5)_2N$.

The resulting alkoxyisobutenes therefore, have the structure of alkyl 1,3,3,3-tetrafluoro-2-(trifluoromethyl) propenyl ethers; their formation can be represented either as direct replacement of a fluorine atom by alkoxyl or as the result of elimination of hydrogen fluoride from alkyl 1,1,3,3,3-pentafluoro-2-(trifluoromethyl) propyl ethers which are formed in the first place.

It is actually found that, when treated with a suspension of KOH in ether, alkyl 1,1,3,3,3-pentafluoro-2-(trifluoromethyl) propyl ethers lose HF with formation of alkyl 1,3,3,3-tetrafluoro-2-(trifluoromethyl) propenyl ethers. However, the formation of the latter by reaction of perfluoroisobutene with alcohols must be regarded as the result of direct replacement of an F atom in a CF_2 group, for under the conditions of reaction (absence of alkali) alkyl 1,1,3,3,3-pentafluoro-2-(trifluoromethyl) propyl ethers are stable. Hence, we have here an unusual case of the replacement of a vinylic chloride atom, which, according to generally accepted ideas, should be inert. This phenomenon may be explained by electronic depletion and the high polarization of the π-bond in perfluoroisobutene due to the presence of two CF_3 groups on one of the carbon atoms. For this reason the polarizability of the π-bond is low and stabilization of the reaction complex originally formed proceeds not only by addition of a proton (Path A), but also by elimination of a fluoride ion (Pathe B):

The character of the double bond of perfluoroisobutene is largely preserved in alkyl 1,3,3,3-tetrafluoro-2-(trifluoromethyl) propenyl ethers; for example, the latter are not brominated even when heated with bromine at 100° for a long time.

Perfluoroisobutene reacts similarly with diethylamine in absolute ether at room temperature, and here the sole reaction product is N,N-diethyl-1,3,3,3-tetrafluoro-2-(trifluoromethyl) propenylamine $(CF_3)_2C{=}CF{-}N{=}(C_2H_5)_2$; its formation may be explained by elimination of hydrogen fluoride from the originally formed α,α-difluoro-amine $(CF_3)_2CH{-}CF_2{-}N(C_2H_5)_2$ or by direct replacement of the vinylic fluorine atom by the diethylamino group. Attempts that we made to direct the reaction toward the formation of the α,α-difluoro amine (addition of diethylamine at low temperature to perfluoroisobutene) were unsuccessful.

N,N-diethyl-1,3,3,3-tetrafluoro-2-(trifluoromethyl) propenylamine does not react with bromine, does not form salts with acids, and is extremely readily hydrolyzed with formation of N,N-diethyl-3,3,3-trifluoro-2-

(trifluoromethyl) propionamide. Reaction of perfluoroisobutene with aniline gives 3,3,3-trifluoro-2-(trifluoromethyl) propionanilide, and an intermediate product can be isolated which, according to the analytical data may be assigned one of the two structures:

Reaction of perfluoroisobutene with ammonia in ethereal solution gives 3,3,3-trifluoro-2-(trifluoromethyl) propionitrile:

The corresponding amide was obtained as by-product.

As regards the reactions of perfluoropropene with alcohols and amines, which have already been partially investigated, we have now succeeded in showing that, in the reaction of perfluoropropene with alcohols, the vinylic fluorine atom is again replaced. This was proved as follows:

The obtaining of derivatives of 2-bromo-2,3,3,3-tetrafluoropropionic acid provides unequivocal proof of the structure of the alkoxyfluoropropenes obtained.

As was shown previously, in the reaction of perfluoropropene with diethylamine in an aqueous medium under pressure, N,N-diethyl-1,3,3,3-tetrafluoropropionamide is formed [1]. By carrying out this reaction in an absolute medium under atmospheric pressure, we succeeded in isolating the intermediate products $CF_3CF=CFN(C_2H_5)_2$ and $CF_3CFHCF_2N(C_2H_5)_2$, though the closeness in boiling point did not permit us to separate them. We succeeded in showing indirectly that the proportion of the propenylamine in the mixture was about 70%.

There is a reference in the literature to the formation of 2,3,3,3-tetrafluoropropionitrile by reaction between perfluoropropene and ammonia, but neither the constants of the product nor the reaction conditions are described [3]. We showed that this reaction proceeds smoothly in aqueous-dioxane solution. For comparison we prepared 2,3,3,3-tetrafluoropropionitrile by another method: dehydration of the corresponding amide:

EXPERIMENTAL

Reaction of Perfluoroisobutene with Alcohols

Reaction with Methanol. Gaseous perfluoroisobutene (67 g, i. e., 0.35 mole) was passed into stirred methanol (50 ml) at room temperature. The mixture was left for some time at room temperature, and was then poured into cold water. The oil that separated was washed with water, with saturated sodium bicarbonate solutions, and again with water; it was dried over calcium chloride. Distillation gave the following fractions: Fraction I, b.p. 68.5-70.5° (754 mm) – methyl 1,1,3,3,3-pentafluoro-2-(trifluoromethyl) propyl ether, yield 50.7 g (64.7%); Fraction II, b.p. 101-104° (754 mm) – methyl 1,3,3,3-tetrafluoro-2-(trifluoromethyl) propenyl ether, yield 5.7 g (8%). This substance decolorized a solution of potassium permanganate in acetone.

After redistillation, methyl 1,1,3,3,3-pentafluoro-2-(trifluoromethyl) propyl ether had the following constants: b.p. 69.5-70° (754 mm); n_D^{20} 1.283; d_4^{20} 1.5000; Found MR 27.41; Calculated* for $C_5F_8H_4O$ MR 28.05

Found %: C 25.83; H 1.63; F 65.65; $C_5F_8H_4O$. Calculated %: C 25.88; H 1.73; F 65.49.

Redistillation of methyl 1,3,3,3-tetrafluoro-2-(trifluoromethyl) propenyl ether gave a substance having b.p. 101-102° (754 mm); n_D^{20} 1.3170; d_4^{20} 1.5078; Found MR 27.65; Calculated for $C_5F_7H_3O$ MR 27.45

Found %: C 28.38; H 1.61; F 62.72; $C_5F_7H_3O$. Calculated %: C 28.32; H 1.43; F 62.71.

Reaction with Ethanol. The procedure was as for methanol. Reaction between 40.6 g (0.27 mole) of perfluoroisobutene and 100 ml of ethanol gave 26.4 g (53%) of ethyl 1,1,3,3,3-pentafluoro-2-(trifluoromethyl) propyl ether, b.p. 84-86° (749 mm) and 5.0 g (10.8%) of ethyl 1,3,3,3-tetrafluoro-2-(trifluoromethyl)propenyl ether, b.p. 110-114° (749 mm).

Redistillation of these products gave ethyl 1,1,3,3,3-pentafluoro-2-(trifluoromethyl) propyl ether, b.p. 83.5-84° (763 mm); n_D^{20} 1.2950; d_4^{20} 1.4061; Found MR 32.67; Calculated for $C_6F_8H_6O$ MR 32.67 (the literature [2] gives b.p. 83° (743 mm); n_D^{20} 1.2908; d_4^{20} 1.3946), and ethyl 1,3,3,3-tetrafluoro-2-(trifluoromethyl) propenyl ether b.p. 113.5-114° (763 mm); n_D^{20} 1.3242; d_4^{20} 1.3932; Found MR 32.52; Calculated for $C_6F_7H_5O$ MR 32.06.

Dehydrofluorination of Alkyl 1,1,3,3,3-Pentafluoro-2-(trifluoromethyl) propyl Ethers

1. A mixture of 8 g (0.034 mole) of methyl 1,1,3,3,3-pentafluoro-2-(trifluoromethyl) propyl ether, 6 g (0.10 mole) of potassium hydroxide powder, and 50 ml of ether was boiled with stirring for three hours. The solution was filtered, ether was distilled off, and distillation of the residue gave 4.4 g (60%) of methyl 1,3,3,3-tetrafluoro-2-(trifluoromethyl) propenyl ether, b.p. 101-103° (744 mm) and n_D^{20} 1.3182.

2. The reaction was carried out as in the preceding experiment. Reaction between 16 g (0.065 mole) of ethyl 1,1,3,3,3-pentafluoro-2-(trifluoromethyl) propyl ether and 6.4 g (0.11 mole) of potassium hydroxide in 50 ml of absolute ether gave 11.6 g (79.1%) of ethyl 1,3,3,3-tetrafluoro-2-(trifluoromethyl) propenyl ether, b.p. 113-115° (756 mm). After redistillation its constants were: b.p. 114-115° (745 mm) n_D^{20} 1.3262; d_4^{20} 1.3994; Found MR 32.62; Calculated for $C_6F_7H_5O$ MR 32.06.

Found %: C 31.92; H 2.34; F 59.04 $C_6F_7H_5O$. Calculated %: C 31.87; H 2.23; F 58.82

Hydrolysis of Alkyl 1,1,3,3,3-Pentafluoro-2-(trifluoromethyl) propyl Ethers

Methyl 3,3,3-Trifluoro-2-(trifluoromethyl) propionate. A mixture of 42 g (0.18 mole) of methyl 1,1,3,3,3-pentafluoro-2-(trifluoromethyl) propyl ether, 13 ml of concentrated sulfuric acid (sp. gr. 1.82), and 9 g of glass powder was heated in an autoclave at 120° for ten hours with constant rotation. The reaction mixture was then poured onto ice, the lower layer was separated, and the upper layer was extracted with ether. The layer first separated was combined with the ether solution, washed with saturated sodium bicarbonate solution and then with water, and dried over magnesium sulfate. The residue remaining after removal of ether came over at 88-89.5° (743 mm); yield 29.4 g (77.5%). After being redistilled, methyl 3,3,3-trifluoro-2-(trifluoromethyl) propionate

* In all cases the atomic refraction of fluorine was taken as 1.24.

had b.p. 89° (743 mm); n_D^{20} 1.3070; d_4^{20} 1.4470; Found MR 27.72; Calculated for $C_5F_6H_4O_2$ MR 27.78.

Found %: C 28.57; H 1.91 $C_5F_6H_4O_2$. Calculated %: C 28.48; H 1.91

Ethyl 3,3,3-Trifluoro-2-(trifluoromethyl) propionate. A mixture of 24.6 g (0.10 mole) of ethyl 1,1,3,3,3-pentafluoro-2-(trifluoromethyl)-propyl ether, 8 ml of concentrated sulfuric acid (sp. gr. 1.82), and 5 g of glass powder was heated in flask fitted with reflux condenser in a water bath for several hours. Treatment of the product as in the preceding experiment gave 15.7 g (70%) of ethyl 3,3,3-trifluoro-2-(trifluoromethyl) propionate, b.p. 101-103° (755 mm). After redistillation the constants were: b.p. 102.5° (750 mm); n_D^{20} 1.3161; d_4^{20} 1.3554; Found MR 32.45; Calculated for $C_6F_6H_6O_2$ MR 32.40.

Found %: C 32.05; H 2.79; F 50.63 $C_6F_6H_6O_2$. Calculated %: C 32.15; H 2.70; F 50.87.

3,3,3-Trifluoro-2-(trifluoromethyl) propionic Acid. A mixture of 33.6 g (0.15 mole) of ethyl 3,3,3-trifluoro-2-(trifluoromethyl) propionate and 56 ml of concentrated sulfuric acid (sp. gr. 1.82) was heated at 100° in a constantly rotating autoclave for 18 hours. The reaction mixture was extracted with methylene chloride. Solvent was distilled off, and the acid was isolated by freezing it out. The product was 12.1 g (41%) of 3,3,3-trifluoro-2-(trifluoromethyl) propionic acid, obtained in the form of colorless crystals, m.p. 49.5-50.5° (from heptane) and b.p. 124-126° (750 mm)(with slight decomposition). The neutralization equivalent was 195.5, 194.5, the theoretical equivalent for $C_4F_6H_2O_2$ being 196.0. The acid chloride was prepared in the usual way with the aid of phosphorus pentachloride: yield 64%; b.p. 57-59° (752 mm); n_D^{20} 1.3086; d_4^{20} 1.5492; Found MR 26.56; Calculated for C_4F_6HOCl MR 26.66. Amide m.p. 154-155.5° (from benzene). Anilide m.p. 166.5-167.5° (from benzene).

Reactions of Ethyl 1,3,3,3-Tetrafluoro-2-(trifluoromethyl) propenyl Ether with Amines

Reaction with Aniline. A mixture of 4.5 g (0.02 mole) of ethyl 1,3,3,3-tetrafluoro-2-(trifluoromethyl) propenyl ether and 3.7 g (0.04 mole) of aniline was shaken and heated until mutual solution occurred. The crystalline mass formed on cooling was washed with dilute hydrochloric acid and with water. The product, amounting to 2.5 g (45%), was 3,3,3-trifluoro-2-(trifluoromethyl) propionanilide, m.p. 168-169° (from aqueous alcohol). In admixture with a sample obtained from the acid chloride and aniline there was no depression of melting point.

Found %: C 44.45; H 2.66; F 42.14; N 5.33 $C_{10}F_6H_7NO$. Calculated %: C 44.28; H 2.58; F 42.06; N 5.17.

Reaction with Diethylamine. A mixture of 11.3 g (0.05 mole) of ethyl 1,3,3,3-tetrafluoro-2-(trifluoromethyl) propenyl ether and 15 ml of absolute ether was prepared in a flask fitted with stirrer, reflux condenser, and dropping funnel and protected from access of atmospheric moisture and carbon dioxide. The mixture was stirred and cooled with ice water, and 8 g (0.11 mole) of pure diethylamine was added over a period of one hour. The precipitate of diethylamine hydrochloride was filtered off, ether was distilled off, and the residue was distilled under reduced pressure. The product, amounting to 11.7 g (84.5%), was 1-ethoxy-N,N-diethyl-3,3,3-trifluoro-2-(trifluoromethyl) propenylamine, b.p. 68-71° (2 mm) and, after redistillation, b.p. 71° (2 mm); n_D^{20} 1.4071; d_4^{20} 1.2407; Found MR 55.10; Calculated for $C_{10}F_6H_{16}NO$ MR 54.34. Hydrolysis of 1-ethoxy-N,N-diethyl-3,3,3-trifluoro-2-(trifluoromethyl) propenylamine with dilute hydrochloric acid at 100° gave N,N-diethyl-3,3,3-trifluoro-2-(trifluoromethyl) propionamide, which melted without depression (m.p. 51-52°) in admixture with the product obtained from perfluoroisobutene and diethylamine.

The reaction of perfluoropropene with methanol was carried out in accordance with the previously described procedure [1]. The constants of 1,1,2,3,3,3-hexafluoropropyl methyl ether were: b.p. 54-55° (750 mm); n_D^{20} 1.2840; d_4^{20} 1.4185; Found MR 22.89: Calculated for $C_4F_6H_4O$ MR 23.15. (the literature [1] gives b. p. 54-55° (750 mm); d_4^{20} 1.429; n_D^{20} 1.2850) The dibromide (1,2-dibromo-1,2,3,3,3-pentafluoropropyl methyl ether) had b.p. 128-132° (732 mm); n_D^{20} 1.3871; d_4^{20} 1.9374; Found MR 39.19;: Calculated for $C_4F_6H_5Br_2O$ MR 38.54. (the literature [1] gives: b.p. 136°; d_4^{20} 1.900; n_D^{20} 1.3700).

1,1,2,3,3,3-Hexafluoropropyl methyl ether was converted by the method described into methyl 2,3,3,3-tetrafluoropropionate, b.p. 94° (750 mm) and n_D^{20} 1.3198 (the literature [1] gives b.p. 96° and n_D^{20} 1.3192.

2,3,3,3-Tetrafluoropropionamide. A mixture of 2.9 g of methyl 2,3,3,3-tetrafluoropropionate and 4 ml of concentrated aqueous ammonia was shaken until the oil had completely dissolved. The solution was evaporated at room temperature, and the residue was vacuum-dried. The product, amounting to 2.6 g (96%), was 2,3,3,3-tetrafluoropropionamide, m.p. 53.5-55.5°, raised by recrystallization from benzene to 58-59°.

Found %: C 24.75; H 2.11; F 52.25; N 9.56 $C_3F_4H_3NO$. Calculated %: C 24.84; H 2.09; F 52.41; N 9.66.

2,3,3,3-Tetrafluoropropionitrile. The dehydration of 7.2 g (0.05 mole) of 2,3,3,3-tetrafluoropropionamide gave 5.1 g (80.3%) of 2,3,3,3-tetrafluoropropionitrile, b.p. 41.5-42.5° (746 mm); n_D^{20} 1.27; d_4^{20} 1.3600.

Found %: C 28.58; H 0.84 C_3F_4HN. Calculated %: C 28.35; H 0.79

Hydrolysis of 1,2-Dibromo-1,2,3,3,3-pentafluoropropyl Methyl Ether. A mixture of 7.6 g (0.024 mole) of the dibromide, 2 ml of concentrated sulfuric acid (sp. gr. 1.82), and 2 g of finely ground glass was heated in a water bath for five hours. The reaction mixture was then decomposed by ice, washed with sodium bisulfite solution, and extracted with ether. The ether solution was washed with sodium bicarbonate solution and with water, and was dried over magnesium sulfate. Removal of ether gave a residue of 3.1 g (56%) of methyl 2-bromo-2,3,3-3-tetrafluoropropionate, b.p. 105-107° and n_D^{20} 1.3620. Redistillation gave a substance of b.p. 106-106.5° (733 mm); n_D^{20} 1.3617; d_4^{20} 1.6257; Found MR 31.06; Calculated for $C_4F_4H_3BrO_2$ MR 30.65.

Found %: Br 33.08; F 31.64 $C_4F_4H_3BrO_2$. Calculated %: Br 33.44; F 31.80.

Treatment of this ester with concentrated aqueous ammonia gave 2-bromo-2,3,3,3-tetrafluoropropionamide, m.p. 90-90.5° (from heptane).

Found %: Br 35.53; N 6.17 $C_3F_4H_3BrNO$. Calculated %: Br 35.68; N 6.28.

Reaction of Perfluoroisobutene with Amines

Reaction with Diethylamine. Dry perfluoroisobutene (26 g, i.e., 0.13 mole) was introduced over a period of 2.5 hours into a vigorously stirred, cooled (0°) solution of 20 g (0.27 mole) of dry diethylamine in 75 ml of absolute ether. When addition was complete, the mixture was left at room temperature for a further 30 minutes and then filtered from the precipitate of diethylamine hydrofluoride (11.6 g, i.e., 0.125 mole). The filtrate was left overnight in a refrigerator. After removal of ether and two fractionations, 16.5 g (65%) of N,N-diethyl-1,-3,3,3-tetrafluoro-2-(trifluoromethyl) propenylamine was obtained as a colorless liquid of characteristic pungent odor. It did not react with a solution of bromine in methylene chloride and hydrolyzed when exposed to the air for a short time; b.p. 66.5-67° (10 mm); n_D^{20} 1.3810; d_4^{20} 1.3256; Found MR 44.31; Calculated for $C_8F_7H_{10}N$ MR 43.60.

Found %: C 38.0; H 3.98; F 52.71; N 5.53 $C_8F_7H_{10}N$. Calculated %: C 37.95; H 3.98; F 52.53; N 5.53.

Hydrolysis of N,N-Diethyl-1,3,3,3-tetrafluoro-2-(trifluoromethyl)-propenylamine. A mixture of 7.1 g (0.028 mole) of the amine and 50 ml of water was stirred vigorously for 14 hours. The crystals formed in the flask were filtered off and washed with water. The product amounting to 6.0 g (85%), was N,N-diethyl-3,3,3-trifluoro-2-(trifluoromethyl) propionamide, m.p. 51-51.5° (from heptane).

Found %: C 38.43; H 4.41; F 45.48; N 5.32 $C_8F_6H_{11}ON$. Calculated %: C 38.25; H 4.013; F 45.42; N 5.57.

Reaction of Perfluoroisobutene with Aniline. A stream of perfluoroisobutene was passed into a vigorously stirred solution of 11 g (0.12 mole) of aniline in 50 ml of ether. The precipitate of aniline hydrofluoride was filtered off, ether was distilled off, and the residue was treated with cold dilute hydrochloric acid and with water; it was dried over magnesium sulfate. Fractionation gave 11.8 g of a substance of b.p. 77-79° (28 mm), n_D^{20}

1.4148; d_4^{20} 1.3869; Found MR 49.26; Calculated for $C_{10}F_7H_9N$ MR 49.97.

Found %: C 43.93; H 2.23; N 5.24 $C_{10}F_7H_9N$. Calculated %: C 43.98; H 2.21; N 5.13.

When treated with concentrated sulfuric acid, the substance of b.p 77-79° (28 mm) gave 3,3,3-trifluoro-2-(trifluoromethyl) propionanilide, m.p. 168.5-169° (from dilute alcohol). There was no depression of melting point in a mixture test with the sample described above.

Reaction of Perfluoropropene with Diethylamine

Dry perfluoropropene (37 g, i.e., 0.245 mole) was passed for two hours into a vigorously stirred solution of 40 g (0.55 mole) of dry diethylamine in 70 ml of absolute ether. When addition was complete, diethylamine hydrofluoride (12 g, i.e., 0.13 mole) was filtered off, ether was distilled off, and the residue was vacuum-distilled. The bulk of the material (32 g) came over at 52-52.5° (55 mm) (n_D^{20} 1.3550; d_4^{20} 1.2279*) and was found to be a mixture of N,N-diethylpentafluoropropenylamine and N,N-diethyl-1,1,2,3,3,3-hexafluoropropylamine. This mixture decomposed very readily in presence of air, reacted with a solution of bromine in methylene chloride, and was readily hydrolyzed by water with formation of N, N-diethyl-2,3,3,3-tetrafluoropropionamide as sole product: b.p. 89-90° (22 mm); n_D^{20} 1.3910 (the literature [1] gives b.p. 89° (22 mm); n_D^{20} 1.3910).

Reaction of Perfluoroisobutene with Ammonia

A solution of 25 g (0.125 mole) of perfluoroisobutene in 100 ml of absolute ether was cooled to −60° and stirred vigorously during the passage of 6 g (0.353 mole) of dry ammonia over a period of 2.5 hours. The temperature of the mixture was then allowed to rise to 0°, 20 ml of water was added, and stirring was continued for a further 1.5 hours. The reaction mixture was then washed, first with water, then with sodium bicarbonate solutions, and again with water; it was dried with magnesium sulfate. Fractionation gave 4.7 g (21%) of 3,3,3-trifluoro-2-(trifluoromethyl) propionitrile, b.p. 64-65° (750 mm); n_D^{20} 1.27; d_4^{20} 1.4560. From the residue in the flask, 2.5 g (13%) of 3,3,3-trifluoro-2-(trifluoromethyl) propionamide, m.p. 154.5-155° (from benzene), was isolated. The same compound was obtained by the action of alcoholic hydrogen chloride on 3,3,3-trifluoro-2-(trifluoromethyl) propionitrile and subsequent treatment with water; it melted at 154.5-155° (from benzene).

Found %: C 24.69; H 1.59; F 58.47 $C_4F_6H_5NO$. Calculated %: C 24.63; H 1.55; F 58.44.

Neither of these substances showed any depression of melting point in admixture with samples prepared from 3,3,3-trifluoro-2-(trifluoromethyl) propionyl chloride and ammonia.

Reaction of Perfluoropropene with Ammonia

Perfluoropropene (63 g, i.e., 0.42 mole) was passed into a cooled stirred mixture of 100 ml of dioxane and 20 ml of 30% aqueous ammonia. During the reaction, 30% ammonia (three 10-ml portions) was added periodically. When the introduction of perfluoropropene was complete, the reaction mixture was rapidly distilled into a well cooled receiver. The 38-95° fraction was poured into water, and the layer that separated was carefully washed free from dioxane with cold water and was dried over calcium chloride. Fractionation gave 23.8g (46.5%) of 2,3,3,3-tetrafluoropropionitrile, b.p. 40-41° (750 mm); n_D^{20} 1.27; d_4^{20} 1.3620.

Treatment of 2,3,3,3-tetrafluoropropionitrile with alcoholic hydrogen chloride and subsequent treatment with water gave ethyl 2,3,3,3-tetrafluoropropionate, which was converted by treatment with aqueous ammonia into 2,3,3,3-tetrafluoropropionamide, m.p. 58-59°. In admixture with the sample described above it melted without depression.

SUMMARY

1. It was shown that, when perfluoroisobutene and perfluoropropene react with alcohols and amines, not only addition occurs, but also replacement of the vinylic fluorine atom.

* The specific gravity and refractive index varied from one experiment to another. The results of elementary analysis were intermediate between those required for N,N-diethylpentafluoropropenylamine and those required for N,N-diethyl-1,1,2,3,3,3-hexafluoropropylamine.

2. The addition and substitution products so obtained were submitted to various reactions with formation of various derivatives of 3,3,3-trifluoro-2-(trifluoromethyl) propionic and 2,3,3,3-tetrafluoropropionic acids.

3. It was found that, with ammonia, perfluoroisobutene and perfluoropropene give 3,3,3-trifluoro-2-(trifluoromethyl) propionitrile and 2,3,3,3-tetrafluoropropionitrile, respectively.

STRUCTURE OF COMPOUNDS FORMED FROM THIOPHENE AND 2-METHYLTHIOPHENE UNDER THE CONDITIONS OF CHLOROMETHYLATION IN PRESENCE OF ZINC CHLORIDE

Ya. L. Goldfarb and Ya. L. Danyushevsky

According to Blicke and Burckhalter [1], in the chloromethylation of thiophene with 40% formaldehyde and hydrochloric acid, not only 2-(chloromethyl) thiophene, but also 2,2'-methylenedithiophene (MDT) (I) is formed. The latter compound is obtained, though here as the main reaction product, also by reaction of thiophene with trioxane in presence of hydrofluoric acid [2]; in the reaction mixture obtained under these conditions a small amount of a compound of composition $C_{14}H_{12}S_3$ can be isolated, and this is assigned [2] the structure of 2,5-di-2-thienylthiophene (DTT) (II). 2,2'-Methylenedithiophene is obtained in higher yield by the condensation of 2-(chloromethyl) thiophene with 2-thienyllithium [3].

2,2'-Methylenedithiophene and 2,5-di-2-thenylthiophene are of interest as starting materials for the preparation of aliphatic compounds having a long carbon chain [4]. A simple method for the synthesis of MDT is described in the present paper; it is based on observations of Lock, who used zinc chloride as a condensing agent in the chloromethylation of benzene [5]. In presence of zinc chloride and hydrochloric acid, thiophene reacts with 35-37% formaldehyde solution at from −7° to 0° with formation of MDT in 50-55% yield. That the compound formed under these conditions is indeed 2,2'-methylenedithiophene (I) is shown by the fact that, when formylated with N-methylformanilide in presence of phosphoryl chloride, it gives 5-(2-thenyl)-2-thiophenecarboxaldehyde, which can be converted into n-decyl alcohol by the action of Raney nickel. It is further confirmed by the fact that a mixture of the compound with the MDT obtained (see experimental part) by reduction of di-2-thienyl ketone [6] by a modified Kizhner method [7] melts without depression.

Apart from MDT, in our experiments we obtained a mixture of high-boiling products, from which, as in the work with hydrofluoric acid (see above), we isolated a compound of composition $C_{14}H_{12}S_3$, m.p. 37.5-38.5°. From the way in which it was formed it was possible to assign the compound the structure (II), but not as the only one permissible, as it was impossible to exclude the possibility of isomerization, associated with migration of the thenyl radical from the α- to the β-position. Moreover, it must be remembered that in MDT (I) which is probably an intermediate product in the formation of the substance of m.p. 37.5-38.5°, the β-position is activated by the thenyl radical attached to the α-carbon atom of the ring. All this applies equally to the compound described as DTT (II) by Cairns, McKusick, and Weinmayr [2], who assumed this structure without giving any data in its support.

As the most probable structure for the substance of m.p. 37.5-38.5° is II (DTT), we decided to prepare it as follows, for comparison:

The ketone (III) is obtained in very low yield (10-12%). Attempts to improve the yield by the use of various condensing agents, change in the medium and the amount of stannic chloride, variations in the order of mixing the reactants, and alteration of temperature were not successful. Experiments on the acylation of MDT with 2-thiophenecarboxylic acid in presence of phosphoric oxide were also unsuccessful: under these conditions the anhydride of the thiophenecarboxylic acid was obtained instead of the expected ketone.

Of the two possible structures of the ketone, (III) and (IV), the second is not very probable, since, according to Hartough and Kosak [8], in the acylation of 2-alkylthiophenes, substitution of the acyl group in the 3-position does not occur to an appreciable extent. Reduction of the ketone (III) gave DTT (II), m.p. 37.5-38°, undepressed by admixture of the above-mentioned substance of composition $C_{14}H_{12}S_3$, isolated together with MDT in the chloromethylation of thiophene in presence of zinc chloride. The two dibromo derivatives, obtained from the reduction product of the ketone (III) and from the substance of m.p. 37.5-38.5°, were also found to be identical. These dibromo derivatives probably have the structure 2,5-bis(5-bromo-2-thenyl) thiophene.

It may, therefore, be considered as established that, under our chosen conditions of chloromethylation, the process proceeds mainly in the direction of the formation of 2- and 2,5-substituted thiophenes of structures (I) and (II). On hydrogenolysis in presence of Raney nickel, the DTT that we isolated from the mixture gave the hydrocarbon $C_{14}H_{30}$, which was identical in properties with n-tetradecane.

Under the above-described conditions, 2-methylthiophene gave a 60-66% yield of a compound of composition $C_{11}H_{12}S_2$, m.p. 38.5-39.5°, together with a high-boiling mixture of products that we did not investigate more closely. In this case also – owing to the presence of an activating group (methyl) in the original alkylthiophene and owing to other causes (see above) – the formation of structures other than (VI) must be admitted as a possibility. However, after synthesizing 2,2'-methylene bis[5-methylthiophene] (VI) according to the scheme:

we convinced ourselves that this is identical with the compound of m.p. 38.5-39.5° mentioned above. Hence, under the given chloromethylation conditions, 2-methylthiophene reacts like thiophene, i.e., mainly in the free α-position. As we have stated, (II) and (VI) can be obtained by Kizhner reduction of the corresponding ketones. The yields of reduction products are quite satisfactory (50-65%). In view of these results, it became clear to us that the statement of the Swedish investigators Lofgren and Tegner [3] to the effect that di-2-thienyl ketone cannot be reduced by the Kizhner method is in error. Actually, in the reduction of this ketone, as also in the reduction of the ketones (III) and (V), we observed no departure from the usual course of reaction and obtained MDT in 65% yield.

The above-described method of synthesizing DTT, which consists in the reduction of the ketone (III) and was used by us as a method of proving the structure of the substance $C_{14}H_{12}S_3$, is not suitable as a method of preparing DTT owing to the fact that the ketone (III) is obtained in low yield. A more suitable method of preparing 2,4-di-2-thenylthiophene consists in the condensation of 2-(chloromethyl) thiophene with the lithium derivative of 2,2'-methylenedithiophene [4]:

Under these conditions DTT is obtained in 47% yield, calculated on the amount of 2,2'-methylenedithiophene that reacted.

EXPERIMENTAL

Reaction of Thiophene with Formaldehyde in presence of Hydrochloric Acid and Zinc Chloride. Hydrochloric acid (82 ml, sp. gr. 1.19) was cooled to −10° and stirred while 108 g (0.78 mole) of anhydrous zinc chloride was added in small portions. When the zinc chloride had dissolved, 100.8 g (1.2 mole) of thiophene was added, and the mixture was stirred at from −7° to 0° while 75 g (0.9 mole) of 37% formaldehyde solution was added dropwise over a period of 1.5-1.75 hours; stirring at this temperature was continued for a further period of one hour.* After being shaken with 150 ml of water, the reaction mixture was extracted with ether; some yellowish-brown resin then separated (about 1 g).** The extract was washed with water, with saturated sodium bicarbonate solution, and again with water. It was dried over calcium chloride, and solvent was distilled off. Vacuum fractionation of the residue gave: Fraction I, b.p. 129-135° (10 mm), 56.3 g, a liquid which solidified after being distilled; Fraction II, b.p. 130-185° (3 mm), 0.8 g, a lemon-yellow liquid; Fraction III, distilling with slight decomposition at 185-240° (3 mm), 16.5 g, n_D^{20} 1.6348, a yellow liquid that thickened after long standing; 24.2 g of residue, a very viscous liquid.

After redistillation Fraction I boiled at 131-133° (11 mm), 54.2 g (50.2%) of 2,2'-methylenedithiophene, m.p. 44.5-46.5° (from alcohol and petroleum ether) being obtained. In some cases the yield of nonrecrystallized product attained 55%. There was no depression of melting point in a mixture test with 2,2'-methylenedithiophene prepared by the reduction of di-2-thienyl ketone (see below).

Found %: C 59.95; 60.24; H 4.55; 4.59; S 35.27; 35.43 $C_9H_8S_2$. Calculated %: C 60.00; H 4.44; S 35.55

After redistillation Fraction III boiled at 184-187° (2 mm), 12.5 g (about 11%) of 2,5-di-2-thenylthiophene being obtained as a yellow oil (n_D^{20} 1.6344) which crystallized when allowed to stand. Recrystallization – from a mixture of butyl alcohol and acetone or of methanol and acetone and then from petroleum ether – gave 2,5-di-2-thenylthiophene in the form of colorless crystals, m.p. 37.5-38.5°.

Found %: C 60.87; 61.13; H 4.36; 4.44; S 34.72; 34.72 $C_{14}H_{12}S_3$. Calculated %: C 60.86; H 4.35; S 34.78
Found: M 271.4 Calculated: M 276.43

---

* Sometimes the reaction mixture solidifies after 10-20 minutes, in which case stirring is stopped.

** When formaldehyde is added rapidly, the temperature of the mixture rises above 0°. The yield of 2,2'-methylenedithiophene is then reduced and the amount of resin formed is increased with formation of difficultly separable suspensions. In this case, the suspension is separated from the aqueous layer, ether is added, and the mixture is shaken; the resin then partially coagulates. The extract is decanted from the settled resin into a separating funnel, ether is again added, and the ether extract is again separated. This procedure is repeated several times.

In admixture with the reduction product from 5-(2-thenyl)-2-thienyl-2-thienyl ketone, this substance showed no depression of melting point.

2,2'-Methylenebis [5-methylthiophene]. The product obtained under the above-described conditions from 34 ml of concentrated hydrochloric acid, 49 g (0.5 mole) of 2-methylthiophene, and 31.2 g (0.386 mole) of 37% formaldehyde solution in presence of 48 g (0.35 mole) of zinc chloride was suitably treated and then distilled at 3 mm. The following fractions were obtained: Fraction I, boiling up to 128.5°, 0.6 g, colorless liquid which solidified almost completely on the introduction of a crystal of 2,2'-methylenebis [5-methylthiophene]; Fraction II, b.p. 128.5-133°, 34.1 g (65.6%), faintly yellow liquid which solidified on standing; Fraction III, b.p. 133-200°, 0.5 g, liquid which solidified on the introduction of a crystal of 2,2'-methylenebis [5-methylthiophene]; Fraction IV, b.p. 200-215° with decomposition, 3.6 g, greenish liquid; residue, 8.7 g, colored vitreous mass. When redistilled, Fraction II boiled at 116-118° (2 mm) and gave 31 g (60%) of a colorless liquid which solidified on standing.

After recrystallization from alcohol 2,2'-methylenebis[5-methylthiophene] had m.p. 38.5-39.5°, undepressed by admixture of the reduction product from bis(5-methyl-2-thienyl) ketone (see below) or of 2,2'-methylenebis [5-methylthiophene] prepared by the method of Emerson and Patrick [9].

Found %: C 63.61; 63.44; H 5.68; 5.76; S 30.84; 30.56 $C_{11}H_{12}S_2$. Calculated %: C 63.44; H 5.77; S 30.77.

Reduction of Di-2-thienyl Ketone. A mixture of 5.82 g (0.03 mole) of di-2-thienyl ketone, 55 ml of diethylene glycol, and 4.5 ml (0.09 mole) of 99% hydrazine hydrate was heated under reflux to 130°. The mixture was cooled, and 6 g (0.10 mole) of potassium hydroxide was added. It was then refluxed for one hour. Water and excess of hydrazine hydrate were then distilled off at 195-200°, and the mixture was again refluxed for three hours. The cooled solution was diluted with 75 ml of water and extracted with ether. This extract was combined with an extract of the aqueous distillate (see above). The extract was shaken with 6 N HCl, with water, with 10% sodium carbonate solution, and again with water; it was then dried over calcium chloride. Solvent was distilled off, and vacuum distillation of the residue gave 3.5 g (65%) of crude di-2-thienyl ketone, b.p. 133-135.5° (12 mm); after recrystallization from alcohol and petroleum ether it melted at 46-47.5°. A mixture of this substance with di-2-thienyl ketone prepared by reaction of thiophene with formaldehyde in presence of hydrochloric acid and zinc chloride melted at 45-47°.

Found %: C 60.00; 60.20; H 4.48; 4.33; S 35.80; 36.09 $C_9H_6S_2$. Calculated %: C 60.00; H 4.44; S 35.55

Reduction of Bis(5-methyl-2-thienyl) Ketone to 2,2'-Methylenebis[5-methylthiophene]. The product obtained by boiling a mixture of 5.55 g of bis(5-methyl-2-thienyl) ketone, 5.6 g of potassium hydroxide, 60 ml of diethylene glycol, and 5 ml of 99% hydrazine hydrate was treated as in the preceding experiment and fractionated at 5 mm. The product, amounting to 3.2 g (62%), was bis(5-methyl-2-thienyl) ketone b.p. 128.5-132°, m.p. 38.5-39.5° (from alcohol).

Found %: C 63.34; 63.23; H 5.74; 5.82; S 30.90; 30.97 $C_{11}H_{12}S_2$. Calculated %: C 63.43; H 5.77; S 30.77.

A mixture of this substance with the bis(5-methyl-2-thienyl) ketone obtained by reaction of 2-methylthiophene with formaldehyde in presence of hydrochloric acid and zinc chloride melted at the same temperature.

Reduction of 5-(2-Thenyl)-2-Thienyl-2-Thienyl Ketone to 2,5-Di-2-thenylthiophene. The product obtained by the action of 1 ml of 99% hydrazine hydrate on 1.5 g of 5-(2-thenyl)-2-thienyl 2-thienyl ketone in 16 ml of diethylene glycol in presence of 1 g of potassium hydroxide was distilled at 3 mm. The product, amounting to 0.72 g (50.5%), was 2,5-di-2-thenylthiophene, b.p. 192-195°, m.p. 37.5-38° (from butyl alcohol).

Found %: C 61.07; 61.28; H 4.23; 4.36; S 34.84; 34.64 $C_{14}H_{12}S_3$. Calculated %: C 60.86; H 4.35 S 34.78.

In admixture with the 2,5-di-2-thenylthiophene obtained in the chloromethylation of thiophene in presence of zinc chloride there was no depression of melting point.

Synthesis of 5-(2-thenyl)-2-thiophenecarboxaldehyde. A mixture of 31.6 g (0.234 mole) of freshly distilled N-methylformanilide and 35.92 g (0.234 mole) of phosphoryl chloride was prepared in a four-necked flask fitted with mercury-sealed stirrer, thermometer, dropping funnel, and calcium chloride tube. After 30 minutes a solution of 32.4 g (0.18 mole) of 2,2'-methylenedithiophene in 40 ml of dry toluene was added at such a rate that the temperature did not rise above 25-35° (one hour was required). The mixture was stirred for a further two hours at this temperature and then left overnight. On the next day it was poured into a mixture of 85 g of crushed ice and 95 ml of water. The diluted reaction mixture was extracted with three 200 ml portions of ether and with one 75 ml portion of toluene. The ether-toluene extract was washed three times with 10% hydrochloric acid solution, several times with saturated sodium bicarbonate solution, and with water. It was dried over calcined magnesium sulfate, and solvent was distilled off. The residue — a dark-red liquid — was vacuum-distilled. The following fractions were obtained: Fraction I, b.p. 122-152° (11 mm), 8 g, a liquid that solidified when a crystal of 2,2'-methylenedithiophene was introduced; Fraction II, b.p. 135-157° (3 mm), 1.1 g, a liquid which did not crystallize when 2, 2'-methylenedithiophene was added; Fraction III, b.p. 158-162° (3 mm), 19 g, n_D^{20} 1.6425, a red oil. A residue of 4.7 g of resin remained in the flask.

Refractionation of Fraction III gave 18 g of oil, b.p. 156-159° (3 mm), n_D^{20} 1.6422, which solidified on standing. Recrystallization from absolute methanol gave 5-(2-thenyl)-2-thiophenecarboxaldehyde, m.p. 33-34°.

Found %: C 58.07; 58.09; H 3.94; 3.74; S 30.86; 30.64 $C_{10}H_8OS_2$. Calculated %: C 57.69; H 3.84; S 30.77.

A mixture of Fractions I and II was again vacuum-fractionated, and 7.3 g (22.5%) of unchanged 2,2'-methylenedithiophene, b.p. 122-130° (10 mm), was obtained. The yield of 5-(2-thenyl)-2-thiophencarboxaldehyde was 48% on the original amount of 2,2'-methylenedithiophene and 63% on the amount that reacted. After recrystallization from alcohol, the semicarbazone of this aldehyde melted at 207-209°.

Found %: N 15.90; 15.77 $C_{11}H_{11}ON_3S_2$. Calculated %: N 15.85.

The oxime melted at 93.5-95° (from dilute alcohol).

Found %: N 6.21; 6.09 $C_{10}H_9ONS_2$. Calculated %: N 6.28.

Preparation of 5-(2-Thenyl)-2-thienyl 2-Thienyl Ketone. A solution of 12.6 g (0.07 mole) of 2,2'-methylenedithiophene in 150 ml of benzene and 10.3 g (0.07 mole) of 2-thiophenecarbonyl chloride were mixed in a four-necked flask fitted with mercury-sealed stirrer, reflux condenser fitted with calcium chloride tube, thermometer, and dropping funnel. The mixture was stirred at 0° for 30 minutes while 18.2 g (0.07 mole) of stannic chloride was added dropwise. The mixture became dark in color and resin appeared on the walls of the vessel. Stirring was continued for a further one hour at room temperature, and 150 ml of 10% aqueous hydrochloric acid was then added. After stirring for three hours and removal of the liquid part, the residual resin was repeatedly shaken and heated with new portions of benzene and hydrochloric acid, but the amount of the resin did not diminish appreciably. The benzene extracts were combined and washed with water, with saturated sodium bicarbonate solution, and again with water. They were dried over calcium chloride, the solvent was distilled off, and the residue was fractionated at 3 mm. The following fractions were obtained: Fraction I, b.p. 101-102°, 1 g, a liquid that solidified when some 2,2'-methylenedithiophene was added; Fraction II, b.p. 232-235°, 2.4 g, a yellow oil that solidified in the receiver; residue, 8.3 g of resin.

Fraction II, after repeated recrystallization from methanol and ethanol, melted at 104.5-105.5°.

Found %: C 57.92; 57.81; H 3.27; 3.31 $C_{14}H_{10}OS_3$. Calculated %: C 57.93; H 3.44.

Found: M 281.5 (cryoscopically)
Calculated: M 290.

The yield of crude 5-(2-thenyl)-2-thienyl 2-thienyl ketone was about 12%.

Reductive Desulfurization of 5-(2-Thenyl)-2-thiophenecarboxaldehyde. Preparation of n-Decyl Alcohol. A mixture of 10.4 g (0.05 mole) of 5-(2-thenyl)-2-thiophenecarboxaldehyde, 750 ml of ethanol, and 100 g of Raney nickel* was stirred under reflux for 3.5 hours in a boiling water bath. The mixture was allowed to settle for 16 hours, and the alcoholic solution was decanted and the catalyst was treated three times with stirring with 200 ml portions of hot ethanol. The catalyst was filtered off. Alcohol was distilled from the alcoholic solution, and about 150 ml of water was added to the residue. The mixture was extracted with chloroform, and the extract was dried over magnesium sulfate. The residue was vacuum-distilled: Fraction I, b.p. 115-117° (13-14 mm) 3.2 g (35.4%), colorless pleasantly smelling liquid, which solidified when cooled strongly; n_D^{20} 1.4380, d_4^{20} 0.8328; Found MR 49.87; Calculated MR 49.90.

Found %: C 75.91; 75.70; H 13.72; 13.59. $C_{10}H_{22}O$. Calculated %: C 75.96; H 13.98.

The residue, 1.2 g, was a viscous mass.

After recrystallization from 95% ethanol, the phenylurethane obtained from Fraction I melted at 58.5-59.5°.

Found %: C 73.41; 73.67; H 9.78; 9.87; N 5.13; 5.31 $C_{17}H_{27}O_2N$. Calculated %: C 73.65; H 9.74; N 5.05.

There was no depression of melting point in admixture with the phenylurethane of a known sample of decyl alcohol. According to the literature [11], this urethane melts at 59.6°.

Reduction Desulfurization of 2,5-Di-2-thenylthiophene. Preparation of n-Tetradecane. The hydrogenolysis product obtained from 9.66 g (0.035 mole) of unrecrystallized 2,5-di-2-thenylthiophene, 100 g of Raney nickel, and 750 ml of ethanol was vacuum-fractionated: Fraction I, b.p. 114-118° (10 mm), 4.1 g (59.2%), n_D^{20} 1.4310, colorless liquid that solidified when cooled strongly;

Found %: C 84.75; 85.01; H 15.13; 15.19 $C_{14}H_{30}$. Calculated %: C 84.85; H 15.15.

Fraction II, b.p. 185-205° (3 mm), 0.75 g, a yellow oil, which solidified in the side tube; residue in flask, 0.3 g, immobile yellow mass.

Redistillation of Fraction I gave:

Fraction Ia: b.p. 109-115° (11 mm); 0.67, n_D^{20} 1.4291.
Fraction Ib: b.p. 115-118° (11 mm) 3.1 g, n_D^{20} 1.4301, d_4^{20} 0.7646, Found MR 67.03; Calculated MR 66.85.

Recrystallization of Fraction II from alcohol gave a sulfur-free crystalline substance of indefinite melting point: it became "wet" at 45°, started to melt at 49.5°, and was completely melted at 57°.

Found %: C 85.38; 85.56; H 14.72; 14.72

This substance is probably a mixture of solid hydrocarbons of high molecular weight.

Bromination of 2,5-Di-2-thenylthiophene. A mixture of 8.28 g (0.03 mole) of 2,5-di-2-thenylthiophene obtained in the chloromethylation of thiophene (see above), 130 ml of benzene, and 130 ml of concentrated hydrochloric acid was cooled to 5-7°, and the mixture was stirred while 253 ml of 0.522 N bromide-bromate mixture was added dropwise over a period of about two hours. The mixture was stirred for three hours further at the same temperature, the organic layer was separated, and the aqueous part was extracted with benzene. The organic layer was combined with the extract and washed with water, with 10% sodium hydroxide solution, with saturated thiosulfate solution, and again with water; it was then allowed to stand over solid potassium hydroxide. The residue remaining after removal of solvent was a dark-colored hard resinous mass. It was boiled with alcohol in presence of activated charcoal. A yellowish crystalline substance was isolated from the

* The catalyst was prepared from 30% nickel-aluminum alloy by the method of Billica and Adkins [10], with the exception that the treatment with water was not carried out in a hydrogen atmosphere and the washing with alcohol was carried out without centrifugation.

alcoholic solution (6 g, i.e., 46%). After repeated recrystallization from alcohol it melted at 59-60°.

Found %: C 38.83; 39.00; H 2.24; 2.38 $C_{14}H_{10}Br_2S_3$. Calculated %: C 38.71; H 2.33.

Bromination of the Reduction Product of 5-(2-Thenyl)-2-Thienyl 2-Thienyl Ketone. This was carried out under the conditions described for the preceding experiment. Reaction was between 0.35 g of the reduction product in 6 ml of benzene, 6 ml of concentrated hydrochloric acid, and 10.4 ml of 0.5161 N bromide-bromate mixture. Recrystallization of the product from alcohol in presence of activated charcoal gave 0.08 g of crystals, m.p. 58-59°.

Found %: C 38.96; 38.84; H 2.36; 2.35 $C_{14}H_{10}Br_2S_3$. Calculated %: C 38.71; H 2.33.

A mixture test of this substance with the dibromo compound obtained from 2,5-di-2-thenylthiophene showed no depression of melting point.

Preparation of Bis(5-methyl-2-thienyl) Ketone [12]. A solution of 6.8 ml (0.0583 mole) of stannic chloride in 7 ml of benzene was added over a period of 40 minutes to a vigorously stirred cooled mixture of 9.4 g (0.0583 mole) of 5-methyl-2-thiophenecarbonyl chloride, 5.72 g (0.0583 mole) of 2 methylthiophene, and 60 ml of dry benzene at from −2° to 0°.

Stirring was continued for one hour without external cooling, and the mixture was treated with 10% aqueous hydrochloric acid. The aqueous layer was extracted with benzene. The benzene solution was washed with water and dried with calcium chloride. Benzene was distilled off, and the residue was vacuum-distilled. The product, amounting to 11.38 g (88%), was bis(5-methyl-2-thienyl) ketone, b.p. 212-214° (13 mm), m.p. 48-49° after recrystallization from dilute methanol (the literature [13] gives m.p. 53°).

Found %: C 59.63; 59.42; H 4.48; 4.46 $C_{11}H_{10}S_3$. Calculated %: C 59.46; H 4.5.

Preparation of 2,5-Di-2-thenylthiophene. The experiment was carried out in an atmosphere of nitrogen. Over a period of 40 minutes at from −3° to 0°, 153 ml of a 0.65 N ethereal solution of butyllithium (0.1 mole) was added to a solution of 22 g (0.122 mole) of 2,2'-methylenedithiophene in 160 ml of absolute methanol, precautions being taken to exclude atmospheric moisture. The contents of the flask were stirred for a further 20 minutes, and at from −2° to 0° 14.2 g (0.107 mole) of 2-(chloromethyl) thiophene in 60 ml of dry ether was added over a period of 70 minutes. After 15 hours at room temperature and six hours under reflux in a boiling water bath, the mixture was decomposed with 100 ml of water. The ethereal layer was separated, washed with water, and dried over calcium chloride. The residue after removal of ether was vacuum-fractionated. The following fractions were obtained: Fraction I, b.p. 60-120 (24 mm), 2.34 g, a yellow liquid of pungent odor; Fraction II, b.p. 95-190° (12-13 mm), 10.9 g, a yellow liquid that partially solidified on standing; Fraction III, b.p. 192-215° (4 mm), 12 g, yellowish-brown liquid that solidified when cooled; residue in flask, 6.64 g, reddish-brown viscous liquid.

Redistillation of Fraction II gave 7 g of unchanged 2,2'-methylenedithiophene, b.p. 128-135° (12 mm) and 0.82 g of 2,5-di-2-thenylthiophene, b.p. 188-193° (3 mm).

On redistillation Fraction III boiled at 188-192° (3 mm), and 10.07 g of 2,5-di-2-thenylthiophene was obtained as a yellowish oil that solidified on standing. The total yield of 2,5-di-2-thenylthiophene was 10.9 g (47% on the amount of 2,2'-methylenedithiophene that reacted). Recrystallization, first from a mixture of butyl alcohol and acetone and then from petroleum ether, gave colorless crystals, m.p. 37.2-38.2°.

Found %: C 60.78; 60.71; H 4.46; 4.46; S 34.65; 34.80 $C_{14}H_{12}S_3$. Calculated %: C 60.86; H 4.35; S 34.78.
Found: M 265
Calculated: M 276.43.

A mixture test of this product and the 2,5-di-2-thenylthiophene obtained in the chloromethylation of thiophene in presence of zinc chloride (see above) showed no depression of melting point (the mixture melted at 37.5-38.5°).

SUMMARY

1. Readily accessible methods for the preparation of 2,2'-methylenedithiophene and 2,2'-methylenebis-[5-methylthiophene] are described.

2. It is shown that the product of composition $C_{14}H_{12}S_3$ formed together with 2,2'-methylenedithiophene under the conditions of chloromethylation of thiophene is 2,5-di-2-thenylthiophene.

3. It is shown that, contrary to reports in the literature, di-2-thienyl ketone can be reduced by the Kizhner method.

4. By hydrogenolysis treatments, 2,5-di-2-thenylthiophene was converted into n-tetradecane and 5(2-thienyl)-2 thiophenecarboxaldehyde was converted into n-decyl alcohol.

5. A method was worked out for the preparation of 2,5-di-2-thenylthiophene.

ACETYLENE DERIVATIVES

COMMUNICATION 177. CONDENSATION OF AROMATIC AND ALIPHATIC-AROMATIC KETONES WITH ACETYLENE UNDER PRESSURE. PART III.

I. N. Nazarov and V. F. Ryabchenko

In previous communications [1] we described a new method for the synthesis of acetylenic alcohols by the condensation of aldehydes and ketones with acetylene under pressure in presence of potassium hydroxide powder. Aldehydes and ketones of the most varied types can be condensed readily and rapidly with acetylene by this method, and in most cases the corresponding acetylenic alcohols are obtained in almost theoretical yield. It was of great interest to make use of this method for the preparation also of acetylenic alcohols containing aromatic radicals.

Attempts made by many investigators [2-4] to effect the condensation of acetylene with aromatic and aliphatic-aromatic ketones with the object of obtaining the corresponding acetylenic alcohols did not generally give satisfactory results, and these alcohols have remained very difficultly accessible. Condensation with acetylene at atmospheric pressure was carried out satisfactorily only for p-tolyl ketones, the corresponding acetylenic alcohols being obtained in yields of about 70% [5]. However, the development of a fairly simple method for the synthesis of various acetylenic alcohols containing aromatic radicals can be of great importance for the further development of acetylene-based organic synthesis. We therefore decided to make a careful investigation of the condensation of acetylene with aromatic and aliphatic-aromatic ketones by our method of reaction under a pressure of acetylene.

It was found that, in presence of potassium hydroxide powder at room temperature, aromatic and aliphatic-aromatic ketones of the benzo- and aceto-phenone types readily condense with acetylene under a pressure of 5-10 atm and give the corresponding tertiary acetylenic alcohols in yields of greater than 90%:

R = alkyl, Ar = aryl.

The success of these condensations depends not only on the use of acetylene under pressure, but also on the use of a considerable excess (2-3 molecular proportions) of potassium hydroxide and a long period (4-6 hours) of reaction. On the other hand, aliphatic, alicyclic, and heterocyclic ketones condense with acetylene under pressure rapidly and almost completely in presence of the equivalent amount of potassium hydroxide.

As already pointed out [1], the yield of acetylenic alcohol is improved appreciably by addition of a little aliphatic alcohol (ethanol) to the reaction mixture; the alcohol serves as a carrier of potassium ions in the organometallic mechanism of this condensation:

$$ROH + KOH \rightleftarrows ROK + H_2O;$$
$$ROK + CH \equiv CH \rightleftarrows CH \equiv CK + ROH.$$

When condensation is not complete, the unchanged ketone can be recovered almost completely. The use of an excess of potassium hydroxide and acetylene under pressure increases the concentration of potassium acetylide in the reaction mixture and ensures that conditions exist for the completion of reaction. In this way we prepared the following acetylenic alcohols:

(I) (II) (III)

(IV) (V) (VI)

By the selective hydrogenation [6] of the resulting acetylenic alcohols in presence of a palladium catalyst almost quantitative yields of the corresponding ethylenic alcohols (IX) were obtained, and dehydration of these gave 2-aryl-1,3-butadienes (X):

2-Aryl-3-buten-2-ols readily lose water under the action of various dehydrating agents (potassium hydrogen sulfate, p-toluenesulfonic acid, alumina, magnesium sulfate, etc.), and the 2-aryl-1,3-butadienes then formed polymerize extremely readily, which makes their isolation difficult. The highest yield of 2-arylbutadienes (about 80%) was obtained by distillation of 2-aryl-3-buten-2-ols under reduced pressure in presence of a small amount of potassium hydrogen sulfate powder (0.1-1%) or by passage of the alcohols, diluted with water, over alumina at 240-280° under somewhat reduced pressure. In all cases it is desirable to carry out the dehydration in an atmosphere of nitrogen and to remove the 2-arylbutadienes as rapidly as possible from the reaction zone in order to avoid polymer (dimer) formation. Some dehydrating agents, e.g., p-toluenesulfonic acid, bring about rapid polymerization of 2-arylbutadienes and are, therefore, not suitable for the dehydration of 2-aryl-3-buten-2-ols.

Of the 2-arylbutadienes that we investigated, 2-p-methoxyphenyl-1,3-butadiene polymerized most rapidly and was most difficult to prepare. The diene properties of 2-arylbutadienes are so marked that, even at room

temperature (during storage), they are fairly rapidly converted into dimers; they condense extremely readily with maleic anhydride with formation of the corresponding adducts (XI):

Ar = C_6H_5, p-$CH_3OC_6H_4$, p-ClC_6H_4.

Instead of the 2-arylbutadienes, the 2-aryl-3-buten-2-ols may be used directly in the diene condensation, but they may be dehydrated under the conditions of the reaction. For example, when 2-p-methoxyphenyl-3-buten-2-ol is treated with maleic anhydride in boiling xylene for 20-25 minutes, the corresponding adduct of 2-p-methoxyphenyl-1,3-butadiene is formed in 60% yield:

EXPERIMENTAL

Substituted acetophenones were prepared by the Friedel-Crafts reaction from the corresponding substituted benzenes and acetic anhydride in presence of aluminum chloride. The condensation of aliphatic-aromatic and aromatic ketones with acetylene under pressure was carried out in a steel reactor, as described in a previous communication [1].

Condensation of Acetylene with Acetophenone

A mixture of 470 g of potassium hydroxide powder, 15 ml of ethanol, and 1600 ml of dry ether was saturated with acetylene at 15° and 8 atm. In the course of 90 minutes 360 g of acetophenone was introduced into the reactor, and stirring of the reaction mixture under these conditions then continued for a further four hours. The pressure was released, and 900 ml of water was added to the reactor. The mixture was stirred carefully, and the aqueous alkaline layer was removed. The ethereal solution was saturated with carbon dioxide and dried with potassium carbonate. Vacuum fractionation of the product gave 398 g of pure 2-phenyl-3-butyn-2-ol (I), b.p. 82-83° (4 mm), m.p. 49° [7]. The yield was 91%.

Found %: C 82.00; 82.06; H 6.94; 7.05 $C_{10}H_{10}O$. Calculated %: C 82.05; H 6.85.

In this experiment, 5 g of the original acetophenone and 20 g of the acetylenic glycol were also isolated. This condensation was carried out in presence of sodamide by Carothers [2], who obtained 2-phenyl-3-butyn-2-ol (I) in a yield of only about 2%.

Condensation of Acetylene with 4'-Methylacetophenone

A mixture of 200 g of potassium hydroxide powder, 400 ml of ether, and 4 ml of ethanol was saturated with acetylene at 30° and 10 atm. In the course of 70 minutes 110 g of 4'-methylacetophenone in 100 ml of ether was introduced into the reactor, and stirring continued for a further five hours. The usual treatment gave 104 g of 2-p-tolyl-3-butyn-2-ol (II), b.p. 103-104° (4 mm); n_D^{20} 1.5304; d_4^{20} 1.0081; Found MR 49.03; Calculated MR 48.92.

Found %: C 82.42; 82.23; H 7.56; 7.61 $C_{11}H_{12}O$. Calculated %: C 82.50; H 7.50.

In addition, 3.4 g of the acetylenic glycol and 16 g of the original 4'-methylacetophenone were isolated. The yield of the acetylenic alcohol (II) was 80% of the amount of 4'-methylacetophenone taken and 93% on the amount that reacted. As Lebedev [5] showed, in the condensation of acetylene with 4'-methylacetophenone in presence of potassium hydroxide at atmospheric pressure, the acetylenic alcohol (II) is formed in only 5% yield.

Condensation of Acetylene with 4'-Methoxyacetophenone

A mixture of 200 g of potassium hydroxide powder, 350 ml of ether, and 3 ml of ethanol was saturated with acetylene at 25° and 10 atm. In the course of 80 minutes 110 g of 4'-methoxyacetophenone was introduced into the reactor, and stirring was then continued for four hours. The usual treatment gave 110 g (86%) of 2-p-methoxyphenyl-3-butyn-2-ol (III) b.p. 108-109° (1 mm), m.p. 35° (from petroleum ether), n_D^{20} 1.5440, d_4^{20} 1.0869, Found MR 50.81; Calculated MR 50.58.

Found %: C 74.76; 74.94; H 6.92; 6.93 $C_{11}H_{12}O_2$. Calculated %: C 75.00; H 6.87.

In addition, 1.6 g of the acetylenic alcohol was obtained.

Condensation of Acetylene with 4'-Chloroacetophenone

A mixture of 200 g of potassium hydroxide powder, 400 ml of ether, and 4 ml of ethanol was saturated with acetylene at 20° and 10 atm. In the course of 80 minutes 110 g of 4'-chloroacetophenone in 100 ml of ether was introduced into the reactor, and stirring was then continued for four hours. The usual treatment gave 122 g (95.5%) of pure 2-p-chloro-3-butyn-2-ol (IV), b.p. 113-114° (5 mm); n_D^{20} 1.5460 [8]; b.p. 43° (from isooctane).

Found %: C 65.50; 65.53; H 5.20; 5.23; Cl 19.53; 19.41 $C_{10}H_9OCl$. Calculated %: C 65.80; H 5.00; Cl 19.66.

Condensation of Acetylene with 3',4'-Dichloroacetophenone

A mixture of 180 g of potassium hydroxide powder, 400 ml of ether, and 4 ml of ethanol was saturated with acetylene at 25° and 10 atm. In the course of 80 minutes 95 g of 3',4'-dichloroacetophenone in 100 ml of ether was introduced into the reactor, and stirring was then continued for five hours. The usual treatment gave 98 g of 2-(3,4-dichlorophenyl)-3-butyn-2-ol (V), b.p. 122-123° (3 mm); n_D^{20} 1.5620; m.p. 112°.

Found %: C 55.86; 55.98; H 3.84; 3.78; Cl 32.98; 32.98 $C_{10}H_8OCl_2$. Calculated %: C 55.80; H 3.72; Cl 32.71.

In addition, 2 g of the acetylenic alcohol and 4.1 g of the original 3',4'-dichloroacetophenone were isolated. The yield of the acetylenic alcohol (V) was 91% on the amount of 3',4'-dichloroacetophenone taken and 96% on the amount that reacted.

Condensation of Acetylene with 4'-Bromoacetophenone

A mixture of 100 g of potassium hydroxide powder, 350 ml of ether, and 3 ml of ethanol was saturated with acetylene at 20° and 10 atm. In the course of 90 minutes 50 g of 4'-bromoacetophenone in 50 ml of ether was introduced into the reactor, and stirring was then continued for five hours. The product, amounting to 45 g, was 2-p-bromophenyl-3-butyn-2-ol (VI), b.p. 120-121° (3 mm); n_D^{20} 1.5720; m.p. 41-42° (from isoctane).

Found %: Br 35.95; 35.86; C 53.25; 53.12; H 4.02; 3.97 $C_{10}H_9OBr$. Calculated %: Br 35.56; C 53.33; H 4.00.

In addition, 0.8 g of the acetylenic glycol and 7 g of the original ketone were obtained. The yield of the acetylenic alcohol (VI) was 80% on the amount of 4'-bromoacetophenone taken and 92% on the amount that reacted.

Condensation of Acetylene with Propiophenone

A mixture of 200 g of potassium hydroxide powder, 400 ml of ether, and 4 ml of ethanol was saturated with acetylene at 25° and 10 atm. In the course of 80 minutes 120 g of propiophenone in 100 ml of ether was introduced into the reactor, and stirring was then continued for five hours. The usual treatment gave 122 g of 3-phenyl-1-pentyn-3-ol (VII), b.p. 86-87° (2 mm); n_D^{20} 1.5302; b.p. 34° [9].

Found %: C 82.57; 82.59; H 7.47; 7.54 $C_{11}H_{12}O$. Calculated %: C 82.50; H 7.50.

Also, 0.8 g of the acetylenic glycol and 5 g of the original propiophenone were obtained. The yield of the acetylenic alcohol (VII) was 85% on the amount of ketone taken and 89% on the amount that reacted.

Condensation of Acetylene with Benzophenone

A mixture of 120 g of potassium hydroxide powder, 250 ml of ether, and 5 ml of ethanol was saturated with acetylene at 10° and 9 atm. In the course of 85 minutes 91 g of benzophenone in 100 ml of ether was introduced into the reactor, and stirring was then continued for five hours. The usual treatment gave 97.5 g of pure 1,1-diphenyl-2-propyn-1-ol (VIII), b.p. 43-44° [10]; yield 93.5%.

Found %: C 86.29; 85.92; H 5.90; 5.78 $C_{15}H_{12}O$. Calculated %: C 86.45; H 5.79

According to Zakharova [4], condensation of benzophenone with acetylene in presence of potassium hydroxide at ordinary pressure gives 1,1-diphenyl-2-propyn-1-ol (VIII) in 30-40% yield, but it is very difficult to isolate it from the mixture with unchanged benzophenone and tetraphenylbutynediol. When 1,1-diphenyl-2-propyn-1-ol (30 g) is exhaustively hydrogenated over a platinum catalyst, it absorbs the theoretical amount of hydrogen (6.6 liters) and gives a quantitative yield of 1,1-diphenyl-1-propanol, m.p. 94-95°.

2-Phenyl-3-buten-2-ol (IX, Ar = C_6H_5)

2-Phenyl-3-butyn-2-ol (I) (128.5 g; m.p. 49°) was hydrogenated in 150 ml of dry methanol in presence of a palladium catalyst [11] supported on calcium carbonate (5% Pd). After the absorption of one molecular proportion of hydrogen (20.8 liters), the hydrogenation was stopped. The selectivity of hydrogenation was verified by testing for an acetylene with ammoniacal silver nitrate (in alcohol), the sensitivity of which is not below 0.5%. When the pure acetylenic alcohol was used, the test did not become negative until exactly one molecular proportion of hydrogen had been absorbed. After the hydrogenation, the catalyst was filtered off, methanol was distilled off, and the residue was vacuum-distilled. The product, amounting to 128 g, was 2-phenyl-3-buten-2-ol (IX, Ar = C_6H_5), b.p. 87-88° (6 mm); n_D^{20} 1.5344 [12].

Found %: C 81.08; 81.28; H 8.14; 8.18 $C_{10}H_{12}O_2$. Calculated %: C 81.10; H 8.11.

When this ethylenic alcohol was exhaustively hydrogenated in presence of a platinum catalyst, it absorbed one molecular proportion of hydrogen and gave 2-phenyl-2-butanol, b.p. 95-96° (13 mm); n_D^{15} 1.5202 [13].

2-p-Methoxyphenyl-3-buten-2-ol (IX, Ar = p-$CH_3OC_6H_4$)

2-p-Methoxyphenyl-3-butyn-2-ol (III) (30 g; m.p. 35°) was hydrogenated as a solution in 50 ml of dry dioxane in presence of a palladium catalyst. When 4025 ml of hydrogen (18°, 755 mm) (i.e., one molecular proportion) had been absorbed, the test for an acetylene became negative and hydrogenation was stopped. The product, amounting to 29 g, was 2-p- methoxyphenyl-3-buten-2-ol (IX, Ar = p-$CH_3OC_6H_4$), b.p. 109-110° (2 mm); n_D^{20} 1.5393; d_4^{20} 1.056; Found MR 52.82; Calculated MR 52.1.

Found % : C 74.16; 74.10; H 7.99; 8.07 $C_{11}H_{14}O_2$. Calculated %: C 74.20; H 7.89.

2-p-Chlorophenyl-3-buten-2-ol (IX, Ar = p-ClC_6H_4)

2-p-Chlorophenyl-3-butyn-2-ol (IV) (52 g; m.p. 43°) was hydrogenated as a solution in 65 ml of dioxane in presence of a palladium catalyst. After the absorption of one molecular proportion of hydrogen (6650 ml at 750 mm and 19°), the test for an acetylene became negative and hydrogenation was stopped. The product was 52 g of 2-p-chlorophenyl-3-buten-2-ol (IX, Ar = p-ClC_6H_4), b.p. 160-107° (5 mm); n_D^{20} 1.5448; d_4^{20} 1.135; Found MR 50.77, Calculated MR 50.71.

Found %: C 65.44; 65.30; H 6.22; 6.19; Cl 20.23; 19.50 $C_{10}H_{11}OCl$. Calculated %: C 65.56; H 6.05; Cl 19.50.

2-Phenyl-1,3-butadiene (X, Ar = C_6H_5)

1. A mixture of 20 g of 2-phenyl-3-buten-2-ol and 0.5 g of finely ground potassium hydrogen sulfate was heated at a bath temperature of 110° in nitrogen at a residual pressure of 10 mm. Crude 2-phenyl-1,3-butadiene (14.8g) came over; drying and redistillation gave 14 g (80%) of pure product, b.p. 62° (13 mm); n_D^{20} 1.5489 [14]. The 2-phenyl-1,3-butadiene so obtained was condensed with maleic anhydride in benzene solution at room temperature for 24 hours, and an almost quantitative yield of the adduct (XI, Ar = C_6H_5), m.p. 104° [14], was obtained. From the residue in the distillation flask, 3.5 g of the dimer of 2-phenyl-1,3-butadiene, b.p. 187-190° (6 mm), was obtained.

2. In nitrogen at a residual pressure of 200 mm, 50 g of 2-phenyl-3-buten-2-ol diluted with an equal amount of water was passed into a catalysis tube filled with granulated alumina (70 g) at a rate of 3 ml per minute. The product was separated from the aqueous layer, dried, and vacuum-distilled. The pure 2-phenyl-1,3-butadiene so obtained amounted to 34.4 g (79%) and had b.p. 62° (13 mm) and n_D^{20} 1.5486; it gave an adduct of m.p. 104° with maleic anhydride. From the residue in the flask, 5.2 g of dimer, b.p. 188-190° (6 mm) was isolated.

2-p-Methoxyphenyl-1,3-butadiene (X, Ar = p-$CH_3OC_6H_4$)

A mixture of 5 g of 2-p-methoxyphenyl-3-buten-2-ol and 5 mg of potassium hydrogen sulfate was heated in nitrogen at a residual pressure of 3 mm at a bath temperature of 100°. The product was dried with calcium chloride and distilled under a reduced pressure of nitrogen. The 2-p-methoxyphenyl-1,3-butadiene obtained (X, Ar = p-$CH_3OC_6H_4$) amounted to 1.5 g (35%) and had b.p. 80° (3 mm); n_D^{20} 1.5554, d_4^{20} 0.934.

Found %: C 82.20; 81.97; H 7.63; 7.69. $C_{11}H_{12}O$. Calculated %: C 82.45; H 7.50.

Condensation of this diene with maleic anhydride in benzene solution gave a quantitative yield of the adduct (XI, Ar = p-$CH_3OC_6H_4$), m.p. 124°.

Found %: C 70.17; 69.93; H 5.69; 5.59. $C_{15}H_{14}O_4$. Calculated %: C 69.99; H 5.45.

The same adduct was obtained in a yield of about 60% also by heating maleic anhydride with 2-p-methoxyphenyl-3-buten-2-ol in boiling xylene for 25 minutes.

When the dehydration of 2-p-methoxyphenyl-3-buten-2-ol was effected with large amounts of potassium hydrogen sulfate (0.5-1%) or in presence of even small amounts of p-toluenesulfonic acid (0.1-0.2%), almost complete polymerization of the resulting 2-p-methoxyphenyl-1,3-butadiene occurred.

2-p-Chlorophenyl-1,3-butadiene (X, Ar = p-ClC_6H_4)

A mixture of 10 g of 2-p-chlorophenyl-3-buten-2-ol and 0.1 g of potassium hydrogen sulfate was heated in nitrogen at a residual pressure of 5 mm at a bath temperature of 100-110°. The distillate was dried with potassium carbonate. Vacuum distillation gave 6.1 g (70%) of 2-p-chlorophenyl-1,3-butadiene, b.p. 64° (3 mm); n_D^{20} 1.5612; d_4^{20} 1.070; Found MR 50.55; Calculated MR 48.91.

Found %: C 72.42; 72.44; H 5.60; 5.52; Cl 22.02; 22.04 $C_{10}H_9Cl$. Calculated %: C 72.80; H 5.47; Cl 21.60.

Condensation of this diene with maleic anhydride in benzene solution gave a quantitative yield of the adduct (XI, Ar = p-ClC_6H_4), m.p. 129°.

Found %: C 64.17; 64.46; H 4.28; 4.37; Cl 14.12; 13.85 $C_{14}H_{11}O_3Cl$. Calculated %: C 64.01; H 4.19; Cl 13.59.

SUMMARY

In presence of potassium hydroxide powder, aliphatic-aromatic and aromatic ketones of the aceto- and benzo-phenone types condense smoothly with acetylene at a pressure of 5-10 atm with formation of the corresponding tertiary acetylenic alcohols in yields of more than 90%. When the 2-aryl-3-butyn-2-ols so obtained are selectively hydrogenated over a palladium catalyst, 2-aryl-3-buten-2-ols are obtained in almost quantitative yield, and dehydration of these gives 2-aryl-1,3-butadienes, which are extremely reactive in polymerization (dimerization) reactions and in the diene condensation.

ACETYLENE DERIVATIVES

COMMUNICATION 178. 2-CYANOETHYL ETHERS OF ACETYLENIC ALCOHOLS CONTAINING AROMATIC SUBSTITUENTS

We have recently described [1] the cyanoethylation of 2-phenyl-3-butyn-2-ol and 1,1-diphenyl-2-propyn-1-ol. Extending this investigation, we have studied the cyanoethylation of some other aliphatic-aromatic acetylenic alcohols that are readily prepared by the condensation of acetylene with substituted acetophenones by the method developed in our laboratory [2].

The cyanoethylation of these acetylenic alcohols proceeds smoothly in presence of 40% aqueous potassium hydroxide, the corresponding 2-cyanoethyl ethers being obtained in yields of more than 90%. In this way we prepared the 2-cyanoethyl ethers of the following acetylenic alcohols: 2-p-tolyl-, 2-p-chlorophenyl-, 2-p-bromophenyl-, 2-p-methoxyphenyl-, and 2-(3,4-dichlorophenyl)-3-butyn-2-ols, and 3-phenyl- and 3-p-methoxyphenyl-1-pentyn-3-ols:

Also, we repeated the cyanoethylation of 2-phenyl-3-butyn-2-ol and 1,1-diphenyl-2-propyn-1-ol under somewhat modified conditions, and we obtained better results than those described in the previous paper [1].

The resulting 2-cyanoethyl ethers of aromatic acetylenic alcohols of general formula

are given in Table 1.

Unlike the 2-cyanoethyl ethers of dialkylethynylmethanols [3], these 2-cyanoethyl ethers of aromatic acetylenic alcohols do not undergo the Mannich reaction, do not give ketones when attempts are made to hydrate the triple bond, and are completely resinified under alcoholysis conditions. By treatment of the 2-

cyanoethyl ethers (I-IX) with alkaline hydrogen peroxide [4] we succeeded in obtaining the corresponding amides in yields of about 90%.

The amides so obtained, general formula

are given in Table 2.

EXPERIMENTAL

Reaction of Acrylonitrile with 2-p-Tolyl-3-butyn-2-ol

A mixture of 58 g (0.36 mole) of 2-p-tolyl-3-butyn-2-ol [b.p. 103-104° (4 mm)] and 8 g of 40% aqueous potassium hydroxide was prepared in a three-necked flask fitted with mechanical stirrer, thermometer, and reflux condenser. The mixture was stirred vigorously for 90 minutes while 21 g (0.4 mole) of acrylonitrile was added. The temperature of the reaction mixture gradually rose to 40-50°. The mixture was stirred for six hours; the temperature fell to 20° during the first two hours and further stirring was continued at room temperature. The mixture was set aside overnight, and on the next day it was neutralized with hydrochloric acid (1 : 1); it was extracted with ether, and the extract was dried with magnesium sulfate. Fractionation gave 75.4 g of the 2-cyanoethyl ether of 2-p-tolyl-3-butyn-2-ol (I), b.p. 134-136° (2 mm) and n_D^{20} 1.5126.

Found %: N 6.26; 6.01 $C_{14}H_{15}NO$. Calculated %: N 6.57.

*From a mixture of diethyl ether and petroleum ether.

**From gasoline.

***From a mixture of benzene and petroleum ether.

Other 2-cyanoethyl ethers listed in Table 1 were prepared similarly.

Reaction of Acrylonitrile with 3-Phenyl-1-pentyn-3-ol

Acrylonitrile (12 g, i.e., 0.26 mole) was added over a period of one hour to a vigorously stirred mixture of 32 g (0.2 mole) of 3-phenyl-1-pentyn-3-ol (b.p. 86-87° (2 mm)), 10 ml of dioxane, and 3 g of 40% aqueous potassium hydroxide. The temperature of the mixture rose spontaneously to 30° and then fell to room temperature in the course of six hours. On the next day the reaction mixture was neutralized with hydrochloric acid (1:1) and was stirred with 5 g of ferrous sulfate for 30 minutes (to destroy oxides). The mixture was extracted with ether, and the extract was dried with magnesium sulfate. Vacuum fractionation gave 40.8 g of the 2-cyanoethyl ether of 3-phenyl-1-pentyn-3-ol (VI), b.p. 127-129° (2 mm) and n_D^{20} 1.5116.

Found %: N 6.13; 6.19 $C_{14}H_{15}NO$. Calulated %: N 6.57.

The 2-cyanoethyl ether (VII) was synthesized in the same way, but without the use of dioxane.

Reaction of Acrylonitrile with 2-Phenyl-3-butyn-2-ol

Acrylonitrile (28 g, i.e., 0.53 mole) was added over a period of 90 minutes to a vigorously stirred mixture of 73 g (0.5 mole) of 2-phenyl-3-butyn-2-ol [b.p. 106-107° (15 mm)], 25 ml of dioxane, and 10 g of 40% aqueous potassium hydroxide. At first the temperature of the mixture rose spontaneously to 40°, and it then fell to room temperature in the course of two hours. On the next day the mixture was neutralized with hydrochloric acid (1:1) and treated as in the preceding experiment (preparation of the 2-cyanoethyl ether (VI)). The product, amounting to 91.4 g, was the 2-cyanoethyl ether of 2-phenyl-3-butyn-2-ol (VIII), b.p. 120-123° (4mm); and n_D^{20} 1.5127, and 5.8 g of the acetylenic alcohol was recovered unchanged.

Reaction of Acrylonitrile with 1,1-Diphenyl-2-propyn-1-ol

A mixture of 35 g (0.17 mole) of 1,1-diphenyl-2-propyn-1-ol [b.p. 125-126° (1 mm)], 10 g (0.19 mole) of acrylonitrile, 35 ml of dioxane, and 5 g of 40% aqueous potassium hydroxide was stirred for six hours and then set aside overnight. The usual treatment gave 43.2 g of the 2-cyanoethyl ether of 1,1-diphenyl-2-propyn-1-ol (IX), b.p. 188-196° (6 mm), m.p. 84-85° (from petroleum ether).

Reaction of the 2-Cyanoethyl Ether of 2-Phenyl-3-butyn-2-ol (VIII) with Diethylamine and Paraform

1. A mixture of 19.9 g (0.1 mole) of the 2-cyanoethyl ether of 2-phenyl-3-butyn-2-ol, 8.0 g (0.11 mole) of diethylamine, 3.3 g (0.11 mole) of paraform, and 12 ml of dioxane was refluxed for 14 hours. Dioxane was distilled off at the water pump, and the residue was dissolved in ether. The solution was dried with magnesium sulfate and vacuum-fractionated. A fraction (6.8 g) of b.p. 85-88° (2.5 mm) was obtained and was not studied further, and 8.2 g of the original 2-cyanoethyl ether (VIII) was recovered unchanged.

2. A mixture of 10 g (0.05 mole) of the 2-cyanoethyl ether (VIII), 6 g (0.55 mole) of diethylamine hydrochloride, 1.8 g (0.06 mole) of paraform, 10 ml of dioxane, and 5 ml of isopropyl alcohol was boiled for 20 hours. Alcohol and dioxane were distilled off at the water pump, and the residue was treated with ether. From the ethereal solution 7.5 g of the 2-cyanoethyl ether (VIII) was recovered unchanged. The ether-insoluble residue was saturated with potassium carbonate and extracted with ether. The ether extract was dried with magnesium sulfate and distilled: 0.4 g of a substance of b.p. 132-138° (3 mm) was obtained.

Reaction of the 2-Cyanoethyl Ether of 1,1-Diphenyl-2-propyn-1-ol (IX) with Diethylamine and Paraform

A mixture of 26.1 g (0.1 mole) of the 2-cyanoethyl ether of 1,1-diphenyl-2-propyn-1-ol, 8 g (0.11 mole) of diethylamine, 3.3 g (0.11 mole) of paraform, and 30 ml of dioxane was refluxed for 14 hours. Dioxane was distilled off under somewhat reduced pressure, and the residue was dissolved in 50 ml of ether and treated with hydrochloric acid (1 : 1). From the ethereal solution 19.3 g of the 2-cyanoethyl ether (IX) was recovered. The acid extract was saturated with potassium carbonate and extracted with ether. Only resinous products were obtained from the extract.

Attempts to Hydrate the 2-Cyanoethyl Ether (VIII)

A mixture of 20 g (0.1 mole) of the 2-cyanoethyl ether (VIII), 2 g of mercuric sulfate, 25 ml of water, 50 ml of dioxane, and 5 drops of concentrated sulfuric acid was prepared in a three-necked flask fitted with mechanical stirrer, thermometer, and reflux condenser. The mixture was stirred at 90° for three hours and then left overnight. The reaction mixture was saturated with potassium carbonate and extracted with ether. The extract was dried with magnesium sulfate and vacuum-fractionated. A light-yellow oil [18 g; b.p. 95-115° (5 mm)] was obtained and was not investigated further.

Alcoholysis of the 2-Cyanoethyl Ether (VIII)

A mixture of 10 g (0.05 mole) of the 2-cyanoethyl ether (VIII) and 75 ml of methanol containing 15 g of dry hydrogen chloride was left in a round-bottomed flask for about four hours at room temperature. The flask was provided with a still head, and methanol was removed at 20° at the water pump. Water (100 ml) was added to the residue, and the mixture was stirred and saturated with potassium carbonate; it was then extracted with ether. A dark-colored sticky resin remained after removal of ether.

Partial Hydrolysis of the 2-Cyanoethyl Ether of 3-Phenyl-1-pentyn-3-ol (VI) with Alkaline Hydrogen Peroxide

A mixture of 11 g (0.051 mole) of the 2-cyanoethyl ether of 3-phenyl-1-pentyn-3-ol, 240 ml of 4% hydrogen peroxide, 2.5 ml of 40% aqueous potassium hydroxide, and 150 ml of acetone was prepared in a three-necked flask fitted with mechanical stirrer, thermometer, and reflux condenser. The mixture was stirred, and the temperature rose spontaneously to 30-35°, when the evolution of bubbles of oxygen began. The reaction mixture was stirred at 50° for five hours, and toward the end of this period the brisk evolution of oxygen had almost completely stopped. The contents of the three-necked flask were transferred to a Favorsky flask, and acetone was distilled off at 50-60° under reduced pressure. The aqueous layer was saturated with potassium carbonate and extracted with ethyl acetate. The extract was dried with magnesium sulfate and vacuum-fractionated. The product, amounting to 9.9 g, was the amide (XV), b.p. 194-196° (4 mm).

Found %: N 6.02; 6.04 $C_{14}H_{17}NO_2$. Calculated %: N 6.06.

The other amides listed in Table 2 were prepared similarly. The amides (XI), (XII), (XIV), and (XVIII) were not distilled, but were purified by crystallization. The amides (XIII) and (XVI) were not purified since they formed very viscous undistillable oils.

Partial Hydrolysis of the 2-Cyanoethyl Ether of 1,1-Diphenyl-2-propyn-1-ol (IX) with Alkaline Hydrogen Peroxide

A mixture of 13 g (0.05 mole) of the 2-cyanoethyl ether of 1,1-diphenyl-2-propyn-1-ol (IX), 250 ml of 4% hydrogen peroxide, 2.5 g of 40% potassium hydroxide solution, and 300 ml of acetone was stirred for six hours at 50°. Acetone was distilled off, and the aqueous residue was saturated with potassium carbonate and extracted with ethyl acetate. After removal of ethyl acetate, 12.9 g of the amide (XVIII), m.p. 117-118° (from a mixture of benzene and petroleum ether) was obtained.

Found %: N 5.35; 5.30 $C_{17}H_{17}NO_2$. Calculated %: N 5.02.

The amides (XI), (XII), and (XVIII) remain after the removal of ethyl acetate in the form of thick oils that are very difficult to crystallize. To accelerate crystallization, these amides were dissolved in alcohol and precipitated out with water; they then crystallized in the course of a night. The amide (XIV) was obtained in the crystalline state immediately after removal of acetone.

SUMMARY

1. Some tertiary acetylenic alcohols containing aromatic radicals were cyanoethylated. The new 2-cyanoethyl ether of aromatic acetylenic alcohols were obtained in yields of greater than 90%.

2. These 2-cyanoethyl ethers of aromatic acetylenic alcohols do not readily undergo the Mannich reaction and the reaction of hydration of the triple bond. They are completely resinified when attempts are made to alcoholyze the nitrile group.

3. These 2-cyanoethyl ethers are converted into the corresponding amides in good yield by the action of alkaline hydrogen peroxide.

α-KETO EPOXIDES AND THEIR REACTIONS

COMMUNICATION 6. α-KETO EPOXIDES FROM CYCLIC KETONES

I. N. Nazarov and A. A. Arkhem

In previous communications [1] we described the preparation of aliphatic α-keto epoxides and keto diepoxides by the oxidation of the corresponding α,β-unsaturated ketones with alkaline hydrogen peroxide. It was considered to be of interest to apply this reaction also for the oxidation of α,β-unsaturated cyclic ketones with the object of obtaining cyclic α-keto epoxides, because only isolated members of this class of compounds—mainly α-keto epoxides from unsaturated cyclic ketones of the terpene series [2-4]—have been prepared. It should be noted that, until recently, the view was prevalent in the literature that α,β-unsaturated cyclic ketones are difficult to oxidize with alkaline hydrogen peroxide [5] and that the cyclic α-keto epoxides that are formed in small amount in this reaction are unstable compounds, which readily lose their epoxide oxygen during distillation [2]. Interest in cyclic epoxides has grown appreciably recently in connection with work on the partial synthesis of corticosteroids, in particular, cortisone [6], which are known to have a hydroxy or carbonyl group at C-11 and also a hydroxy group at C-17.

We began by studying the oxidation of the simplest cyclic α,β-unsaturated ketones with the intention of proceeding further to the oxidation of more complex polycyclic systems, including tetracyclic ketones related to steroids. Oxidation of 2-methyl-2-cyclopenten-1-one (I) with alkaline hydrogen peroxide in methanol gave 2,3-epoxy-2-methylcyclopentanone (II) in a yield of about 40%; hydrolysis of this product with hot 3% hydrochloric acid gave a low yield of a crystalline substance of m.p. 104-105°, which corresponded in analysis to a diketone of formula (IV) or (V):

The product is acid to Congo red, and with aqueous ferric chloride it gives a violet coloration that changes to red on addition of sodium acetate. The hydrolysis of the α-keto epoxide (II) is probably accompanied by rearrangement of the resulting keto glycol (III) with migration of the methyl group and formation of the α-diketone (IV) instead of the expected β-diketone (V). According to the literature [7], the α-diketone (IV) melts at 105-106°, whereas the β-diketone (V) melts at 212° [8]. We did not succeed in isolating the corresponding keto glycol (III) in the pure state.

By the action of alkaline hydrogen peroxide on 2,4-dimethyl-2-cyclopenten-1-one (VI) [9] in methanol solution, 2,3-epoxy-2,4-dimethylcyclopentanone (VII) was obtained in a yield of about 30%.

Hydrolysis of the keto epoxide (VII) with dilute hydrochloric acid gave a product of m.p. 84-87° corresponding in analysis to the diketone (IX) or (X). In this case, together with the diketone, we obtained also the keto glycol (VIII). When the hydrolysis of the keto epoxide (VII) was effected with water, the main reaction product was the keto glycol (VIII), which probably consisted of a mixture of geometric isomers.

The oxidation of 3,5-dimethyl-2-cyclopenten-1-one (XI) [10] was more difficult, and we did not succeed in isolating the α-keto epoxide (XII) in the pure state: it was characterized only in the form of its semicarbazone. In the oxidation of the ketone (XI), the formation of the keto epoxide (XII) was accompanied by the formation of a small amount of the hydroxy keto epoxide (XIII), m.p. 68°, corresponding to the further oxidation of the keto epoxide (XII):

(XI) (XII) (XIII)

We met a similar oxidation previously in the case of mesityl oxide [11].

Oxidation of 2-cyclohexen-1-one (XIV) with alkaline hydrogen peroxide gave a 50% yield of the corresponding α-keto epoxide (XV), which was hydrolyzed by water in the cold with formation of the crystalline α-keto glycol (XVI), probably in the transconfiguration.

(XIV) (XV) (XVI)

In the hydrolysis of the keto epoxide (XV), a crystal hydrate of (XVI), m.p. 115°, was first formed. This hydrate contained one molecule of water to every six of the glycol, and this water was lost when the hydrate was sublimed with formation of the anhydrous keto glycol (XVI), m.p. 87°. According to the results of Kötz and Richter [12], 2-cyclohexen-1-one (XIV) cannot be oxidized with hydrogen peroxide.

Oxidation of 2-methyl-2-cyclohexen-1-one (XVII) with alkaline hydrogen peroxide gave the corresponding α-keto epoxide (XVIII) in a yield of about 70%. Hydrolysis of the product with dilute hydrochloric acid gave the keto glycol (XIX), which solidified after distillation as a gumlike mass:

(XVII) (XVIII) (XIX)

EXPERIMENTAL

Preparation of the α-Keto Epoxide (II)

In the course of 45 minutes, 50 ml of 12% hydrogen peroxide and 3.5 ml of 4 N NaOH were added simultaneously from two dropping funnels to a continuously stirred cooled (to −8° with ice and salt) solution of 15 g of 2-methyl-2-cyclopenten-1-one (I) [b.p. 49° (13 mm); n_D^{22} 1.4780] [13] in 100 ml of methanol. Reaction proceeded with appreciable evolution of heat: at first the temperature rose rapidly by 14° (from −8° to +6°), but

was then maintained in the range from −5° to −2°. Forty minutes after the addition of the oxidizing agent, only 0.4 g of hydrogen peroxide was present in the reaction mixture. The colorless solution was neutralized with dilute sulfuric acid (8 ml of 10% sulfuric acid), excess of hydrogen peroxide was decomposed with manganese dioxide, precipitated sodium sulfate was filtered off, and the solution was diluted with an equal amount of water, saturated with ammonium sulfate, and extracted with ether. The ether extracts were dried with anhydrous sodium sulfate, ether was distilled off, and the residue was vacuum-fractionated. The product, amounting to 8 g, was 2,3-epoxy-2-methylcyclopentanone (II) in the form of a colorless liquid, b.p. 56.5-57° (10 mm); n_D^{20} 1.4537; d_4^{20} 1.0902; Found MR 27.80; Calculated MR 27.86.

Found %: C 64.20; 64.47; H 7.36; 7.20 $C_6H_8O_2$. Calculated %: C 64.29; H 7.14.

Hydrolysis of the Keto Epoxide (II) with Dilute Hydrochloric Acid

Concentrated hydrochloric acid (5 ml) was added to a solution of 5 g of the epoxide (II) (b.p. 50-55° (11 mm); n_D^{20} 1.4630) in 50 ml of distilled water (the epoxide dissolves completely in 6 volumes of water). The solution was left overnight at room temperature and was then boiled for 30 minutes. The hydrochloric acid present was neutralized with sodium bicarbonate, the solution was repeatedly extracted with ether, and the ether extracts were dried with anhydrous sodium sulfate. After removal of ether, the sirupy residue (about 2.5 g) was cooled with ice and salt, and 0.5 g of crystals and about 2 g of a thick oil were obtained. When the liquid product was distilled, about 0.5 g of a substance of b.p. 65-70° (11 mm) and n_D^{20} 1.4797 came over; it was not investigated further. The residue, which turned into a thick paste, was combined with the above-mentioned crystals and recrystallized from alcohol; a small quantity of white mat needles, m.p. 104-105°, was obtained.

Found %: C 64.50; 64.60; H 7.27; 7.43 $C_6H_8O_2$. Calculated %: C 64.29; H 7.14.

According to the literature [7], the α-diketone (IV) melts at 105-106°, whereas the isomeric β-diketone (V) melts at 212° [8].

Preparation of the α-Keto Epoxide (VII)

Under the conditions described above, 100 g of 2,4-dimethyl-2-cyclopenten-1-one (VI) (b.p. 167-169°; n^{20} 1.4681) [9] in 200 ml of methanol was oxidized with the aid of 120 ml of 28% hydrogen peroxide and 20 ml of 4 N NaOH. By cooling and regulation of the rate of adding oxidizing agent, the reaction temperature was maintained at 8-10°. The oxidizing agent was added over a period of one hour. Reaction proceeded with evolution of heat and lasted until the theoretical amount of oxygen had been consumed (2.5 hours). Fractionation of the reaction product through a column gave 20 g of 2,3-epoxy-2,4-dimethylcyclopentanone (VII) as a colorless mobile liquid of pungent odor, b.p. 51° (5 mm); n_D^{20} 1.4445; d_4^{20} 1.0211; Found MR 32.81; Calculated MR 32.48.

Found %: C 66.52; 66.45; H 8.73; 8.53 $C_7H_{10}O_2$. Calculated %: C 66.66; H 7.94.

Found: M 127, 123 (in benzene) $C_7H_{10}O_2$. Calculated: M 126.

Hydrolysis of the α-Keto Epoxide (VII)

a) A mixture of 18 g of the keto epoxide (VII) (b.p. 73.5° (23 mm); n_D^{20} 1.4452) and 140 ml of distilled water was heated in a sealed tube at 155-160° for ten hours. Removal of water under reduced pressure gave about 10 g of a thick yellow sirup. Two vacuum fractionations of this gave 3 g of the keto glycol (VIII) as a thick faintly colored sirup, b.p. 124-124.5° (3 mm); n_D^{20} 1.4848; d_4^{20} 1.1546; Found MR 35.73; Calculated MR 35.39.

Found %: C 58.85; 58.81; H 8.48; 8.64 $C_7H_{12}O_3$. Calculated %: C 58.38; H 8.34.

The keto glycol (VIII) does not give a 2,4-dinitrophenylhydrazone.

b) Concentrated hydrochloric acid (7 ml) was added to a solution of 6 g of the keto epoxide (VII) (b.p. 69.5-71° (19 mm); n_D^{18} 1.4477) in 110 ml of distilled water, and the solution was left for ten days at room temperature.

The solution was then heated in a boiling water bath for two hours. The solution, which had turned yellow, was evaporated to half bulk in a vacuum, neutralized with potassium carbonate, and extracted with ether. The extract was dried with anhydrous magnesium sulfate, and ether was distilled off. Vacuum fractionation of the residue gave 0.5 g of a substance of b.p. 66° (1 mm) and n_D^{19} 1.4930, which rapidly solidified to colorless crystals. These crystals became pink after two hours, and after two days they turned into a liquid, which could not then be crystallized. Also, it was not found possible to recrystallize the crystals. The crystals of the freshly distilled product, probably the diketone (IX), were washed on the filter with petroleum ether and were then found to melt at 84-87°.

Found %: C 65.99; 65.22; H 8.04; 8.02 $C_7H_{10}O_2$. Calculated %: C 66.66; H 7.94.

When the substance was not analyzed immediately after isolation, a very low carbon content was obtained. The substance did not form a dioxime. It gave a blue coloration with aqueous ferric chloride.

Preparation of the α-Keto Epoxide (XII)

3,5-Dimethyl-2-cyclopenten-1-one (XI) (50 g; b.p. 180-182°; n_D^{20} 1.4785) [10] was oxidized with alkaline hydrogen peroxide as described above. Fractional distillation of the reaction products gave 15 g of 2,3-epoxy-3,5-dimethylcyclopentanone (XII) as a colorless liquid, b.p. 59.5-60° (8 mm); n_D^{20} 1.4568; d_4^{20} 0.9951. Elementary analysis indicated that the substance contained some of the original ketone as impurity. The ketone epoxide (XII) gave a semicarbazone of m.p. 173-174° with decomposition. A mixture of this with the semicarbazone of the original ketone (XI) (m.p. 175-176°) melted at 165-173°.

Found %: N 23.12; 23.83 $C_8H_{13}O_2N_3$. Calculated %: N 22.95.

In addition, about 4 g of the hydroxy keto epoxide (XII) was obtained in the form of colorless needles, m.p. 68° (from a mixture of diethyl ether and petroleum ether), b.p. 110-112° (7 mm), and n_D^{17} 1.4662.

Found %: C 59.22; 59.23; H 7.31; 7.17 $C_7H_{10}O_3$. Calculated %: C 59.15; H 7.04.

Found: M 141; 131 (in benzene) $C_7H_{10}O_3$. Calculated: M 142.

This substance did not give a semicarbazone.

Analysis by the Chugaev-Tserevitinov method gave only about 6% of hydroxyl groups, instead of the 12% required theoretically.

Preparation of the α-Keto Epoxide (XV)

Over a period of 40 minutes, 24 ml of 15% hydrogen peroxide solution (1 mole) and 5 ml of 4 N NaOH were added dropwise simultaneously to a vigorously stirred, cooled (ice and salt) solution of 15 g of 2-cyclohexen-1-one (XIV) (b.p. 70° (21 mm), n^{21} 1.4840) [13] in 80 ml of methanol. Much heat was evolved at first, but the temperature of the reaction mixture was maintained at not above 0°. Two hours after the additions of the oxidizing agent, 1.5 g of hydrogen peroxide remained in the solution. After a further one hour alkali was neutralized with dilute sulfuric acid and residual hydrogen peroxide was decomposed with manganese dioxide. The solution was filtered, methanol was distilled off under reduced pressure, and the product was extracted with ether. The extract was dried with anhydrous magnesium sulfate and vacuum-distilled. The product, amounting to 8 g, was 2,3-epoxycyclohexanone (XV), a colorless liquid, volatile in steam and methanol vapor, b.p. 43.5° (1 mm); n_D^{20} 1.4720; d_4^{20} 1.1313; Found MR 27.72; Calculated MR 27.86.

Found %: C 63.63; 63.74; H 7.62; 7.75 $C_6H_8O_2$. Calculated %: C 64.29; H 7.14.

When kept for a long time, the keto epoxide (XV) turned yellow with gradual increase in refractive index (in 18 months n_D^{20} rose to 1.4810).

Found: M 106; 116 (in benzene) $C_6H_8O_2$. Calculated: M 112.

The semicarbazone of the keto epoxide (XV) was precipitated immediately, but we could not recrystallize it because, after being dissolved, it did not come out of solution in a crystalline form. Washing on the filter with methanol and ether gave colorless crystals, m.p. 183-185° with decomposition (the semicarbazone of the original cyclohexenone melted at 161°).

Found %: N 24.62; 24.79 $C_7H_{11}O_2N_3$. Calculated %: N 24.85.

Hydrolysis of the α-Keto Epoxide (XV)

The keto epoxide (XV) (2.5 g) was dissolved in 30 ml of distilled water, and the solution was set aside for 15 days at room temperature. Water was distilled off under reduced pressure, and the sirupy residue (about 2.7 g) solidified with evolution of heat when seeded with a small crystal (taken off a capillary). The resulting finely crystalline powder was insoluble in the usual organic solvents and sparingly soluble in hot water. Repeated washing on the filter with alcohol and ether and drying in a vacuum desiccator over phosphoric oxide gave a product of m.p. 115° (the cooled melt remelts at 82-83°).

Found %: C 54.73; 54.46; H 7.80; 7.70 $(C_6H_{10}O_3)_6 + H_2O$. Calculated %: C 54.13; H 7.77.

Found %: OH 29.20 (in pyridine) $[C_6H_8O(OH)_2]_6 + H_2O$. Calculated %: OH 29.95.

When the crystals were sublimed at 1.5 mm and at 96-97°, they lost their water of crystallization and were converted into the anhydrous keto glycol (XVI), which formed colorless crystals, m.p. 87° (from a mixture of diethyl ether and petroleum ether), readily soluble in the usual organic solvents.

Found %: C 55.29; 55.34; H 7.74; 7.61 $C_6H_{10}O_3$. Calculated %: C 55.31; H 7.61.

Found: M 132 (in benzene) $C_6H_{10}O_3$. Calculated: M 130

Found %: OH 31.57 (in pyridine) $C_6H_8O(OH)_2$. Calculated %: OH 26.15.

Preparation of the α-Keto Epoxide (XVIII)

2-Methyl-2-cyclohexen-1-one (XVII) (30 g; b.p. 62° (13.5 mm); n_D^{20} 1.4828) [13] was oxidized in 100 ml of methanol with the aid of 64 ml of 19% hydrogen peroxide and 10 ml of 4 N NaOH, as described above. The oxidation reaction was complete in about two hours. Vacuum fractionation gave 27 g (80%) of the α-keto epoxide (XVIII) in the form of a colorless liquid having a feeble characteristic odor, b.p. 80.5-81° (16 mm); n_D^{20} 1.4629; d_4^{20} 1.0753; Found MR 32.27; Calculated MR 32.48.

Found %: C 67.02; 66.93; H 8.18; 8.26 $C_7H_{10}O_2$. Calculated %: C 66.67; H 7.94.

Found: M 116 (in benzene) $C_7H_{10}O_2$. Calculated: M 126.

The semicarbazone of the keto epoxide (XVIII) was precipitated immediately in the form of colorless well-formed crystals, m.p. 120-124° with decomposition, but we did not succeed in recrystallizing it; we therefore washed with ether on the filter and dried it in a vacuum desiccator over phosphoric anhydride.

Found %: N 22.60; 23.00 $C_8H_{13}O_2N_3$. Calculated %: N 22.95.

Hydrolysis of the Keto Epoxide (XVIII)

Water (80 ml) was added to 4 g of the keto epoxide (XVIII), and the mixture was set aside overnight at room temperature. On the next day, 7 ml of concentrated hydrochloric acid was added to the reaction mixture, which was then heated at 90° for 15 minutes. The solution was cooled, saturated with potassium carbonate, and extracted with ether. The extract was dried with magnesium sulfate. Vacuum fractionation gave 1.5 g of the glycol (XIX) as a colorless viscous sirup, b.p. 102° (2.5 mm) and n_D^{17} 1.4920; it was solidifying even during the distillation into a vitreous mass. Before being analyzed, the glycol (XIX) was kept for three days in a vacuum desiccator over phosphoric oxide.

Found %: C 58.13; 58.46; H 8.40; 8.51 $C_7H_{12}O_3$. Calculated %: C 58.33; H 8.33.

Found: M 149; 143 (in benzene) $C_7H_{12}O_3$. Calculated: M 144

Found %: OH 25.11; 26.48 (in pyridine) $C_7H_{12}O_3$. Calculated %: OH 23.61.

SUMMARY

1. A study was made of the oxidation of the simplest alicyclic α,β-unsaturated ketones with alkaline peroxide. The corresponding cyclic α-ketone epoxides were obtained in 30-80% yield.

2. It was shown that, contrary to indications in the literature, epoxides derived from alicyclic α,β-unsaturated ketones are relatively stable compounds which can be vacuum-distilled without decomposition.

3. A study was made of the hydrolysis of cyclic α-keto epoxides to the corresponding α-keto glycols. In some cases it is accompanied by rearrangement with formation of cyclic diketones.

DEMETHYLATION AND ISOMERIZATION OF o-XYLENE OVER ALUMINOSILICATES

A. V. Topchiev, G. M. Mamedaliev and Yu. G. Mamedaliev

Linear aromatic polyesters are widely used for the manufacture of synthetic fibers. For example, polyethylene terephthalate (Terylene), the synthesis of which is based on terephthalic acid and ethylene glycol, has recently become widely acclaimed for its valuable properties and there has been a corresponding great increase in the scale of its manufacture. In this connection the development of a rational method of synthesizing p-xylene becomes of great practical importance. One promising direction in which the solution of the problem of the manufacture of p-xylene may be sought is its preparation on the basis of the isomerization of m- and o-xylenes.

Several investigations have been devoted to the isomerization of xylenes. Dobryansky and Saprykin [1] subjected o-, m-, and p-xylenes to pyrolysis and investigated the reaction products. In the transformation of o-xylene in a porcelain tube at 750° they observed the formation of 12.8% of toluene, 20.5% of high-boiling aromatic hydrocarbons, and 14.8% of gas. It was shown that the xylene fraction of the pyrolyzate contained some m- and p-xylenes as well as o-xylene. With rise in temperature from 700° to 770°, the m-xylene content increased from 5.0% to 38.2%. The formation of p-xylene was of minor significance, and only at 770° did its content attain 10.6%.

In the pyrolysis of p-xylene, the yields of toluene, higher aromatic hydrocarbons, gaseous products, and unchanged xylene were 13.3, 49.2, 19.3, and 14.8%, respectively, on the original material. An appreciable amount of o- and m-isomers was formed. In the products of the thermal decomposition of m-xylene at temperatures below 700° no o- and p-xylenes were detected. Baddeley and Kenner [2], in a study of the pyrolysis products of m-xylene obtained by passing the vapor through a quartz tube at 800°, found not only benzene, toluene, naphthalene, anthracene, and compounds of still higher boiling point, but also small amounts of o- and p-xylenes. It was thus shown that in the pyrolysis of xylenes, apart from the main decomposition and condensation reactions, partial thermal isomerization occurs. m-Xylene has comparatively high thermal stability to isomerization.

Investigations have been carried out also on the catalytic isomerization of various alkyl benzenes. Thus, Anschutz and Immendorf [3] and Heise and Töll [4] studied the isomerization of xylenes in presence of aluminum chloride. There are references to the isomerization of pseudocumene into mesitylene [5], of durene and isodurene into prehnitene [6], etc. A review of the literature on the isomerization of hydrocarbons, including aromatic hydrocarbons, is given in the monograph of Egloff, Hulla, and Komarewsky [7].

Norris and coworkers [8, 9] studied the isomerization of xylenes in presence of aluminum chloride, reaction being promoted by a stream of hydrogen chloride. It was shown that the extent to which isomerization of xylenes occurred depended to a considerable extent on the reaction temperature and consumption of aluminum chloride. For a contact time of 25 minutes at 94°, o-xylene is isomerized with formation of 38.6% of m-xylene and 13.4% of p-xylene. Aluminum chloride has a somewhat lower isomerizing effect of m-xylene. For a contact time of 20 hours at 50°, the isomerization product from m-xylene was found to contain 15.0% of o-xylene and 16.0% of p-xylene.

TABLE 1

Dealkylation of o-Xylene with Associated Alkylation of Benzene

Characteristics of experiment	Original mixture: molar ratio of benzene to o-xylene = 2:1		Temperature 525°, rate 0.5:1, duration of cycle 50 minutes

In one of our previous papers [10] we gave the results of a study of the isomerization of m- and o-xylenes over aluminosilicates. At not above 450° and for a rate of 0.5 : 1 [ratio of volume of reactant passing per hour to volume of catalyst], isomerization proceeded to a maximum extent in experiments at atmospheric pressure and in those carried out under vacuum conditions. It was shown that increase in pressure favors the reaction of disproportionation with formation of appreciable amounts of toluene and trimethylbenzenes.

Bodeker and Erner [11] studied the vapor-phase catalytic isomerization of commercial m-xylene (84% m-xylene, 9% p-xylene, 5% o-xylene, and about 2% ethylbenzene) over aluminosilicate cracking catalysts. At 515° and for a rate of feed of 0.7 at atmospheric pressure, in addition to the isomerization of xylene, the reaction of redistribution of methyl groups occurred. The catalyzate consisted of a mixture of 1.2% of benzene, 13% of toluene, 32.2% of m-xylene, 18.9% of p-xylene, 13.0% of o-xylene, 5.10% of ethylbenzene, and 16.5% of C_9 aromatic hydrocarbons. Some experiments were carried out under vacuum conditions. The p- and o-xylene contents were then increased from 9 and 5% in the raw material to 18-20 and 7-9% in the catalyzate. The use of a vacuum, however, favored the formation of an appreciable amount of ethylbenzene.

EXPERIMENTAL

Experiments were carried out on the demethylation and isomerization of o-, m-, and p-xylenes. The present paper gives the results on the isomerization of o-xylene and its demethylation in presence of benzene over aluminosilicates.

Fig. 1. Laboratory flow-type apparatus for reactions under pressure: 1) nitrogen cylinder; 2) reservoir of raw material; 3) reactor; 4) tube furnace; 5) rheostat; 6) galvanometer; 7) reduction valve; 8) refrigerated condenser; 9) receiver; 10) gas condenser; 11) flowmeter; 12) gas meter; 13) gas holder.

The experiments were carried out in the laboratory flow-type reaction apparatus shown diagrammatically in Fig. 1.

Our raw materials were "pure for cryoscopy" coal-tar benzene (b.p. 79.74-80.10°; bromine value 0.03; density 0.8782; refractive index 1.5010; sulfonatables 99.6%) and o-xylene having b.p. 143-144°; d_4^{20} 0.8800; n_D^{20} 1.5050; sulfonatables 100%. By the oxidation method it was shown that the "o-xylene" contained 98.7% of o-xylene and 1.3% of m-xylene.

Demethylation and Isomerization of o-Xylene in presence of Benzene

Experiments were carried out on the demethylation of o-xylene with associated methylation of benzene. In treatments of a mixture of these hydrocarbons over a synthetic aluminosilicate, in addition to the main reaction of toluene formation, isomerization of o-xylene was observed. The most characteristic results are given in Table 1.

The effects of temperature, pressure, and other factors were studied and the optimum values of the parameters for toluene formation were established. For a single passage of a mixture of o-xylene and benzene at a molar ratio of 1 : 2, a pressure of 5 atm, a temperature of 525°, and a rate of 0.5 : 1, the yield of catalyzate was 97.1%, and 0.9% of coke and 0.8% of gas were obtained. In the course of the process, part of the benzene was alkylated to toluene, and its content fell from 58% in the original mixture to 49.4% in the catalyzate.

A considerable fraction of the o-xylene was demethylated to toluene, so that the content of the xylene fraction fell from 34.9 to 17.7%. The rest of the o-xylene was isomerized to m- and p-xylenes. The boiling range of the xylene fraction was lowered appreciably, and there was a corresponding reduction in density and refractive index. Increase in pressure to 15 atm directed the process toward maximum formation of toluene. Its content in the catalyzate was increased to 27-28%. The yields of catalyzate, coke, and gas (percent by weight on original mixture) varied over the ranges 94.3-95.2%, 1.9-2.2%, and 1.7-2.3%, respectively. Spectrum analysis of the xylene fraction of the catalyzate showed that it contained 16% of o-xylene, 38% of m-xylene, 23% of p-xylene, and 20% of ethylbenzene.

Our results give us reason to suppose that in the catalytic treatment of a mixture of o-xylene and benzene the demethylation reaction is preceded by the isomerization of o-xylene. The p-xylene formed is fairly readily dealkylated under the conditions of the experiment with formation of toluene. The reaction of dealkylation of xylene with associated alkylation of benzene proceeds over aluminosilicates without any accompanying decomposition or condensation side reactions. The formation of unsaturated hydrocarbons and high-boiling condensation products is not observed. The iodine value of the catalyzate is zero, and its sulfonatable content is 100%. The bromine value of the toluene isolated from the catalyzate is 0.03, its density varies in the range 0.8665-0.8670, and its refractive index is 1.4969-1.4972.

On the basis of the values of the conversions of benzene and xylene and of the yields of toluene and trimethylbenzenes we calculated the relative contributions of the reactions taking part in the formation of toluene. The results are given in Table 2.

For temperature 525°, rate 0.5 : 1, duration of reaction cycle 50 minutes, and pressure 15 atm, the contributions of the reactions of dealkylation of xylene and associated alkylation of benzene in the formation of toluene are almost equal and vary in the range 44-47%. The contribution of the disproportionation of xylene is 9-10%. In the catalytic treatment of a mixture of o-xylene and benzene, in addition to these reactions and the reaction of redistribution of hydrogen, the hydrogenolysis of one methyl group of xylene with formation of toluene and methane may occur to a small extent. Analysis showed that the gaseous reaction products consisted mainly of a mixture of methane and hydrogen.

The catalytic treatment of a mixture of o-xylene and benzene over aluminosilicates under optimum conditions for toluene formation is characterized by the simultaneous occurrence of the following main reactions:

1) Demethylation of xylene with associated methylation of benzene:

2) Redistribution of methyl groups by disproportionation of xylene:

3) Isomerization of o-xylene with formation of m- and p-xylenes:

The formation of ethylbenzene probably occurs as a result of the alkylation of benzene by fragments formed in the decomposition of the coke-forming macromolecular condensation products.

Isomerization of o-Xylene

A series of experiments was carried out on the isomerization of o-xylene over a synthetic aluminosilicate catalyst. The effects of pressure and temperature were studied, and their optimum values for the isomerization process were determined. The xylene fractions obtained were analyzed by Ullmann oxidation [12]. The xylene fractions of catalyzates obtained in experiments carried out under optimum conditions were subjected to spectrum analysis. Also, the mixtures of phthalic acid and its isomers obtained in the oxidation were investigated by x-ray analysis [13].

Our experimental results showed that the application of pressure accelerates the disproportionation of xylene. As a result, with increase in pressure the contents of toluene and trimethylbenzenes in the reaction product increase appreciably. At atmospheric pressure in the temperature range 400-450° the process consists mainly in the isomerization of xylene. The results of experiments on the isomerization of o-xylene are given in Table 3.

At 400° at a rate of feed of 0.5, a single passage of o-xylene over the catalyst results in the formation of 97.9% of catalyzate, 0.6% of coke, and 0.02% of gas. The lower boiling limit of the catalyzate was 107°, and

the upper was 158°. The toluene content of the catalyzate was 1.2%. A considerable proportion of the o-xylene was isomerized and passed into the fraction boiling over the range 136-140°. Thus, the yield of this fraction was increased from 1.3% in the raw material to 58.5% in the catalyzate. There was a corresponding lowering of the density of the catalyzate from 0.8803 to 0.8702, and the refractive index was lowered from 1.5055 to 1.4985. Analysis of the fraction by the oxidation method indicated that it contained 29.0% of o-xylene, 48.8% of m-xylene, and 22.2% of p-xylene.

Rise in temperature to 450° increased the extent to which isomerization occurred. The yield of the 136-140° was increased to 69%. There was a marked reduction in the yield of the o-xylene fraction (9.9%). The disproportionation of xylene proceeded somewhat more vigorously, and the yields of the toluene and trimethylbenzene fractions therefore increased. The contents of o-, m-, and p-xylenes in the 136-140° fraction were 30.2, 47.1, and 22.6%, respectively. Analysis of this fraction by the Raman-spectrum method indicated contents of 35, 43, and 22%, respectively.

Further rise in temperature to 500° and 525° appreciably accelerated the reaction of disproportionation of methyl groups. The catalyzate obtained at 525° had a comparatively high p-xylene content, but a considerable proportion of the original o-xylene was consumed in the formation of toluene and trimethylbenzenes, so that, on the whole, the extent of isomerization was lowered.

These results on the analysis of catalyzates indicate that maximum isomerization of o-xylene into p- and m-xylenes over synthetic aluminosilicates is attained at atmospheric pressure in the temperature range 450-500°.

Considerable practical interest is presented by the isomerization of m-xylene. The large available supplies of this compound open up wide possibilities for the industrial development of p-xylene manufacture. Our investigations show that the maximum effect in the isomerization of m-xylene is attained in the temperature range 400-450° under vacuum conditions. The results of these investigations will be published in our next communication.

SUMMARY

1. An investigation was made of the reaction of demethylation of o-xylene with associated methylation of benzene over a synthetic aluminosilicate catalyst. It was shown that at the optimum temperature of 525°, at a rate of feed of 0.5 volume of o-xylene per unit volume of catalyst per hour, and for a reaction cycle of 50 minutes the application of pressure directs the process toward maximum formation of toluene, the yield of which comprises 27-28% on the amount of catalyzate.

2. In the formation of toluene, not only is the demethylation of xylene important, but also the associated methylation of benzene. A little toluene is formed by the disproportionation of xylene. o-Xylene undergoes isomerization to a considerable extent with formation of m- and p-xylenes.

3. The isomerization of o-xylene was studied. It was shown that maximum isomerization over a synthetic aluminosilicate catalyst is attained in the temperature range 450-500°. In a single passage of o-xylene, 50-60% of it is converted into p- and m-xylenes. The xylene fraction of the catalyzate contains 22-23.5% of p-xylene.

CATALYTIC VAPOR-PHASE HYDROGENATION OF ISOPROPYLCYCLOPROPANE AND ISOPROPENYLCYCLOPROPANE

B. A. Kazansky, M. Yu. Lukina and A. I. Malyshev

As we have recently shown [1], at room temperature in an alcohol medium in presence of platinum or palladium black, the three-membered ring of isopropylcyclopropane does not undergo hydrogenolysis. On the other hand, under the same conditions and with the same catalysts isopropenylcyclopropane undergoes complete or partial hydrogenolysis. Thus, in presence of palladium black [2] two molecules of hydrogen add to one isopropenylcyclopropane molecule with formation of 2-methylpentane, and in presence of platinum black [1] addition of 1.3 molecules occurs with formation of a mixture consisting of 30% of 2-methylpentane and 70% of isopropylcyclopropane. It should be noted that isopropenylcyclopropane remains unchanged when shaken for a long time with a reduced palladium catalyst in absence of hydrogen [2].

The observed rupture of the C–C bond adjacent to the substituent in the three-membered ring in the hydrogenation of isopropenylcyclopropane is not in accord with various cases described in the literature in which, almost without exception, hydrogen, reacting with an alkylcyclopropane in presence of catalysts adds at the C–C bond lying opposite to the substituent [3-5]. This fact prompted us to suggest that the cause of the different course of the hydrogenolysis of the three-membered ring in isopropenylcyclopropane is the conjugation of the ring with the double bond of the side chain, which lowers the stability of the C–C bonds (3,4 and 3,4') adjacent to the substituent:

It must be pointed out that in the cases described in the literature the catalytic hydrogenolysis of alkylcyclopropanes was not carried out under the conditions indicated above, but at a higher temperature (70-150°) and without solvent. In the present investigation, therefore, we studied the vapor-phase hydrogenolysis of both isopropyl- and isopropenyl-cyclopropanes in presence of platinum and palladium, the experimental conditions being identical for the two hydrocarbons.

It was found that isopropylcyclopropane was completely hydrogenolyzed at 120°* and at a space velocity of 0.2 with formation, irrespective of which catalyst was used, of only 2,3-dimethylbutane, the product of the rupture of the C–C bond lying opposite to the substituent:

* Hydrogenolysis proceeds also at lower temperatures of 80° upwards.

Experiments on the hydrogenation of isopropenylcyclopropane under the same conditions showed that, as in liquid-phase hydrogenation at room temperature, the composition of the catalyzate depends on the identity of the catalyst. Over palladized charcoal, 2-methylpentane is again the only hydrogenation product, whereas in presence of platinized charcoal a mixture of 2-methylpentane and 2,3-dimethylbutane is obtained, the latter being formed evidently as a result of hydrogenolysis at this temperature of the isopropylcyclopropane first formed:

Isopropenylcyclopropane was prepared as follows [6]:

Isopropylcyclopropane was prepared by the hydrogenation of isopropenylcyclopropane in presence of a copper-chromium catalyst. However, in spite of Slabey's results [7], we did not succeed in preparing the pure hydrocarbon by this method. In all cases isopropylcyclopropane was obtained in admixture with 2-methylpentane. After distillation of the mixture through a 70-plate column we obtained isopropylcyclopropane which we estimated to have a purity of about 97%. All the experiments described below were carried out with the preparation.

EXPERIMENTAL

5-Bromo-2-pentanone. A mixture of 204 g (2.0 moles) of 5-hydroxy-2-pentanone (b.p. 103-108° (20 mm); n_D^{20} 1.4395) and 600 ml of 55% hydrobromic acid (sp. gr. 1.59) was prepared at room temperature. After ten hours the reaction mixture was poured into four times its volume of water. The bromo compound was extracted three times with ether. The extract was dried, ether was distilled off, and the reaction product was fractionated. It gave 220.0 g (63.0%) of 5-bromo-2-pentanone, b.p. 76-77° (10 mm); n_D^{20} 1.4693; d_4^{20} 1.3895.

Cyclopropyl Methyl Ketone. Water (10 ml) was added to 100 g (0.6 mole) of freshly distilled 5-bromo-2-pentanone, and the mixture was shaken vigorously while 48.0 g (1.17 moles) of potassium hydroxide powder was added in small portions. Reaction was exothermic and was complete within a few minutes. Water was added, and the ketone was steam-distilled off, salted out with potassium carbonate, separated, and dried. After distillation through a 30-plate column having a glass filling, 44.2 g (76.0%) of the ketone was obtained; b.p. 112.8-113.0° (760 mm); n_D^{20} 1.4248; d_4^{20} 0.8993.

2-Cyclopropyl-2-propanol. A mixture of 146.0 g (6.0 moles) of magnesium turnings and 500 ml of absolute ether was prepared in a Grignard-reaction apparatus, and methyl chloride was passed in from a cylinder until most of the magnesium had reacted. The mixture was warmed and stirred for one hour, and was then cooled to +5° in a current of nitrogen. At this temperature, a solution of 420.0 g of distilled cyclopropyl methyl ketone in

1 liter of absolute ether was added. The mixture was heated for eight hours at the boiling point of ether. It was then cooled and poured onto ice.* After extraction and drying, ether was distilled off, and the alcohol was distilled through a 30-plate column having a glass filling. The product, amounting to 298.0 g (60%), had b.p. 123.5-123.7° (760 mm); n_D^{20} 1.4333; d_4^{20} 0.8792.

Isopropenylcyclopropane. 2-Cyclopropyl-2-propanol (99.2 g, i.e., 1.0 mole) was heated with 2 drops of concentrated sulfuric acid in a flask fitted with a column having a glass filling. The isopropenylcyclopropane then formed was distilled off, washed with water, dried and boiled over sodium. Fractionation through a 40-plate column gave 60.0 g (74%) of isopropenylcyclopropane, b.p. 70.5° (760 mm); n_D^{20} 1.4255; d_4^{20} 0.7517; The literature [8] gives b.p. 70.33° (760 mm) n_D^{20} 1.42550; d_4^{20} 0.75153.

Isopropylcyclopropane. A mixture of 82.8 g (1.0 mole) of isopropenylcyclopropane, 62 ml of distilled ethanol, and 8.3 g of copper-chromium catalyst prepared by the method described in the literature [9] was prepared in a 500-ml autoclave. The hydrogenation went at 100-130° under a pressure of hydrogen of 105-140 atm. Absorption of hydrogen was observed only after 6-8 hours' heating, and it was complete in 48 hours. The reaction product was separated from the catalyst and distilled. After being washed with water it was boiled over the sodium and distilled through a 60-plate column. The results of the fractionation are given in Table 1.

TABLE 1

Fraction	B.p. (°C)	Amount (g)	n_D^{20}	d_4^{20}	Aniline point (°C)
I	54.2—58.4	2.9	1.3840	—	—
II	58.4	18.1	1.3859	0.6968	34.9
III	58.4- 58.5	17.1	1.3854	0.6958	—
IV	58.5—58.6	7.4	1.3852	—	—
V	Residue	20.0	1.3775	—	—
	Losses	2.4	—	—	—

Fraction II was isopropylcyclopropane in admixture with about 3% of 2-methylpentane. For isopropylcyclopropane the literature [8] gives b.p. 58.37° (760 mm); n_D^{20} 1.38639; d_4^{20} 0.69829.

Vapor-phase Hydrogenation of the Hydrocarbons. This was carried out in a flow system by the procedure described previously [4]. The catalysts were palladized and platinized charcoals prepared according to Zelinsky and Turova [10]. The platinized charcoal wascharacterized by its behavior in the ring-opening of cyclopentane [11]. After the passage of cyclopentane at 300° and at a space velocity of 1.0, the catalyzate contained 55% of pentane. The results of the hydrogenation experiments are given in Table 2.

The results of the fractionations of the catalyzates of Series I, II, and III are given in Table 3.

Data in the literature on the constants of 2-methylpentane and 2,3-dimethylbutane are given in Table 4.

It will be clear from a comparison of the data in Tables 3 and 4 that the hydrogenation of isopropylcyclopropane (Series I and III) over platinized and palladized charcoal gives 2,3-dimethylbutane, the constants of which differ a little from the reported values owing to a little 2-methylpentane impurity in the original isopropylcyclopropane, whereas hydrogenation of isopropenylcyclopropane over palladized charcoal (Series II) gives 2-methylpentane. The catalyzate from Series IV was fractionated through a 30-plate column having a copper filling. The results of the fractionation are given in Table 5 and in the figure.

*About 400 ml of glacial acetic acid was added to 2-3 kg of ice.

TABLE 2

Catalyst	Series of experiments*	Hydrocarbon	Temperature (°C)	Space velocity (hour^{-1})	n_D^{20}
Pd on charcoal (10 ml, i.e., 2.7 g)	I	Isopropylcyclopropane	150	0.2	1.3743
			120	0.2	1.3743
			80	0.2	1.3743
			70	0.2	1.3743
	II	Isopropenylcyclopropane	120	0.2	1.3713
			120	0.2	1.3713
			120	0.2	1.3713
Pt on charcoal (10 ml, i.e., 2.9 g)	III	Isopropylcyclopropane	150	0.2	1.3743
			120	0.2	1.3743
			80	0.2	1.3743
			70	0.2	1.3750**
	IV	Isopropenylcyclopropane	120	0.2	1.3731
			120	0.2	1.3731***

*All the catalyzates from the experiments of a given series were combined and fractionated.

**The catalyzate obtained at 70° was not added to the catalyzates of the other experiments of this series.

***12.0 ml of catalyzate was collected.

TABLE 3

Series of experiments	Amount of substance (g)	B.p. in °C p in mm	n_D^{20}	d_4^{20}	Aniline point (°C)
I	5.4	57.3—57.7 (742.5)	1.3742	0.6598	72.2
II	4.1	58.5—58.8 (733.2)	1.3713	0.6530	73.7
III	3.9	57.1—57.5 (742.3)	1.3743	0.6600	72.0

TABLE 4

Hydrocarbon	B.p. (°C)	n_D^{20}	d_4^{20}	Aniline point (°C)
2-Methylpentane [12]	60.271	1.3715	0.6532	74.6
2,3-Dimethylbutane [12]	57.99	1.3750	0.6616	71.9

The substance fractionated amounted to 12.0 ml (7.9 g) and had n_D^{20} 1.3731 and d_4^{20} 0.6575. Toward the end of the distillation 10 ml of heptane was added as a displacer.

TABLE 5

Fraction	Temperature (°C at 760 mm)	Amount (g)	n_D^{20}	d_4^{20}	Aniline point (°C)
I	57.6—58.5	1.6	1.3752	0.6634	70.6
II	58.5—58.8	1.4	1.3739	0.6599	—
III	58.8—60.3	3.3	1.3722	0.6563	—
IV	60.3—60.4	0.7	1.3712	0.6532	73.9
	Losses	0.9			

The data in the figure and in Table 5 enable us to conclude that the catalyzate from Series IV experiments is a mixture of approximately equal amounts of 2-methylpentane and 2,3-dimethylbutane, which could not be resolved in the column used owing to the closeness of the boiling points of these hydrocarbons.

SUMMARY

1. A study was made of the hydrogenation of isopropyl- and isopropenyl-cyclopropanes over palladized and platinized charcoals at 120° at a space velocity of 0.2.

2. Substantial differences were found in the behaviors of the two hydrocarbons in the reaction of catalytic hydrogenation: irrespective of the identity of the catalyst, isopropylcyclopropane is converted into 2,3-dimethylbutane; in presence of palladium isopropenylcyclopropane is converted into 2-methylpentane, and in presence of platinum it is converted into a mixture of 2-methylpentane and 2,3-dimethylbutane.

KINETICS OF THE DEHYDROGENATION OF ISOPROPYL AND ETHYL ALCOHOLS OVER MANGANOUS OXIDE

A. A. Tolstopyatova, A. A. Balandin and E. M. Dmitriev

Manganous oxide is a good, cheap catalyst for the ketonization of acids. As Sabatier and Maihle showed [1], fatty acids are decarboxylated over MnO at 400-450° with formation of ketones in good yield; e. g., adipic acid gives cyclopentanone. Zelinsky and Ryakhina [2] effected the ketonization of naphthenic acids over manganous oxide. There are also various papers [3] on the dehydrogenation of alcohols over MnO, and in these it is shown that dehydrogenation proceeds without side reactions, although MnO has lower activity than copper and other catalysts. We were the first to make a kinetic investigation of the dehydrogenation of alcohols over manganous oxide: one of us [4] investigated the rate of dehydrogenation of cyclohexanol, and in the present investigation we have studied the kinetics of the dehydrogenation of ethyl and isopropyl alcohols.

EXPERIMENTAL

a) Apparatus. The kinetic experiments were carried out in the usual flow apparatus with automatic feed. The volume of gas formed was measured in a eudiometer having a constant lower level; the measurement was accurate within 0.5 ml. The end of the pocket of the chromel-alumel thermocouple was in the middle of the catalyst layer. The temperature was registered on a potentiometer accurately within 0.5°. The reactor was a quartz tube, 16 mm in diameter. It was connected by means of ground joints to an automatic spray and to a receiver, which was fitted with a water-cooled reflux condenser.

b) Starting Substances. Commercial ethyl alcohol was distilled through a column and then had d_4^{15} 0.8118, which corresponds to 93.93% by weight or 94.0 mole % of alcohol. Isopropyl alcohol was rendered absolute by boiling it for 20 hours with quicklime and distilling it through a column. The fraction used in the experiments had b.p. 81.5-82° (75 mm), n_D^{20} 1.5782 and d_4^{20} 0.7867 (the literature [5] gives n_D^{20} 1.5770 and d_4^{20} 0.7870). Acetone used for the preparation of binary mixtures with isopropyl alcohol was purified by boiling it for six hours with potassium permanganate, distilling through a column, and redistilling over anhydrous potassium carbonate. The acetone so obtained had the following constants: 56° (752 mm); n_D^{20} 1.3590; d_4^{20} 0.7920 (the literature gives n_D^{20} 1.3583 [6] and d_4^{20} 0.7906 [7]).

Binary mixtures of isopropyl alcohol and acetone were prepared by mixing the appropriate volumes of isopropyl alcohol and acetone; they contained 24.98, 49.32 and 73.75 mole % of $(CH_3)_2CHOH$. As the differences in density between the mixtures were very small, the rate of passage was the same for all of the mixtures. The required mole-percentage compositions of the mixtures with hydrogen were attained by changing the rates of feed of alcohol and the current in the electrolyzer. For each mixture, the necessary current strength was calculated from Faraday's law. The amount of hydrogen evolved was checked with the aid of the eudiometer so as to ensure the absence of complications. Hydrogen was obtained by the electrolysis of sodium hydroxide solution; it was purified from oxygen over palladium and dried with sulfuric acid.

c) Catalysts. Manganous oxide was prepared from manganese nitrate ("Chemically Pure Brand") and crystalline sodium carbonate ("Pure"). A saturated solution of manganese nitrate was added dropwise to a stirred 10% solution of crystalline sodium carbonate; the latter was in excess (5% more than the calculated amount). The mixing of the solutions was carried out at 45°. The white precipitate of manganese carbonate was washed with distilled water by decantation until a test for nitrate (with diphenylamine in sulfuric acid) was negative; it was filtered off and pressed out between filter papers on a pipe-clay tile.

The paste of manganous carbonate was placed in a glass tube, 35 mm in diameter, and heated in an electric furnace in an atmosphere of nitrogen at 200° for three hours (until the liberation of water ceased). The tube was cooled, and the manganese carbonate was placed in the quartz reaction tube and decomposed at 400° for four hours in a current of dry nitrogen. The completeness of the decomposition of the carbonate was determined by the absence of carbon dioxide in the exit gases. In order to create a reducing atmosphere, methanol was first used. Doubly distilled commercial methanol was passed into the reaction tube from a spray at the rate of 0.2 ml per minute at 400°. This method of reduction to MnO was used in all the above-mentioned investigations with this catalyst [1-3].

We found that in the decomposition of manganese carbonate, methanol can be successfully replaced by hydrogen. Also, hydrogen is able to restore the activity of the catalyst when it is not too strongly poisoned. In further work the decomposition was always carried out in a stream of electrolytic hydrogen purified from oxygen and dried at the temperature of the experiment (350-420°) until water ceased to separate (two hours). In the early experiments the catalyst was used in powder form, but is rapidly dispersed. In further work we used a molded catalyst. Such a catalyst is pale green, but immediately becomes brown when brought into contact with air. The oxidation of manganous oxide is highly exothermic, and there is therefore, a sharp rise in temperature in the first minutes of passage of air in the regeneration of the catalyst.

d) Experimental Procedure. After being reduced in the reaction tube, the catalyst did not again come into contact with air: during and after the experiments it was in an atmosphere of nitrogen, hydrogen, or alcohol vapor. During the heating of the furnace, the catalyst was in a stream of nitrogen. When the required temperature was reached, the nitrogen was turned off and the reactant was sprayed into the reactor. After the establishment of a stationary state, regular readings were taken (ml) of the amount of gas that had separated. The experiment continued for 30-35 minutes. In the interval between experiments hydrogen was passed, but before the beginning of the next experiment the hydrogen was replaced by nitrogen. The volume of gas separating was reduced to the standard state. The gas was analyzed in a VTI apparatus. We shall now consider the results for ethyl and isopropyl alcohols separately.

Dehydrogenation of Ethyl Alcohol

The experiments on the dehydrogenation of ethyl alcohol were carried out in the temperature range 295-400°. The rate of passage of alcohol was 0.2 ml per minute. In all, 80 experiments were carried out with four portions of the same catalyst; in Experiments 1-45 the length of the catalyst layer was 15 cm and the catalyst was reduced with methanol, but in Experiments 46-80 the length of the catalyst layer was 7.5 cm and the catalyst was reduced with hydrogen. The activity of the catalyst was constant for 15-20 experiments, but after 8-10 hours' work, its activity fell and we were unable to restore its original activity. The gas separating contained 70-95% of hydrogen, 1-12% of unsaturated hydrocarbons, 4-10% of carbon dioxide, 1-5% of carbon monoxide, and 0.5-2% of saturated hydrocarbons. With rise of temperature the amount of gas separating increased. However, the hydrogen content of the gas fell and the contents of unsaturated hydrocarbons and carbon dioxide simultaneously rose.

Figure 1 shows the dependence of gas composition on temperature. From this graph and the total amount of gas separating in 3 minutes (STP) we calculated the values of m (amount of hydrogen (ml) in 3 minutes at STP). Figure 2 shows the dependence of the extent of conversion of alcohol on temperature. Hydrogen used for hydrogenation is not taken into account owing to the low content of saturated hydrocarbons. For each new portion of catalyst the activation energy was determined (ε_1 for the first portion, ε_2 for the second, and so on). These results are given in Table 1 and Figures 3-6.

The activation energy ε was calculated from the formula

$$\varepsilon = \frac{4.575\,(\lg m_1 - \lg m_2)}{\frac{1}{T_2} - \frac{1}{T_1}}. \qquad (1)$$

Fig. 1

Fig. 2

The determination of the activation energy gave the mean value of 29,500 cal/mole. The points fit satisfactorily to straight lines. The value of the activation energy was the same in Experiments 46-66 (Fig. 6) as in Experiments 11-45, in spite of the fact that the catalyst layer was half the length in the first series. Straight

lines were obtained in Figures 3, 4 and 5. In Figure 6 there is appreciable curving of the line at higher temperatures. This indicates that the dehydrogenation of ethyl alcohol does not proceed according to a zero-order law. For the establishment of the kinetic equation it was necessary to determine the relative adsorption coefficients of the reaction products, the true rate constants, and the true activation energies, and this was done for isopropyl alcohol. The dehydrogenation reaction proceeds smoothly without formation of by-products. We observed that a completely oxidized catalyst also has catalytic activity toward ethyl alcohol. The results of two experiments with an oxidized catalyst are given in Table 2.

There is a reference in the literature to the dehydrogenation of ethyl alcohol over manganic oxide [8].

Dehydrogenation of Isopropyl Alcohol

a) Determination of the Rate of Dehydrogenation. The experiments were carried out in the temperature

Fig. 3

Fig. 4

Fig. 5

Fig. 6

range 300-400°. The length of the catalyst layer was 7.5 cm. The rate of passage of alcohol was 0.15 ml/minute. The results are given in Table 5 (Columns 1-3). The determination of true rate constants and true activation energies from these data requires the determination also of the relative adsorption coefficients of the reaction products, hydrogen and acetone.

TABLE 2

Reduced	77	343	94	1	0.5	4.5	0
Oxidized	78	343	70	1.5	3.5	2.5	0

b) Method of Determining the Constants.

Balandin [9] proposed a kinetic method of determining relative adsorption coefficients experimentally. Later, in a paper by Bork and Balandin [10] on the kinetics of the dehydrogenation of ethyl and propyl alcohols over copper, the equation

$$k = \frac{N \cdot m}{N - \frac{m}{2}} \qquad (2)$$

was derived for the case in which the relative adsorption coefficient of one of the products α_2/α_1 is unity, and that of the other α_3/α_1 is zero (cf. [11]). This Equation was extended [12] to the case when the sum of the coefficients is unity, $\alpha_2/\alpha_1 + \alpha_3/\alpha_1 = 1$, and the equation

$$\alpha_2/\alpha_1 = \frac{kM - m(k/2 + M)}{m(N - M)}, \qquad (3)$$

was derived in which M is the amount of the original substance (moles) passed into the catalysis tube (M may be expressed also as the amount of gas (ml) that would be formed if the whole of the original reactant underwent the reaction); N is the total amount of substance (moles) passed into the catalysis tube in unit time, irrespective of the chemical nature of the molecules (N may be expressed as the amount of gas (ml) that may be formed); m is the number of moles that react (m may also be expressed as ml of gas); α_1 and α_2 are adsorption coefficients; k is the rate constant for the reaction $k = k_1 \cdot \omega$, the product of the rate constant, the active surface of the catalyst, and the length of the catalyst layer. The applicability of Equations 2 and 3 was proved for the dehydrogenation of alcohols over copper [13] and the dehydrogenation and dehydration of alcohols over alumina [14].

For the calculation of rate constants from experimentally determined values of m, in the present investigation we used the general kinetic equation of Balandin [15], in which no limitations are imposed on the values of α_1, α_2 and α_3. In its application to the present reaction, this equation takes the form

$$\frac{dm}{d\tau} = k \frac{A_1 - m}{A_1 + (z_2 + z_3 - 1)\, m} \tag{4}$$

or after integration

$$k = (z_2 + z_3)\, A_1 \cdot \ln \frac{A_1}{A_1 - m} - (z_2 + z_3 - 1)\, m, \tag{5}$$

in which k is the rate constant (k is expressed in different units in Equations 4 and 5); m is the number of moles of substance that reacts in unit time (milliliters of hydrogen liberated in 3 minutes); A_1 is the number of moles of the original substance entering the tube in unit time (milliliters of gas which would be formed in three minutes if the substance reacted completely); z_2 and z_3 are relative adsorption coefficients.

The calculation of relative adsorption coefficients was carried out by the formula [16]

$$z_2 = \frac{2B_1\, H - B_1 Y - HY}{(1 - B_1)\, Y}, \tag{6}$$

in which

$$Y = \frac{m}{\Sigma A_r}; \quad B_1 = \frac{A_1}{\Sigma A_r}; \quad H = \frac{kl}{2\Sigma A_r}; \quad H = \frac{Y_0}{2 - Y_0}.$$

For experiments with the pure reactant Equation 6 is identical with Equation 3, for $Y = \frac{m}{N}$; $B_1 = \frac{M}{N}$; $H = \frac{k}{2N}$; $z_2 = \frac{\alpha_2}{\alpha_1} \Sigma\nu_r$ ($\Sigma\nu_r$ is the sum of the stoichiometric coefficients).

Equation 6 is applicable for the case in which

$$Y_2 \ll \frac{B_1 H}{2\Sigma\nu_r z_r}. \tag{7}$$

The applicability of Equation 5 was proved in a series of investigations [17-21]. Agronomov [17], for the dehydrogenation of isopropyl alcohol over zinc oxide, and Balandin and Klabunovsky [18], for the dehydrogenation of sec. butyl alcohol over nickel, calculated z (the value of which must be substituted in Equation 5

from Equation 6, as we have done. The relative adsorption coefficients required for substitution in Equation 5 may be calculated also from the approximate equation

$$z_r = \frac{m_0/m - 1}{100/p - 1}, \qquad (8)$$

in which m_0 is the number of milliliters of hydrogen formed in the passage of the pure substance, and m is the number of milliliters of hydrogen formed in the passage of a mixture having a mole-percentage content of p. Equation 8 was used for the calculation of z in the papers of Balandin, Bogdanova and Shcheglova [19, 20] on the dehydrogenation of butene, and of Balandin and Isagulyants [21] on the dehydrogenation of cyclohexane, methylcyclohexane, dimethylcyclohexane, tetralin, and methyltetralin over chromic oxide.

c) Determination of Relative Adsorption Coefficients. Experiments with mixtures, which were required for the determination of relative adsorption coefficients, were alternated with experiments with the pure alcohol in order to prove absence of irreversible poisoning. In work with isopropyl alcohol — hydrogen mixtures the catalyst maintained constant activity in the course of the whole series of experiments, and the experiments were

therefore carried out one after the other without regeneration of catalyst. The results of these experiments are given in Table 3. In work with mixtures of isopropyl alcohol and acetone, the catalyst was greatly poisoned. Hence, before each experiment the catalyst was regenerated for two hours with air and was then reduced with hydrogen in order to restore its activity. The activity was checked each time in experiments with pure isopropyl alcohol, and the value of the activity found was taken as m_0 for the subsequent experiment with the mixture. The results of experiments on mixtures of isopropyl alcohol and acetone are given in Table 4.

Fig. 7

Fig. 8

Figures 7 and 8 show the relationships found between the amount of hydrogen liberated m and the percentage composition of the mixture at various temperatures. Points below the additive straight line correspond to $z > 1$, and points above the straight line correspond to $z < 1$. As will be seen from Figures 7 and 8, for all three temperatures the adsorption coefficients of acetone are very close to unity, but the adsorption coefficients of hydrogen are considerably less than unity and increase with rise in temperature. The relative adsorption coefficients given in Tables 4 and 5 are calculated from Equation 6. Calculation of z from the approximate Equation 8 and, at low temperatures, from Equation 3 gives very similar results. Thus, for Experiment 149 (Table 4) z was calculated from all three equations, and the following values were obtained: Equation 3 gave $z = 0.92$; Equation 6 gave $z = 0.96$; Equation 8 gave $z = 0.97$.

d) Calculation of Reaction-rate Constants and True Activation Energies. The rate constant k was calculated from Equation 5. The values of z_2 and z_3 in Equation 5 were found from the graph in Fig. 9, which expresses the relation between relative adsorption coefficients and temperature. For the calculation of true activation energies we constructed the graph in Fig. 10, in which log k, calculated from Equation 5, is plotted as ordinate and 1/T is plotted as abscissa (Curve 1). The true activation energy was calculated from Equation 1, log m being replaced by log k, and a value of 23,650 cal/mole was found.

Fig. 9

In Figure 10 Curve 2, obtained from log m, is given for comparison. Table 5 gives the experimental values of m, the rate constants k, and the percentage conversion of the alcohol in the dehydrogenation of isopropyl alcohol.

e) Determination of the Thermodynamic Quantities ΔF, ΔH and ΔS. By the method given previously [22] we may calculate from z (Tables 3 and 4) the changes in free energy ΔF, in heat content ΔH, and in entropy ΔS occurring in the displacement of isopropyl alcohol by acetone and hydrogen from the active centers of manganous oxide:

$$\Delta F = -RT \cdot \ln z;\ \Delta H = \frac{4.57\,(\log z_1 - \log z_2)}{\frac{1}{T_2} - \frac{1}{T_1}};\ \Delta S = \frac{\Delta H - \Delta F}{T}.$$

The results so obtained are given for isopropyl alcohol– hydrogen in Table 6 and for isopropyl alcohol– acetone in Table 7.

f) Discussion of Results of Experiments on Isopropyl Alcohol. Table 5 gives values of the rate constants k for the dehydrogenation of isopropyl alcohol– as determined, and as calculated from the Arrhenius equation for $\epsilon = 23{,}650$ cal/mole. These values differ very little from one another, which indicates the correctness of

Fig. 10

the calculated activation energy. The values of the logarithm of the pre-exponential term which are given in Table 5 were calculated from the equation

$$\log k_0 = \frac{\epsilon}{4.57\,T} + \log k. \qquad (9)$$

The scatter of the values obtained is not great, so that Equation 5 is applicable. From the mean value of log k_0 we determined the value of the pre-exponential term $k_0 = 6.12 \cdot 10^8$ and the reciprocal of the scattering parameter $\epsilon/\log k_0 = 2.42 \cdot 10^3$. The true activation energy calculated from log $\underline{k}$ (ϵ = 23,650 cal/mole) differs from the activation energy calculated from log $\underline{m}$ (ϵ = 20,500 cal/mole), see Fig. 10, Curves 1 and 3. This indicates that the dehydrogenation of isopropyl alcohol is not a zero-order reaction, but proceeds according to Equation 4. The relative adsorption coefficient depends on temperature, and, in fact, increases with rise in temperature (Fig. 9). It can be seen that the relative adsorption coefficient of acetone is close to unity and changes little with temperature, whereas the relative adsorption coefficient of hydrogen is fairly close to zero and increases with rise in temperature. If log $\underline{z}$ is plotted as ordinate and 1/T as abscissa, then straight lines are obtained (Fig. 11).

Fig. 11

At low temperatures the kinetic Equation 2 was found to be applicable; this does not contain adsorption coefficients. This can be seen from the fact that, if $\underline{k}$ is calculated from Equation 2 and log $\underline{k}$ is plotted against 1/T, the points lie on a straight line up to a point at which the temperature can no longer be considered low. At high temperatures the points fall below the straight line. Equation 2 is applicable because, in the given reaction at low temperatures z_a is approximately unity and z_s is approximately zero, i. e., just those conditions obtain for which Equation 2 was derived. At higher temperatures z_s increases and z_a, although still small, also increases; it is to be expected, therefore, that Equation 2 will no longer apply.

SUMMARY

1. A study was made of the kinetics of the dehydrogenation of isopropyl alcohol over manganous oxide. It was shown that this reaction obeys the kinetic Equation 4.

2. The relative adsorption coefficients $\underline{z}$ of acetone and hydrogen were determined. In the temperature range 330-400° the relative adsorption coefficient of acetone is close to unity. For hydrogen it varies from 0.10 to 0.36, increasing with rise in temperature from 317° to 345°.

3. From the values found for the relative adsorption coefficients, the thermodynamic quantities ΔF, ΔH and ΔS were determined for the displacement of isopropyl alcohol by acetone and hydrogen.

4. The rate constants and the true activation energy were determined for the dehydrogenation of isopropyl alcohol (ϵ = 23,650 cal/mole).

COORDINATION NUMBERS OF Rb^+ AND Cs^+ IONS IN AQUEOUS SOLUTIONS

O. Ya. Samoilov

With the aid of a specially developed thermochemical method we have previously determined the coordination numbers of various ions, including Li^+, Na^+ and K^+ [1], in dilute aqueous solution. The present paper gives results of the determination of the coordination numbers of Rb^+ and Cs^+ ions. The integral heats of solution were measured for rubidium and cesium chlorides in water and in aqueous hydrochloric acid at 25°. An improved calorimeter having an isothermal jacket was used [2]. The temperature was read on a Beckmann thermometer, with the aid of a magnifier, accurately within 0.001°. The measurement of current strength and the introduction of the weighed sample were carried out as described previously [2]. The final RbCl and CsCl concentrations in the solution were 0.050 and 0.047 moles, respectively, of salt in 50 moles of water. The results of the measurements are given in the table. Heats of solution (L) are given in kcal/mole, and the HCl concentration (m) in moles of HCl per 50 moles of water. Individual measurements of L were accurate within about 1%.

TABLE

Integral Heats of Solution of RbCl and CsCl in Aqueous HCl Solutions at 25°

Dissolved salt	m	L	Dissolved salt	m	L
RbCl	0.00	−4.18	CsCl	0.00	−4.31
	0.72	−4.22		0.72	−4.17
	1.47	−4.14		1.47	−3.92
	2.08	−4.12		2.09	−3.80
	3.02	−3.95		3.03	−3.49

The relationships between L and m for RbCl and CsCl are shown in the figure together with the corresponding relationships for lithium, sodium, and potassium chlorides. In order to present these on one graph we have displaced the curves (straight lines) along the axis of ordinates while preserving contancy of scale.

The values of $\delta = -\Delta L/\Delta m$, determined by the method of least squares, are −85 and −274 for RbCl and CsCl respectively. The values of the coordination numbers of Rb^+ and Cs^+ may be found from the relation [1]

$$1.17 \cdot 10^3 \left(\frac{n}{r + 1.38} - \frac{4.4}{3.19} \right) = \beta,$$

in which n is the coordination number of the cation and r is its crystallographic radius; the coordination number and radius of the Cl^- ion are taken to be 4.4 and 1.81 A respectively [1]. Using the Goldschmidt radii of the Rb^+ and Cs^+ ions (1.49 and 1.65 A), we find that $n_{Rb^+} = 3.8$ and $n_{Cs^+} = 3.5$. The values of $\rho^{\frac{1}{3}}$ [1] for Rb^+ and Cs^+ are 0.037 and 0.030 A^{-1} respectively. These cations are characterized by negative hydration (for Cs^+

Dependence of integral heats of solution of alkali-metal chlorides (L) on the concentration of HCl in the solvent (m).

$\Delta E = -0.33$ kcal/mole [3]). This fact is probably of great importance for the behavior of Rb^+ and Cs^+ in the natural aqueous solutions of the earth's crust. In particular, it is significant that the temperature coefficient of the mobility of ions that have negative hydration is less than that of water molecules [4].

SUMMARY

1. The coordination numbers of the cations Rb^+ and Cs^+ were determined in dilute aqueous solutions by the thermochemical method and found to be 3.8 and 3.5, respectively.

2. The Rb^+ and Cs^+ cations are characterized by negative hydration.

HEAT OF ATOMIZATION OF CARBON

G.V. Bykov

In the course of establishing the relationship between electronic charges of bonds and heats of formation of saturated hydrocarbons the author [1] found that the energies of the C–C and C–H bonds formed by two σ-electrons are 16.108 and 64.616 kcal/mole respectively, and the heat of atomization of carbon is 32.216 kcal/g-atom. As the heat of sublimation of diamond probably lies between 124 kcal (lower limit) and 170 kcal (upper limit) and the values calculated on this basis for the energy of the C–H bond in methane are 87.6 and 91.1 kcal respectively, the values obtained by the author require some further substantiation.

According to Cottrell's data ([2], pp. 226-227), the bond energies in HF, H_2O and NH_3 are $D_{HF} = 135$, $D_{OH} = 110.6$ and $D_{NH} = 84.3$ kcal. According to the position of carbon in the periodic system, the energy of the C–H bond in CH_4 should be still less. We may attempt to evaluate this bond energy on the assumption that the difference $D_{NH} - D_{CH}$ is similar to $D_{HF} - D_{OH} = 24.4$ and $D_{OH} - D_{NH} = 26.3$ kcal. D_{CH} should then be about 59 kcal, to which our figure is the closest.

Some theoretical chemists, and particularly Long [3, 4], have developed the idea that bond energies calculated in the usual way cannot be correlated with interatomic distances, force constants, and other bond characteristics, and that such correlation is possible only for "true" ("natural", "absolute," or "intrinsic") bond energies. We obtain the latter if in our calculations we take not the heat of atomization of carbon into atoms in their "fundamental" state, but the heat of an atomization process in which the atoms obtained preserve the valence state that they had in the molecules. As neither the energy of the valence state nor true bond energies can be determined directly, attempts were made to evaluate them by indirect methods, but no reliable results were obtained. The author considers that the value he has found of about 30 kcal/g-atom is the required heat of atomization of carbon to atoms in their valence state, and we shall term this the valence heat of atomization of carbon and denote it by L_{C_v}.

Let us consider the usual thermochemical scheme used in the calculation of the heat of formation (atomization) of a gaseous hydrocarbon C_nH_m.

$$C_nH_m(g) + \left(n + \frac{m}{4}\right)O_2(g) = nCO_2(g) + \frac{m}{2}H_2O(l) + \Delta H^0_{C_nH_m}\ (\text{combust}) \qquad (1)$$

$$nC(s) + nO_2(g) = nCO_2(g) + n\Delta H^0_{CO_2} \qquad (2)$$

$$\frac{m}{2}H_2(g) + \frac{m}{4}O_2(g) = \frac{m}{2}H_2O(l) + \frac{m}{2}\Delta H^0_{H_2O}. \qquad (3)$$

Subtracting (1) from the sum of (2) and (3), we obtain

$$nC(s) + \frac{m}{2}H_2(g) = C_nH_m(g) + \Delta H^0_{C_nH_m}\ (el), \qquad (4)$$

in which the heat of formation of the hydrocarbon C_nH_m from its elements is

$$\Delta H^0_{C_nH_m}(\text{el}) = n\Delta H^0_{CO_2} + \frac{m}{2}\Delta H^0_{H_2O} - \Delta H^0_{C_nH_m}(\text{combust}) \quad (5)$$

For the calculation of the heat of formation of the hydrocarbon C_nH_m from its atoms we require two more equations:

$$nC(s) = nC(g) + n\Delta H^0_C; \quad (6)$$

$$\frac{m}{2}H_2(g) = mH(g) + \frac{m}{2}\Delta H^0_{H_2}. \quad (7)$$

Subtracting (6) and (7) from (4), we obtain

$$nC(g) + mH(g) = C_nH_m(g) + \Delta H^0_{C_nH_m}(\text{at}), \quad (8)$$

in which

$$\Delta H^0_{C_nH_m}(\text{at}) = \Delta H^0_{C_nH_m}(\text{el}) - \frac{m}{2}\Delta H^0_{H_2} - n\Delta H^0_C \quad (9)$$

or in accordance with (5)

$$\Delta H^0_{C_nH_m}(\text{at}) = n\Delta H^0_{CO_2} + \frac{m}{2}\Delta H^0_{H_2O} - \Delta H^0_{C_nH_m}(\text{combust}) - \frac{m}{2}\Delta H^0_{H_2} - n\Delta H^0_C \quad (10)$$

The first four terms of the right-hand side of this equation are experimentally determinable quantities and cannot give rise to doubt. However, the true value of the so-called heat of sublimation of diamond ΔH^0_C is unknown and, what is more important, the substitution of a value for this in Equation 6 is not permissible if we are proposing to calculate true bond energies.

Actually, the processes represented by Equations 1, 2 and 4 consist in the passage of carbon from one compound to another with preservation of its valence state.* Similarly, in Equation 8 carbon C (g) passes into the valence state. Hence, in Equation 6 also, contrary to usual practice, we must introduce C (g) in the fundamental state and identify ΔH^0_C with the heat of sublimation of diamond in this equation and also in Equations 9 and 10. If we could in some way solve Equation 9 or 10 numerically for ΔH^0_C, we should obtain not the heat of sublimation of diamond, but the valence heat of atomization of carbon. As the author has shown [1], this can be done in the case of saturated hydrocarbons by use of the relationship

$$-\Delta H^0_{C_nH_{2n+2}}(\text{at}) = a\Sigma A^v_{CC} + b\Sigma A^v_{CH}, \quad (11)$$

* We neglect the differences in the valence states of carbon in CO_2, diamond, graphite, and hydrocarbons in the present case, although it would be necessary to take them into account in more precise calculations.

in which ΣA^{σ}_{CC} and ΣA^{σ}_{CH} are summated σ-electron charges of C–C and C–H bonds, respectively, calculated from the equation proposed by the author; $\underline{a} = \frac{1}{4} L_{C_V}$; and $\underline{b}$ can be readily expressed in an explicit form in terms of $\underline{a}$.

In Long's opinion, the energy of the valence state of the carbon atom is higher (approximately by 60–70 kcal) than the energy of the fundamental state, and the true bond energies are higher than those calculated in accordance with the usual scheme. However, we do not really know anything definite about the valence states of carbon (see [2], p.104 et seq.); every such statement must have a hypothetical character. Evidence against Long's view is found in the fact that, in accordance with the high energy of the valence state, atomic carbon gas–being, it is thought, in the fundamental state– should be fairly stable, which is not in accord with experiment. The facts can be given another explanation: the quadrivalent state of carbon is energetically the most favorable and any transition from this state to any other is accompanied by absorption of energy. For example, according to the author's estimation, 35 kcal is required for the conversion of one g-atom of carbon from the quadrivalent state (in methane) into the tervalent state (in the methyl radical). This is to be explained by the fact that the dissociation energy of the C–H bond in methane, and particularly of the C–C bond in ethane, is considerably greater than the true bond energy.

SUMMARY

1. The energy of the C–H bond in methane is about 64 kcal and is in accord with the position of carbon in the periodic system.

2. The heat of atomization of carbon into atoms that preserve their valence state is approximately 32 kcal/g-atom.

SYNTHESIS OF CANCEROLYTIC PEPTIDES

I. L. Knunyants, O. V. Kildisheva and N. E. Golubeva

By reaction of the N-formyl derivative of 3-p-(bis-2-chloroethylamino)-phenylalanine ("Sarcolysine") with various amino-acid esters we obtained a series of previously unknown peptides containing the bis-2-chloroethylamino group (see table). For the condensation we made use of dicyclohexylcarbodiimide, previously proposed by Sheehan for the preparation of simple peptides [1].

EXPERIMENTAL

Previously purified DL-3-p-(bis-2-chloroethylamino) phenylalanine [2], m.p. 179-180° with decomposition, was heated in a mixture of anhydrous formic acid and acetic anhydride (3:1) in a water bath at 45-50° for 45 minutes. The resulting DL-3-p-(bis-2-chloroethylamino) phenyl-N-formylalanine was isolated by diluting the cooled solution with water. It formed colorless needles from methanol, m.p. 148-150°. Yield 65-70%.

Found %: C 50.24; H 5.51; N 8.45 $C_{14}H_{18}N_2Cl_2O_3$. Calculated %: C 50.46; H 5.44; N 8.47

Successive additions were made of equimolecular amounts of dicyclohexylcarbodiimide and the appropriate racemic amino-acid ester in chloroform to a suspension of 1 mole of DL-3-p-(bis-2-chloroethylamino) phenyl-N-formylalanine in chloroform. The mixture was shaken vigorously and then left at room temperature for 5-6 hours. The precipitated 1,3-dicyclohexylurea was filtered off, chloroform was distilled from the filtrate, and the residue was mixed with a little alcohol and allowed to crystallize in a refrigerator. The precipitated dipeptide was filtered off and recrystallized from alcohol (see table). By this general method we prepared the ethyl esters of (N-formylsarcolysyl) phenylalanine, (N-formylsarcolysyl)-β-alanine, (N-formylsarcolysyl) valine, and (N-formylsarcolysyl) leucine, and also the methyl ester of (N-formylsarcolysyl) tryptophan. The properties of these peptides are shown in the table.

SUMMARY

New peptides containing a bis-2-chloroethylamino group were prepared by condensing DL-3-p-(bis-2-chloroethylamino) phenyl-N-formylalanine with amino-acid esters.

CIS–TRANS ISOMERISM OF 1,2-BISTRICHLOROSILYLETHYLENE

M. I Batuev, V. A. Ponomarenko, A. D. Matveeva

and A. D. Snegova

1,2-Bistrichlorosilylethylene [1,1,1,4,4,4-hexachloro-1,4-disilabut-2-ene] was prepared by dehydrochlorination of $Cl_3SiCH(Cl)CH_2SiCl_3$ with the aid of quinoline. Under these conditions formation of unsymmetrically substituted ethylenes is not observed.* The boiling point of $Cl_3Si-CH=CH-SiCl_3$ is 192-192.5° (744.5 mm) and its melting point is about 36°. The Raman spectrum of this substance was determined on a Soviet ISP-51 three-prism spectrograph with a central camera; the exciting radiation was the 4358 A line from a mercury lamp.

$\Delta\nu$ cm^{-1}: 97 (1), 115 (1), 129 (6), 153 (5*), 171 (4*), 194 (4), 301 (1*), 316 (9*), 351 (0), 464 (0), 483 (1*), 498 (9*), 581 (3*), —591 (3*) —807 (3*), (band), 620 (0), 743 (1), 757 (0), 774 (0), 1282 (6*), 1297 (6*), 1559 (5), 1602 (5), 2889 (1), 2957 (5 d)

d Denotes doublet, and the asterisks indicate lines occurring on a general background.

The presence in the spectrum of distinct and widely spaced lines in the double bond region having identical intensities—1559 (5) and 1602 (5)— definitely indicates that the substance investigated is a mixture of two isomers, cis and trans, present in approximately equal amounts:

This explains the comparatively large number of lines in the spectrum for a symmetrical compound of this type and the presence of closely placed or double (nor sharply split into two) lines (1282 and 1297, 2975 (d)); the two lines of each of these pairs belong to different isomers. The effect of the chlorine atoms of the trichlorosilyl groups is manifested by a somewhat low level of frequencies of the double bond for both isomers.

* The unsymmetrical derivative $(SiCl_3)_2C=CH_2$ was obtained [1], together with the symmetrical derivative $Cl_3Si-CH=CH-SiCl_3$ from $Cl_3Si-CH(Cl)CH_2-SiCl_3$ by dehydrochlorination with the aid of $AlCl_3$. The resolution of the products of the methylation of $Cl_3Si-CH=CH-SiCl_3$ into cis and trans isomers was not carried out either chemically or spectrographically in the investigation [1].

As fairly extensive experimental data show, in cis isomers the vibrational frequency of the double bond is generally somewhat lower than in the corresponding trans isomers [2], e.g., (cm^{-1}):

$H_3C-CH=CH-CH_3$	cis	1669
	trans	1681
$H_3C(CH_2)_n-CH=CH-CH_3$	cis	1658
	trans	1674
$H_3C(CH_2)_3-CH=CH-(CH_2)_3CH_3$	cis	1653
	trans	1667
$H_3C-CH=CH-CO\cdot OCH_3$	cis	1644
	trans	1655
$H_5C_6-CH=CH-C_6H_5$	cis	1640
	trans	1652

A similar relation of frequencies is evidently found in the isomers under consideration (cm^{-1}):

$Cl_3Si-CH=CH-SiCl_3$	cis	1559
	trans	1602

but in this case the difference in frequency of the double bond in the two isomers (43 cm^{-1}) is substantially greater than for the cis and trans isomers cited above for comparison (11-16 cm^{-1}).

Owing to the almost identical boiling points of these isomers, we did not succeed in separating them chemically (by fractionation).

It may be noted that in [1] the authors found a very broad line (breadth about 20 cm^{-1}) in the spectrum of $(CH_3)_3Si-CH=CH-Si(CH_3)_3$ in the double-bond region. They did not associate it with the presence of cis and trans isomers in the substance under investigation. In the light of our results there can be no doubt that in [1] the authors were dealing with a mixture of the cis and trans isomers of $(CH_3)_3Si-CH=CH-Si(CH_3)_3$, which are characterized by different frequencies in the double-bond region, these, however, being not so far apart as in the cis and trans isomers of $Cl_3Si-CH=CH-SiCl_3$ so that in the experiment of the authors of [1] they were merged into one broad line.

SUMMARY

The existence of cis and trans isomers of 1,2-bistrichlorosilylethylene was detected spectrographically. It was noted that the frequencies of the double bonds of the cis and trans isomers of 1,2-bistrichlorosilyethylene are unusually far apart as compared with the frequencies found for the cis and trans isomers of other compounds.

ISOMERIZATION OF ISOPROPENYLCYCLOBUTANE ON SILICA GEL UNDER THE CONDITIONS OF CHROMATOGRAPHIC ADSORPTIONAL ANALYSIS

B. A. Kazansky, M. Yu. Lukina, L. A. Nakhapetyan
V. T. Aleksanyan and Kh. E. Sterin

We have previously observed that alkylcyclobutanes [1], unlike alkylcyclopropanes [2], do not isomerize in contact with silica gel under the conditions of chromatographic adsorptional analysis. It was, therefore, somewhat unexpected that pinene, which contains a four-membered ring, should be found [3] to be isomerized into a mixture of camphene, dipentene and terpinolene when attempts were made to purify it by chromatographic adsorption on silica gel.

As isopropenylcyclobutane was available to us, we decided to investigate its behavior toward silica gel, for its structure is reminiscent of the part of the pinene molecule that participates in the isomerization.

Our experiments showed that, after contact with silica gel at room temperature, isopropenylcyclobutane had been isomerized completely with enlargement of the ring to a five-membered system. The Raman spectrum of the hydrogenated isomerization product showed that it was a mixture of 1,2- and 1,1-dimethylcyclopentanes.

The reaction may be represented as follows:

EXPERIMENTAL

Isopropenylcyclobutane (7.8 g; b.p. 98.7° n_D^{20} 1.4347; d_4^{20} 0.7743) was filtered through a column containing 128 g of silica gel (Quality KSM (a) 12.0). The product distilled at 100-105° (760 mm) and had n_D^{20} 1.4426; d^{20} 0.7918. The isomerization product was hydrogenated in alcoholic solution at room temperature over platinized charcoal in a hydrogenation flask. The resulting hydrocarbon was steam-distilled, and the hydrocarbon layer was washed free of traces of alcohol with water, dried over calcium chloride, and distilled. The yield of hydrocarbon was 5.8 g; b.p. 92-97°; n_D^{20} 1.4152; d_4^{20} 0.7578.

Investigation of the Raman spectrum of this hydrocarbon showed that it was a mixture of 70% of trans-1, 2-dimethylcyclopentane (262, 398, 529, 607, 766, 897, 955 and 1080 cm^{-1}), 15% of cis-1,2-dimethylcyclopentane (498, 766 and 889 cm^{-1}), and 15% of 1,1-dimethylcyclopentane (562 cm^{-1}).

SUMMARY

It was shown that, under the conditions of chromatographic adsorptional analysis on silica gel, isopropenylcyclobutane is isomerized with enlargement of the ring.

CURRENT EVENTS

SECOND CONFERENCE ON METHODS OF INVESTIGATING THE STRUCTURE OF HIGHLY DISPERSED AND AND POROUS BODIES

The second conference on methods of investigating the structure of highly dispersed and porous bodies, organized by the Institutes of Physical Chemistry and of Silicate Chemistry of the Academy of Sciences of the USSR, took place on June 13-18, 1956, at the Institute of Silicate Chemistry in Leningrad (the first conference took place in 1951). Representatives of other Academy and branch institutes interested in this subject took part in the work of the conference.

Such conferences are very valuable because of the wide use of sorbents and catalysts in industry and of the great practical importance of thenature of their porosity. As a result of the first conference, plans were made for interrelated investigations on the structure of porous bodies with the aid of various methods, so that these methods could be checked against one another and the limits of applicability of each method could be more precisely defined. The second conference showed that the projected program had been substantially completed thanks to the joint investigations carried out by various institutes.

The second conference was planned as a working conference of narrow scope and of a methodological character. It was devoted to an examination of the theory of individual methods of investigating the structure of highly dispersed bodies and to an examination also of the practical results achieved in the development of these methods during the last five years. New data about the porous structure of various bodies were examined as illustrations of the possibilities of individual methods of investigation. In all, twenty papers were read, and they prompted a lively discussion.

First of all, an examination was made of methods based on the small-angle scattering of x-rays and on the use of the electron microscope. E. A. Porai-Koshits (Inst. Silicate Chem.) reported on new possibilities of extending the limits of application of the method of small-angle scattering of x-rays: the use of recently developed apparatus makes it possible, for example, to make an approach to the determination of regions of heterogeniety corresponding in dimensions to formations made up of only a few atoms. Use of the replica method in electron-microscopy has made it possible to show very clearly that porous bodies fall into two groups: 1) those of globular structure (silica gels, aluminosilicate catalysts, titania gels, etc.), and 2) those of spongy structure (active charcoals and porous glasses). Quantitative verification of the accuracy of the replica method for particles of the order of 100 A showed that in this case the error in the determination of dimensions is of the order of 10% (E. A. Lentyev and V. M. Lukyanovich, Inst. Phys. Chem.).

Considerable attention was devoted to the capillary condensation method, as a fundamental method in the investigation of the structure of porous bodies permitting the systematization of the enormous amount of experimental material in existence. Examining the sorption process as a combination of adsorption and capillary condensation, M. M. Dubinin (Inst. Phys. Chem.) gave an analysis of the assumptions and made an evaluation of the lower limit of pore dimensions for which the use of these methods is physically justified. He then examined methods of calculating the distribution of the volumes and surface areas of pores of sorbents with respect to their dimensions and methods of introducing corrections for the thicknesses and volumes of adsorption layers; he also made an appraisal of simplified methods of calculation.

The process of capillary condensation of vapor in bodies of globular structure was subjected to detailed analysis. A. V. Kiselev (Inst. Chem. Physics and Moscow State University) raised the general questions of the

structure of adsorbents in its relation to their formation. He stated various facts that enable us to assign a corpuscular – in particular, globular – structure to the skeleton of many gel adsorbents. In such structures the primary particles probably preserve their individuality; their dimensions determine the specific surface of the sorbent and the pores are the spaces between the particles. The other extreme case is that of spongy structures, which are formed by the attack of corrosive gases or solutions on solids. L. V. Radushkevich (Inst. Phys. Chem.) gave a rigorous calculation of the isotherms of reversible capillary condensation for a model adsorbent formed by spherical particles in contact. Close agreement of these theoretical calculations with experiment was found for a sample of compressed carbon black made up of nonporous particles of diameter greater than 1000 A, as measured under the electron microscope. In the development of these ideas, A. P. Karnaukhov (Moscow State University) expounded the theory of capillary-condensation hysteresis in regularly packed globular structures considered as a function of the coordination number. As was pointed out in the discussion, the above-mentioned papers enable us to understand the peculiar features of the capillary-condensation process in model systems and, in the future, we must try to estimate the extent to which the usual sorbents of globular structure approach these models.

S. P. Zhdanov (Inst. Silicate Chem.), taking porous glasses as his examples, pointed out some peculiarities of sorption processes in bodies of spongy structure. D. P. Dobychin (State Optical Inst.) demonstrated the power of the capillary-condensation method in the determination of the changes in the structure of porous glasses under the action of thermal treatment. V. S. Nabokov, E. N. Paleolog and N. D. Tomashov (Inst. Phys. Chem.) reported the successful application of the capillary-condensation method in the study of the porosity of films on anodized aluminum. The general laws determining change in sorption properties and form of isotherm were found for fluorinated (I. E. Neimark, Inst. Phys. Chem.) and chlorinated (K. D. Shcherbakova, Moscow State University) silica gels. The effects due to modification of the chemical nature of the sorbent surface are of great theoretical and practical interest and require further investigation, as was pointed out in the discussion. Simplified methods of calculation in the analysis of the porous structure of natural sorbents were analyzed by G. V. Tsitsishvili (Inst. Chem. Acad. Sci. Georgian SSR).

After an examination of the possibilities of these methods, a separate session was devoted to a comparison of the results obtained by independent methods of investigation. A study of the structures of various silica gels, aluminosilicate catalysts, and carbon sorbents by electron-microscope methods and by the method of small-angle scattering of x-rays (A. V. Kisel, V. M. Lukyanovich and E. A. Porai-Koshits) showed that, in the main, there was agreement between the results of different methods as regards the sizes of the particles making up these bodies. Apart from mutual confirmation, these data made it possible to obtain a more complete picture of the structure of certain bodies, particularly aluminosilicate catalysts. Nevertheless, in certain cases discrepancies appeared which demanded further investigation. The combined use of the method of small-angle scattering of x-rays and the method of capillary condensation for bodies of spongy structure was demonstrated by E. A. Porai-Koshits and S. P. Zhdanov for the case of porous glasses of variable structure.

Another separate session was devoted to some methods of determining the specific surfaces of highly dispersed systems. The adsorption method was not considered, because it was analyzed in detail at the 1951 conference. B. V. Deryagin, N. N. Zakhavaeva, M. V. Talaev and V. V. Filippovsky (Inst. Phys. Chem.) considered filtration methods of determining the specific surfaces of powders and porous bodies. These methods are simple in operation, and in some cases they are sufficiently accurate. By a combination of measurements made by methods of stationary and nonstationary streams, indications may be obtained of the presence and extent of pores in the particles. A. M. Smirnova, N. G. Zaitseva and V. P. Sukhova (Inst. Phys. Chem.) reported the application of the labeled-atom method to the measurement of the specific surface of cements in the hydration process. The method makes it possible to follow the changes in the specific surface of solids in an aqueous medium, although it is often difficult to distinguish between surface exchange and exchange that goes deep into the crystal lattice. A promising simple dynamic method of determining the structures and specific surfaces of adsorbents was described by V. T. Bykov and O. E. Presnyakova (Far-East Affiliated Inst. of Acad. Sci. USSR). By using substances having molecules of different sizes and analyzing the form of the efflux curves, the authors were able to draw conclusions regarding the structures of several natural adsorbents and regarding the rate of the adsorption process. The method of adsorption chemistry was discussed in a paper by S. Yu. Elovich and L. Ya. Margolis (Inst. Phys. Chem.): investigating the chemisorption of carbon monoxide on manganese dioxide, the authors were able to estimate the surface of individual elements of the lattice, in particular oxygen, and so break down the general surface of the body into its elements.

Papers by T. G. Plachenov and G. M. Belotserkovsky (Leningrad Technological Inst.) dealt with the use of the method of forcing mercury into the sorbent for analyzing its porous structure. In the discussion on this question it was pointed out that the fact that different amounts of mercury remained in different samples after removal of pressure opened up new possibilities for the understanding of the porous structure of sorbents— investigations in this direction must be extended. By the introduction of improvements in the method, S. A. Semenova succeeded in extending the range of applicability of the method in the direction of low pressures and carrying out reliable measurements of the volume of the large macropores in active carbons. The method of mercury porometry was used for measuring large pores in natural sorbents and showed the difference in porous structure between genetically differing groups of these sorbents—diatomites, tuffs, etc., (N. I. Zalevsky and V. T. Bykov, Far-East Polytechnical Institute).

In the discussions that followed papers on allied and border-line topics, considerable attention was devoted to the principles underlying the methods and to an analysis of the assumptions made. These topics are closely associated with the problem of the interpretation of experimental results, the solution of which is often difficult owing to the great variety of porous structures and the frequent complexity of their character. The capillary-condensation method, for example, is based on the derivation of the distribution of pore volume with respect to pore size from the desorption branch of the isotherm, i.e., the complex structure of the real porous body is represented as that of some equivalent sorbent, which, in the simplest case, may be a collection of capillaries of different diameters. The validity of this representation is the greater, the more closely the form of the pores of the real sorbent approximates to cylindrical or to that assumed in the equivalent model sorbent. However, as V. V. Serpinsky (Inst. Phys. Chem.) pointed out, the characterization of a porous structure with the aid of a distribution with respect to a linear parameter is not the only one possible and may not be the best method. It is possible to characterize the porosity of a sorbent on the basis of adsorption isotherms in a way satisfying practical requirements without introducing the concept of pores having a fictitious cylindrical form of definite radius. On the other hand, as was pointed out in the discussion, the existing method has the advantage of presenting a lucid picture of the phenomenon and enabling us to systematize extensive experimental material.

An urgent general problem in all the methods is the establishment of physically well-grounded limits of applicability. For the capillary-condensation method the whole matter rests on the determination of the lowest pore diameter in which a liquid meniscus is formed. In the method of mercury porometry the increase in pressure must not be too great owing to deformation of sorbent and for other reasons. In electron microscopy the exact limits of resolution attainable in the replica method have not been determined, and so on. This matter was analyzed in the discussion for these and other methods. One of the most important methods of solving this problem, and also the problem of the interpretation of experimental results, is the method of joint coordinated investigations of model samples of porous bodies by the use of various methods.

Many of the various methods of investigating the structure of porous and highly dispersed bodies are associated with a great variety of practical problems. Each method has its advantages and limitations, and all methods must be developed. Some of these methods are widely used in industry, and in the future it is necessary, on the one hand, to carry out work on the standardization of simplified methods for direct application in practice and, on the other to push on with the development of other promising methods.

In the resolution carried at the conference it is noted that the conference has carried out fruitful work. A critical analysis was made of the premises lying at the basis of various methods, the practical achievements of the last five years were examined, and plans were laid for the further development of joint investigations on the structure of highly dispersed and porous bodies by the various available methods. An important condition for the successful performance of joint investigations is the preparation of series of standard sorbents in which structural characteristics are varied in a regular manner. Industry provides very few standardized adsorbents, and these cannot meet practical requirements for the purposes of recuperation, chromatographic separation of mixtures, etc. The conference, therefore, asked the Division of Chemical Sciences of the Academy of Sciences of the USSR to request the Ministry of Chemical Industry to organize the manufacture of series of standardized adsorbents in which structural characteristics are varied in a regular manner (in the first place, silica gels and active carbons).

The conference plans to distribute work on the preparation of standard adsorbents and the development of individual methods of investigating the structure of highly dispersed and porous bodies over several laboratories. It is essential to aim at the greatest possible development of conjoint investigations, and the main problem must

be the analysis and correlation of the structural characteristics, as found by the aid of different methods.

The conference noted the importance of studying the processes by which a porous structure is formed in a body. Investigation of these processes is bound to aid in the development of more profound concepts of the structure of porous systems, particularly with respect to their assignment to the globular or spongy type (new possibilities in this direction are provided by the elegant method described by N. M. Kamakin (Grozny Petroleum Researach Institute) in which gels are "frozen" and the dispersion medium is sublimed; this makes it possible to follow changes in structure in the transition from hydrogels to xerogels).

The conference elected a committee under the chairmanship of M. M. Dubinin for the coordination of conjoint investigations and the organization of the preparation and exchange of standard samples. The conference commissioned the committee to approach the directorates of various institutes with requests for cooperation in the development of individual methods of investigating the structure of porous bodies and for the inclusion of appropriate investigations in the plans of the institutes.

The work of the conference will be published in the form of a collection of transactions.

In conclusion we must remark on the excellent organization of the conference: the sessions began on time, the lecturers kept strictly to the regulations, and, as the time allowed for the papers was 20-30 minutes, there remained adequate time for discussion.

V. M. Lukyanovich

CONGRESS OF AUSTRIAN AND GERMAN CHEMISTS

A congress of Austrian and German chemists was held at the end of April 1956 at Salzburg, Austria. Two Soviet scientists took part: N. N. Vorozhtsov, Doctor of Chemical Sciences, Professor of the D. I. Mendeleev Institute of Chemistry and Technology, Moscow, and M. A. Klochko, Doctor of the Chemical Sciences, Director of the Laboratory of the N. S. Kurnakov Institute of General and Inorganic Chemistry of the Academy of Sciences of the USSR. The work of the congress occupied three days, April 26-28. The first two days were devoted to scientific papers, and the third to excursions to various institutes and other undertakings and to tours of the city of Salzburg.

The congress was opened on the morning of April 26. After addresses of welcome from representatives of the Austrian Ministry of Education, the City Council, and other organizations, the plenary session was held. At this session two papers were read, and work then continued for the rest of the day — with a break for dinner — in two sessions: organic chemistry and inorganic and physical chemistry. Most of the participants were from Austria, the German Federal Republic and the German Democratic Republic. Chemists also came from Britain, Belgium, Switzerland, the USA, Italy, and other countries. In all, more than five hundred people took part in the congress. Papers were read by chemists from Austria, the German Federal Republic and the German Democratic Republic. Respresentatives from the USA and Holland gave one paper each; one paper was in the names of Austrian and Swedish chemists, and one was in the names of Austrian and Egyptian investigators.

The first paper of the morning session of April 26 was by Professor L. Audrieth of Illinois University (Urbana, Ill.); it was entitled "Recent Progress in the Chemistry of Hydrazine." Professor Audrieth has carried out many fruitful investigations on the chemistry of hydrazine and its derivatives, which he has made into a orderly system. His paper described this work. The second paper, "Intermediate Compounds in Chemical Reactions With Solids," was given by Professor G. F. Huttig of the Technical High School in Graz (Austria). Professor Huttig is a specialist on reactions in the solid state and has published many experimental and theoretical papers on interaction between solids and on the catalytic properties of solids (which depends not only on composition, but also on the method of preparing the catalysts). He has recently turned his attention to grinding processes regarded from the chemical viewpoint. Professor Huttig discussed investigations on phase transitions in the solid

state at different temperatures and the associated changes in various properties of the system.

At the plenary session of April 27, papers were read by Professor R. Huisgen of Munich University on "Recent Results on the Chemistry of Medium-Sized Rings" and by Professor K. G. Peters of Vienna Technical High School on "New Methods of Separating Chemically Related Elements." Professor Peters described some interesting results obtained in the study of compounds formed by various metals with oxalic acid and its salts. For example, by the use of aluminum oxalate Peters has succeeded in separating rare earths.

At the section devoted to inorganic and physical chemistry on April 26 and 27, papers were read and discussed on inorganic, analytical and physical chemistry, and also on geochemistry. Abstracts of the papers had been published beforehand in a special issue of Osterreichische Chemiker Zeitung (57, 9/10, 1956), which was distributed to participants of the congress. Among papers on inorganic chemistry, great interest was aroused by a communication from P. Ehrlich (Chemical Institute of the J. Liebig High School, Giessen, German Federal Republic) on hydride-halides of alkaline-earth metals. These compounds were prepared by fusing the hydride and anhydrous halide together, or by fusing themetal with the halide in a hydrogen atmosphere. The author has studied the physical and chemical properties of these compounds.

A. Meuwsen and H. Tischler (Institute of Inorganic Chemistry, Erlangen University, German Federal Republic) discussed methods of preparing hydrazinesulfonates.

M. Baudler and L. Schmidt (Chemical Institute, Cologne University) reported on new methods for preparing pure P_2H_4, a substance that is extremely light-sensitive and unstable. The Raman spectrum of this substance and its reactions with various compounds were studied. At this section a paper was read also by G. Fritz and W. Raabe (Institute of Silicon Chemistry, Marburg University) on the "Preparation of Cyclic Sila-hydrocarbons by the Thermal Decomposition of $Si(CH_3)_4$." Among the products formed was a compound with a six-membered ring in which CH_2 and $Si(CH_3)_2$ groups alternated.

Another paper which might be described equally as inorganic or organic chemistry was on the subject "Acetylenic Derivatives of Boron" and was given by U. Kruerke of the Institute of Inorganic Chemistry, Munich University. These substances, which have the formula $\equiv B-C\equiv C-R$ and are called ethynylboron compounds, are closer in properties to etherates of boron ($\equiv B-O-C\equiv$) than to alkylborons ($\equiv B-C-C\equiv$).

A group of papers was devoted to analytical chemistry and geochemistry. H. Baliczo and H. Schiffner of Vienna University reported on a new gravimetric method of determining fluorine by precipitation with a solution of triphenyltin chloride in chloroform. The precipitate formed at the interface between the two phases (aqueous and chloroform) is free from excess of precipitant and from salt contaminants which may be present in the solution under investigation. There were two communications on geochemistry. The first, which was by E. Broda, K. Nowotny, T. Schonfeld and O. Suschny (Chemical Laboratory, Vienna University) was devoted to the determination of the uranium content of the ash of Austrian brown coals. Eighteen samples were analyzed by the radiochemical method, and 8-100 g of uranium per metric ton of ash was found. The second discussed the investigation of the uranium contents of sea-bed deposits in the Baltic Sea. The authors -- F. Hecht, F. Kotzy (Goteborg, Sweden), R. Patzak and E. Tomic (Vienna University) -- associate the uranium content of samples with the closeness of the sampling point to estuaries of rivers that flow across various rocks. Sedimentary rocks are more enriched in uranium than primary rocks, and this affects the composition of river water. Uranium compounds are precipitated in the colloidal state and are carried out to sea, where they join the sea-bed deposits.

A series of papers was devoted to various branches of physical chemistry -- problems relating to the chemical bond, molecular structure, kinetics, etc. E. Harter and O. Glemser (Gottingen University) reported on the determination of the distance between metal and oxygen in hydroxides, basic salts, and hydrates by the optical method.

W. Bues (Technical High School, Stuttgart) has investigated the structure of polyphosphate melts. In his paper he pointed out that results obtained by the study of Raman and infrared spectra indicate partial preservation of the orderly arrangement peculiar to a crystalline structure even in the liquid state somewhat above the melting point. K. H. Lieser (Technical High School, Darmstadt) reported a study of the temperature-dependence of various properties of silver iodide (specific heat, coefficient of thermal expansion, electrical conductivity) with the object of obtaining data on the degree of order in various modifications of this substance.

Among papers on the kinetics of chemical processes was one by H. Schmid and E. Hallaba (Institute of Physical Chemistry, Technical High School, Vienna and Alexandria University, Egypt) on the "Kinetics and Mechanism of the Diazotization of Chloroaniline in Hydrochloric Acid Solution." H. Han and F. Burou (Kiel University) described the determination of the enthalpy of formation of gallium and indium sulfides, selenides, and tellurides by combustion in oxygen of the compounds and also mixtures of the two elements in a microcalorimetric bomb. For each metal, the enthalpy falls from the sulfide to the telluride.

In the Organic Chemistry Section, of 25 papers 14 were devoted to the synthesis of various substances and 11 to biochemistry. Among the first group was a paper by R. Koster (Max Planck Coal Research Institute, Mulheim an der Ruhr) entitled "New Preparative Possibilities in Boron and Silicate Chemistry," which could have been placed, with equal justification, in the Inorganic Section. Of the papers devoted to organic synthesis we may note one other communication, which was made by G. Drefahl (Friedrich Schiller University, Jena, German Democratic Republic) on the subject "Addition of Acetyl Nitrate to Olefins." The action of acetyl nitrate or a mixture of nitric acid and acetic anhydride on olefins results in the formation of the corresponding acetyl nitro compounds, the reduction of which gives acetyl derivatives of amino alcohols.

It is of interest to note the application of radioactive isotopes in biochemical investigations. Papers in this field were given by G. Kellner, L. Stockinger, B. Figdor, O. Suschny, R. Ukusik, and E. Broda (Vienna University) ("Investigations with Radioactive Carbon on Cultures of Cancerous Tissues") and by A. Becker (Organic Institute, Berlin Technical University, Charlottenburg) ("Cause of the Stability of Bacteria. Investigation with Radioactively Labeled Compounds").

Papers on natural organic compounds were given by A. Butenandt and coworkers (Max Planck Biochemical Institute, Tübingen) (on coloring matters) and by W. Pfleiderer (Technical High School, Stuttgart) (on the structure of urea).

It will be seen from our short review, which does not cover the whole of the work of the congress, that a wide range of chemical problems was discussed.

Having spent three days in Salzburg, on April 29, we went to Vienna, where we stayed until May 4, visiting the chemical laboratories of the university and technical high school and conversing with researchers and professors. We were interested in the organization of scientific and teaching work and in the equipment of the laboratories. Chemical research in Austria is carried out mainly in higher technical teaching establishments and in universities. At Vienna University we conversed with Professor E. Broda and Dr. T. Schönfeld, who work on radiochemistry, with Professor I. Breitenbach — a specialist in macromolecular chemistry — and Professor O. Gromatka, the director of the organic section of the First Chemical Laboratory, Vienna University. We made ourselves acquainted with the objects of the research work going on in these laboratories, with the teaching syllabuses, and with the organization of the practical work of students on physical and organic chemistry.

In Vienna Technical High School we inspected the Institute of Inorganic Chemical Technology (Director, Professor Hans Hohn), the Institute of Inorganic and Analytical Chemistry (Director, Professor Streubinger), and the Institute of Organic Chemistry (Director, Professor Waldmann).

In the Institute of Inorganic Technology extensive investigations are being carried out on solutions, metallic systems, and particularly on amalgams. Under the general supervision of Professor Hohn, investigations are proceeding on the preparation of pure metals (zinc, aluminum, lead, manganese and others) by electrolysis with a mercury cathode, and also on the preparation of sodium oxalate from carbon dioxide in presence of sodium amalgam. Dr. Franz Lihl is investigating the structure and properties of binary alloys obtained by the distillation of mercury from amalgams of the metals concerned or by coprecipitation at a mercury cathode. In this way the systems copper-nickel, copper-zinc, etc, have been investigated. Work on corrosion is being carried out by Professor H. Hohn in collaboration with Dr. E. Fitzer. W. Gutmann is studying the properties of nonaqueous solutions.

The Organic Chemistry Laboratory of the Technical High School is at present being refitted, and part of it is already completed. The walls, ceiling, floor and benches are all covered with a composition that is resistant to acids, alkalies, and organic solvents. The benches are movable , and the water, gas, and drain pipes are not mounted in the walls, but are fixed at a certain distance from them. This arrangement facilitates the inspection and repair of the gas, water and drainage systems.

During our stay in Austria, we were treated most attentively and cordially by the scientists; they willingly showed us their laboratories, told us about their investigations, and gave us reprints of their papers.

We received great help and attention from Professor Fritz Wessely, a prominent Austrian chemist who is President of the Second Chemical Institute of Vienna University and editor of Monatshefte für Chemie. He made us acquainted with the organization of the work of the congress.

We are very grateful also to Professor H. Hohn, who kindly acquainted us with the work going on in his laboratories, to Professor E. Broda, who assisted us in our inspection of the university laboratories, to Professors Streubinger and Waldmann, who showed us their laboratories and to several other Austrian chemists.

The Austrian scientists with whom we conversed showed a great interest in the Soviet Union, in the organization of scientific work in our country, and in the scientific literature that we publish.

INTERPHASE PARTITION IN SYSTEMS CONTAINING ANOMALOUS MIXED CRYSTALS

COMMUNICATION 5. THE SYSTEMS $NH_4Cl-CdCl_2-H_2O$ AND $NH_4Cl-NiCl_2-H_2O$

E. M. Ioffe

Study of the partition of a microcomponent between liquid and solid phases in systems consisting of ammonium and heavy-metal chlorides has revealed a marked difference in behavior between ter- and bi-valent metals [1]. Whereas in the systems $NH_4Cl-FeCl_3-H_2O$ and $NH_4Cl-CrCl_3-H_2O$ there is a lower formation limit, which is indicated by a fall in the partition coefficient as the microcomponent concentration falls in the solution, in the systems $NH_4Cl-MnCl_2-H_2O$ and $NH_4Cl-CuCl_2-H_2O$ the partition coefficient remains constant in all concentration ranges that we have investigated. In previous investigations [1, 2] it was shown that the difference in partition behavior in these two groups of anomalous mixed crystals is very probably to be explained by the scheme proposed by Greenberg and Walden [3] for the system $NH_4Cl-MnCl_2-H_2O$.

The radius of the cadmium ion differs greatly from the radii of the manganese and copper ions, and Nikitin suggested that this fact must have its reflection in a marked difference in the character of partition in the system $NH_4Cl-CdCl_2-H_2O$. Moreover, as we know from the work of Kumakov and Egorov [4], in the system $NH_4Cl-NiCl_2-H_2O$ the "guest" component is the double salt $NH_4Cl \cdot NiCl_2 \cdot 2H_2O$, which differs in composition from the double salts in the systems containing manganese and copper ($2NH_4Cl \cdot MCl_2 \cdot 2H_2O$). Nikitin [1] suggested that in the nickel system partition between liquid and solid phases may conform to a type of partition found in the iron system, i.e. that the mixed crystals of ammonium and nickel chlorides may have a lower formation limit. All these considerations suggested the need for a study of partition in the systems $NH_4Cl-CdCl_2-H_2O$ and $NH_4Cl-NiCl_2-H_2O$.

We adopted the procedure developed by Khlopin and his school for the study of the partition of small amounts of a substance between solid and liquid phases. Crystallization was carried out from supersaturated solutions with rapid stirring. The system was studied at 0°. For the determination of the microcomponent in the solid phase, crystals were filtered off under suction after the experiment and were washed free from mother liquor with ammonium chloride solution which was saturated at 0° and was applied at that temperature. No cadmium or nickel impurity could be detected in the reagents by spectrum analysis.

The System $NH_4Cl-CdCl_2-H_2O$. We know of the existence of solid solutions of ammonium and cadmium chlorides from the work of Lehman [5], St. Kreutz [6], Gaubert [7], and others. Rooseboom [8] showed also that cubic mixed crystals containing a little cadmium salt separate from ammonium chloride solutions containing $CdCl_2$. We studied partition in this system for various concentrations of cadmium in the original solution and with precipitation of various relative amounts of solid phase. We used two methods of investigation: chemical and radiochemical. In the chemical method we determined cadmium as oxide in the crystals and in the original solution, and in the radiochemical method we used the radioactive cadmium isotope Cd^{115}, which has a half-life of 43 days. The β-radiation was measured with a Type B apparatus having a B_1 tube. The results are given in Table 1.

As will be seen from Table 1, in the first and second series of experiments (Cd concentrations in solution of $1.2 \cdot 10^{-1}$ and $6.1 \cdot 10^{-2}$ M), the crystals contain about 43% of the cadmium and the partition coefficient is 1.7. With a threefold reduction of the cadmium content of the original solution, the proportion passing into the crystals rises considerably to 65% and the partition coefficient rises correspondingly to 4.5. Further reduction of the cadmium concentration of the solution leads to further increase in the partition coefficient, namely, to 6.8 in

the fourth series of experiments, to 9.3 in the fifth, to 11.3 in the sixth, and to 78.8 in the seventh. Further reduction of the cadmium concentration to $2.9 \cdot 10^{-3}$ and $1.1 \cdot 10^{-3}$ M results in the passage of almost the whole of the cadmium into the crystals. Hence, as the cadmium concentration of the solution changes from $1.2 \cdot 10^{-1}$ to $1.1 \cdot 10^{-3}$ M, the partition coefficient, originally 1.7, rises regularly and tends to infinity. The whole of the cadmium found in the crystals after the experiment must be accounted for by the process of cocrystallization, for special experiments showed that the washings obtained by treating the crystals after the experiment with ammonium chloride solution saturated at 0° contained not more than 0.2% of the total amount of cadmium taken, so that the amount adsorbed on the crystal surface must have been negligible. Experiments that we carried out with a solution containing cadmium at a concentration of $5.2 \cdot 10^{-3}$ M showed that for this concentration Khopin's law

is applicable to the system, for with change in the amount of solid phase from 25 to 40% the partition coefficient remained constant (Table 2).

The System $NH_4Cl-NiCl_2-H_2O$. This system has been known since the time of Lehman, who found that it belongs to the iron–ammonium chloride type of anomalous solid solutions. The colored cubes that separate from solution show strong birefringence and appreciable pleochroism. Later, the fact that ammonium and nickel chlorides form mixed crystals was confirmed by several author, of whom we may mention Foot and Saxton [9,10]

and Clendinnen [11]. The most detailed investigation of this system was carried out by Kumakov and Egorov [4], who, after studying the solubility isotherms of this system at 0, 25, and 50°, concluded that the yellow coloration of ammonium chloride crystals depends on the presence of microdispersed inclusions of a dihydrate of a nickel carnallite of composition $NH_4Cl \cdot NiCl_2 \cdot 2H_2O$. As we have already stated, this fact prompted us to study the partition of nickel chloride between the crystals and a saturated ammonium chloride solution. The nickel contents of the original solution and of the crystals were determined by the Chugaev-Brunk method of precipitating nickel with alcoholic dimethylglyoxime. The results are given in Table 3.

As will be seen from Table 3, in the first series of experiments, in which the nickel concentration of the original solution is $6.5 \cdot 10^{-1}$ M, for precipitation of 30% of the ammonium chloride, the crystals contain, on the average, 6.5% of the nickel and the partition coefficient is 0.15.

In the second series of experiments, in which the nickel concentration of the original solution was reduced by a factor of 2.5, the proportion of the nickel passing into the crystals was reduced by about one-half and the partition coefficient was reduced correspondingly to 0.08. In the third series, with a reduction of the nickel concentration to one-tenth of its value in the preceding series, the partition coefficient fell to 0.044, and for a concentration of $5.2 \cdot 10^{-2}$ M it was already 0.026. In the fifth series it had a mean value of 0.0098, and in the sixth series, for a nickel concentration in the solution of $2.6 \cdot 10^{-4}$ M, it was reduced to 0.0042. Hence, with change in the nickel concentration in the original solution from $6.5 \cdot 10^{-1}$ to $2.6 \cdot 10^{-4}$ M, the partition coefficient is reduced from 0.15 to 0.0042, i.e., by a factor of about 36. The fall in the partition coefficient with reduction in the nickel concentration of the solution indicates the existence of a lower formation limit in this system, so that Nikitin's suggestion [1] is completely substantiated. We see, in fact, that in the nickel system the character of the partition of the microcomponent between solid and liquid phases is analogous to that found in the iron system, and that Greenberg and Walden's scheme, which satisfactorily explains the partition behavior of manganese and copper, is quite inapplicable to the system $NH_4Cl-NiCl_2-H_2O$. In this example we have once more found convincing evidence of the important part played by complex formation in systems containing anomalous mixed crystals. In order to compare the behavior of the systems $NH_4Cl-CdCl_2-H_2O$ and $NH_4Cl-NiCl_2-H_2O$ between themselves, and also with the manganese, copper, iron, and chromium systems that we have studied previously—we have plotted the negative logarithms of the molar concentrations of the microcomponent in the solution C_m as abscissas and the partition coefficients expressed as percentage of the maximum value for the given system as ordinates (see figure).

It will be seen from the figure that the mixed crystals formed by ammonium chloride with manganese and copper chlorides behave like true mixed crystals, for the value of the partition coefficient is here independent of the concentration of the microcomponent in the solution. The nickel system behaves like the ferric and chromic systems, for with reduction in the nickel concentration of the original solution the partition coefficient falls and tends to zero, just as in the iron and chromium systems; here, therefore, there is again a lower limit of formation. The cadmium system differs radically from all the other systems of ammonium and heavy-metal chlorides which we have studied, for in this case the partition coefficient increases with reduction in the cadmium concentration of the solution. Whereas the curves for the relation between partition coefficient and concentration of microcomponent in the solution are parallel to the axis of abscissas in the case of manganese and copper, they descend at an angle for iron, chromium, and nickel systems; in the case of the cadmium system, however, the curve moves upward. Other systems have been reported in the literature in which the partition of microcomponent between liquid and solid phases follows the pattern of the cadmium system.

For example, as early as 1932, Käding [12] found that lead (ThB) forms anomalous mixed crystals with alkali-metal halides, and it appeared to be characteristic of these that the partition coefficient rises as the lead concentration increases. The question of the mechanism of the formation of mixed crystals of this sort has not yet been resolved.

SUMMARY

1. The system $NH_4Cl-CdCl_2-H_2O$ differs radically from all previously studied systems formed by ammonium and heavy-metal chlorides, for in this case reduction in the cadmium concentration of the solution is associated with rise in the partition coefficient, which tends to infinity.

2. The system $NH_4Cl-NiCl_2-H_2O$ is similar to the analogous iron system, for reduction in the nickel concentration of the original solution is associated with a fall in the partition coefficient, which tends to zero. This indicates that the nickel system has a lower formation limit.

3. Greenberg and Walden's scheme, which satisfactorily explains the behavior of bivalent manganese and copper in their partition between crystals and saturated solution of ammonium chloride, is not applicable to the cadmium and nickel systems.

ATTEMPT TO SET UP A SEMIQUANTITATIVE THEORY OF MUTUAL EFFECTS OF ATOMS IN ORGANIC COMPOUNDS

COMMUNICATION 2. ELECTRONIC CHARGES OF BONDS AND PHYSICAL PROPERTIES OF MOLECULES

G. V. Bykov

Force Constants and Characteristic Frequencies. In our first communication [1] we considered the calculation of σ-electronic charges in compounds not containing π-bonds. A knowledge of force constants and characteristic frequencies sometimes enables us to calculate total (σ- + π-) electronic charges of bonds. It is not possible to make very wide application of the methods of calculation which we are about to consider, but the results of their application are of fundamental importance and can provide basic data for calculations carried out by other methods.

The calculated values of force constants f obtained by various authors are not generally in agreement with one another. This is to be explained by the different simplifying assumptions that are made in the calculations. The most reliable values appear to be those obtained by Stepanov for simple molecules (Table 1).

TABLE 1

Force Constants, Characteristic Frequencies, and Electronic Charges of Bonds in Hydrocarbons

Hydrocarbon	Bond	f* (×10⁵ cm⁻²)	f** (×10⁵ dynes/cm)	A(f) (electrons)	ν*** (cm⁻¹)	A(ν) (electrons)
Methane	C—H	8.34	5.31	2.000	2914	2.000
Ethane	C—C	7.02	4.47	(2.272)****	993	(2.272)****
	C—H	8.08	5.14	(1.955)	2880	(1.955)
Ethylene	C—C	14.2	9.04	3.72	1623	4.10
	C—H	8.60	5.47	2.042	3019	2.095
Acetylene	C—C	~27	~17	~5.4	1974	5.18
	C—H	—	—	—	3371	2.445

* From results of Stepanov and Volkenshtein [2].

** The values of f given in this column were obtained from those in the preceding column by multiplication by the conversion factor $6.385 \cdot 10^{-5}$ g·cm²·sec⁻² [3].

*** From the latest edition of Landolt-Börnstein's Tables [4].

**** The values in parentheses are calculated from electronegativities (see [1]).

Fox and Martin found [5] that the energy of the C–C bond in saturated and unsaturated hydrocarbons varies as $f^{0.6}$. In the first communication we showed that there is direct proportionality between energies and σ-electronic charges of bonds. It is therefore rational to try, in the first place, the following equation for the relation between force constants and electronic charges of bonds:

$$f^m = \Delta' \cdot A. \qquad (1)$$

TABLE 2

Constants of Equations (1) and (2)

Bond	m	Δ^f	Δ^ν
C—C	(0.60)	$1.008 \cdot 10^3$	$1.737 \cdot 10^3$
C—H	0.70	$5.088 \cdot 10^3$	$3.553 \cdot 10^4$

Substituting f_{CC} (dynes/cm and A_{CC} for ethane in this formula and assuming, following Fox and Martin, that $m_{CC} = 0.6$, we may determine the proportionality coefficient Δ^f_{CH}. Substituting f_{CH} (dynes/cm) and A_{CH} for methane and ethane in Equation 1, we obtain two equations, which allow us to determine m_{CH} and Δ^f_{CH}. The results of these calculations are given in Table 2.

Using these constants, we calculated the total electronic charges A(f) of C−C in ethylene and acetylene and of C−H in ethylene from Equation 1 (Table 1, Column 5). In order to check the scheme of calculation we shall calculate the total electronic charge of the whole ethylene molecule:

$$\Sigma A(f) = 3.72 + 4 \cdot 2.042 = 11.89 \text{ electrons.}$$

The bonds in ethylene are made up of 12 valence electrons, so that the absolute error of calculation is 0,11 electron and the relative error is less than 1%. This indicates the possibility of apply Equation 1 also to unsaturated compounds.

In organic compounds, characteristic frequencies ν are possessed by bonds whose frequencies lie outside the frequency range of C−C bonds and are therefore relatively independent of the frequencies of other bonds and bond angles. The greater the difference between frequencies, the weaker the interaction between them. Hence, in the simplest hydrocarbons (ethane, ethylene, and acetylene) for example, the vibrations of C−C and C−H bonds are characteristic; to a first approximation they can be regarded as the vibrations of diatomic molecules and it may be supposed that ν^2 is proportional to f; taking Equation 1 into consideration we then obtain

$$\nu^{2m} = \Delta^\nu A, \qquad (2)$$

in which Δ^ν is a constant.

For the determination of Δ^ν_{CC} we shall use the frequency and charge of the C−C bond in ethane, and for the calculation of Δ^ν_{CH} the frequencies and charges of the C−H bonds in methane and ethane. The values obtained for the coefficients are given in the last column of Table 2. $\Delta^\nu_{CH} = 3.553 \cdot 10^4$ is the mean of two values, $3.542 \cdot 10^4$ and $3.564 \cdot 10^4$, obtained from the data for methane and ethane respectively.

The frequencies that we used for the calculation of Δ^ν correspond to the symmetrical vibrations of the bonds. Hence, in other calculations with these values of Δ^ν we may use only vibrations that are similar in form, i.e. symmetrical vibrations. Table 1 gives the frequencies ν of symmetrical vibrations and the values, calculated from these with the aid of Equation 2, of the total electronic charges $A(\nu)$ of the bonds in ethylene and acetylene. That the results may be regarded as quite satisfactory can be seen from calculations of the total electronic charges of the ethylene and acetylene molecules. For ethylene

$$\Sigma A(\nu) = 4.10 + 4 \cdot 2.095 = 12.48 \text{ electrons}$$

instead of 12; the relative error is 4%.* For acetylene

$$\Sigma A(\nu) = 5.18 + 2 \cdot 2.445 = 10.07 \text{ electrons}$$

instead of 10 electrons; the relative error is less than 1%.

The satisfactory results obtained in the calculation of m_{CH} and Δ^{ν}_{CH}, and also the closeness of the values A_{CH} in ethylene obtained by two different methods, indicate that the most reliable results are those for the electronic charges of C–H bonds calculated from Equations 1 and 2. It is therefore desirable to calculate the total electronic charges of C–C bonds in these compounds not directly from their force constants or vibrational frequencies, but from the difference between the number of valence electrons and ΣA_{CH}. With this method of calculation the total electronic charge of the C–C bond in acetylene is found to be $A_{CC} = 5.11$ electrons.

Knowing the total electronic charges of bonds, we may calculate the electronegativities of carbon atoms; in fact, according to Equation 1 of the first communication the total electronic charge of the C–H bond in acetylene is

$$A_{CH} = 1 + \frac{4 \cdot E_H}{E_H + E_C}.$$

so that $2.445 = 1 + \frac{4}{1 + E_C}$ and $E_C = 1.768$. Using this value of the electronegativity of carbon and applying the same Equation 1 of the first communication, we may calculate separately the σ- and π-electronic charges of C–C and C–H bonds in acetylene: $A^{\sigma}_{CC} = A^{\pi}_{CC} = 2.554$ electrons, $A^{\sigma}_{CH} = 1.723$ and $A^{\pi}_{CH} = 0.723$.

Bond Lengths. As is well known, the lengths of bonds having π-electronic charges are less than the lengths of the corresponding "pure" σ-bonds. The author, proceeding on the assumption that the shortening of a bond is proportional to its π-electronic charge,

$$L_{XY} - l_{XY} = \Delta^{l}_{XY} \cdot A^{\pi}_{XY}, \qquad (3)$$

carried out numerous calculations of π-electronic charges in hydrocarbons and their halogen derivatives, and also oxygen- and nitrogen-containing organic compounds [6, 7]. In Equation 3, L_{XY} is the length of a standard σ-bond, l_{XY} is the length of the given X–Y bond having a π-electronic charge of A^{π}_{XY}, and Δ^{l}_{XY} is the proportionality coefficient. In Table 3 we compare the results of calculations of π-electronic charges of bonds from Equation 3 and from Equation 1 of the first communication [1] together with Nekrasov's scale of relative electronegativities also cited in [1].

Table 3 gives the most typical organic compounds and bonds. There is on the whole close agreement between the results of the calculation of π-electronic charges by two methods that differ in principle.

Since my first calculations of π-electronic charges and bond lengths, i.e. 1951, much experimental material has accumulated which now enables us to calculate the constants L and Δ^{l} of Equation 3 with greater accuracy and to calculate or recalculate the π-electronic charges in a large number of organic compounds. Only after the completion of this work will there be a basis for an extensive comparison of the results of these two different methods of calculating π-electronic charges, and only then will it be desirable to come to conclusions concerning the π-electronic structure of ethylenic and aromatic compounds.

* It is possible that the choice of the frequency of the symmetrical vibration of the C–C bond may be incorrect, for if the frequency $\nu_{CC} = 1444$ is used in the calculation from Equation 2 we obtain $A_{CC}(\nu) = 3.56$ and $\Sigma A(\nu) = 11.94$ electrons, the relative error being 0.5%.

Additive Scheme for the Calculation of Heats of Formation of Unsaturated Hydrocarbons. As in the case of the additive scheme that we proposed in the first communication for the calculation of heats of formation of saturated hydrocarbons, we may write

$$\Delta_{CC}^{h\sigma}\cdot\Sigma A_{CC}^{\sigma}+\Delta_{CH}^{h\sigma}\Sigma A_{CH}^{\sigma}+\Delta_{CC}^{h\pi}\Sigma A_{CC}^{\pi}+\Delta_{CH}^{h\pi}\cdot\Sigma A_{CH}^{\pi}= \\ =H_{C_nH_m}^{el}+mL_H+4n\Delta_{CC}^{h\sigma}, \qquad (4)$$

in which $\Delta_{CC}^{h\sigma}$ and $\Delta_{CH}^{h\sigma}$ are the specific σ-electronic energies of C–C and C–H bonds respectively, $\Delta_{CC}^{h\pi}$ and $\Delta_{CH}^{h\pi}$ are the specific π-electronic energies of the C–C and C–H bonds, ΣA_{CC}^{σ} and ΣA_{CC}^{π} are summated σ- and π-electronic charges of C–C bonds, ΣA_{CH}^{σ} and ΣA_{CH}^{π} are the summated charges of C–H bonds, $H_{C_nH_m}^{el}$ is the heat of formation of the hydrocarbon C_nH_m from its elements, taken with the reverse sign, and L_H is the heat of atomization of hydrogen.

TABLE 3

Lengths and π-Electronic Charges of Bonds in Organic Compounds

Formula*	Bond	l	$A^{\pi}(l)$	$A^{\pi}(E)$	Δ_A

* The index π attached to the symbol for an element indicates that the given atom is the donor of one π-electron; the index 2π indicates a donor of two π-electrons.

** The values in parentheses $A^{\pi}(E)$, are calculated from the electronegativity of acetylenic carbon $E_{C^{2\pi}}=1.768$.

We shall demonstrate the application of this scheme for the calculation of heats of formation and electronegativities for the case of alkynes. The figures obtained will in no sense have any final significance, since the experimental errors in the determination of the heats of formation of alkynes attain ± 0.5 kcal/mole. Nevertheless, some interesting inferences can be made from these figures.

For the calculation of the individual π-electronic energies $\Delta^{h\pi}_{CC}$ and $\Delta^{h\pi}_{CH}$, we shall use values of the heat of formation of 2-butyne and acetylene (Table 4). In 2-butyne $\Sigma A^{\pi}_{CH} = 0$ and $\Sigma A^{\pi}_{CC} = 4$.

We shall calculate the summated σ-electronic charges of C–C and C–H bonds in the way shown in the first communication, but taking into consideration that $E_{C^{2\pi}} = 1.768$. Substituting all numerical values in Equation 4, we obtain an equation with one unknown $\Delta^{h\pi}_{CC}$:

$$8{,}054 \cdot 6{,}966 + 32.308 \cdot 11{,}034 + \Delta^{h\pi}_{CC} \cdot 4 + \Delta^{h\pi}_{CH} \cdot 0 = \\ = -34.97 + 6 \cdot 52.089 + 4 \cdot 4 \cdot 8.054.$$

Substituting in Equation 4 the corresponding values for acetylene, including the value just calculated for $\Delta^{h\pi}_{CC}$, we can determine $\Delta^{h\pi}_{CH}$ (Table 5).

TABLE 4

Heat of Formation of Alkynes (with reversed sign)

Compound	Formula	$H^{el}_{C_nH_{2n-2}}$ *	Δ_H **
2-Butyne	$CH_3-C^{2\pi}-C^{2\pi}-CH_3$	−34.97	—
Acetylene	$H-C^{2\pi}-C^{2\pi}-H$	−54.194	—
Propyne	$H-C^{2\pi}-C^{2\pi}-CH_3$	−44.319	+0.54
1-Butyne	$H-C^{2\pi}-C^{2\pi}-CH_2-CH_3$	−39.48	+2.08
1-Pentyne	$H-C^{2\pi}-C^{2\pi}-CH_2-CH_2-CH_3$	−34.50	+2.66

* The values of heats of formation are taken from the work of Rossini and coworkers referred to in the first communication.

** $\Delta_H = H^{el}_{calc} - H^{el}_{expt}$.

TABLE 5

Specific Electronic Energies of C–C and C–H Bonds

Bond	$\Delta^{h\sigma}$	$\Delta^{h\pi}$
C–C	8.054	−1.54
C–H	32.308	−9.38

It is notable that the specific π-electronic energy is negative, and no possible corrections that may be made in the future in the experimental data can alter the negative value of $\Delta^{h\pi}_{CH}$. Hence, in spite of the fact that the total electronic charge of the C–H bond in acetylene is 2.445 electrons, which is more than in ethane (1.955 electrons), the energy of the $C^{2\pi}-H$ bond in acetylene, $D_{C^{2\pi}H} = 32.308 \cdot 1.723 - 9.38 \cdot 0.723 = 48.88$ kcal/mole, is less than the energy of the bond in ethane, $D_{CH} = 32.308 \cdot 1.955 = 63.16$ kcal/mole. This conclusion, however, will not appear paradoxical if we bring it into relation with the well known experimental fact that the protonization of hydrogen in acetylene proceeds much more readily than in ethane.

In Equation 4 let us substitute the corresponding numerical values for propyne, 1-butyne, and 1-pentyne calculated on the assumption that the electronegativity of a methyl or methylene carbon atom is $E_C = 1.19$. For propyne (Table 4) we obtain a discrepancy Δ_H between the calculated and experimental heats of formation which is quite of the same order as the experimental heats of formation which is quite of the same order as the experimental error. For the two succeeding hydrocarbons the discrepancy is considerably greater. This is not difficult to foresee. In fact, for the calculation of the heat of formation of propyne it is a matter of indifference what electronegativity we assume for the carbon of the methyl group, although a carbon directly attached to a highly negative acetylenic carbon must itself have high electronegativity. For the calculation of the heat of formation of 1-butyne, it is no longer a matter of indifference what electronegativity we assume for the carbon in the α-position to the acetylenic carbon, and this

enables us to estimate the electronegativity of the methylene carbon in this compound. In the calculation of the heat of formation of 1-butyne we obtained an error of $\Delta_H = +2.08$ kcal/mole. This error arises from the fact that we assigned too low a value to the electronegativity of the α-carbon atom with a resulting error in the calculation of the σ-electronic charge of the $C_\alpha - C_\beta$ bond and the three $C_\beta - H$ bonds of the methyl group. This error arose because, as we took took too low a value for the electronegativity of the α-carbon, the calculated summated σ-electronic charge of C–H bonds was too great by x electrons, and that of the C–C bonds was too small by the same amount; consequently:

$$8.054\,(\Sigma A^{\sigma}_{CC} - x) + 32.308\,(\Sigma A^{\sigma}_{CH} + x) = \\ = 8.054 \cdot \Sigma A^{\sigma}_{CC} + 32.308 \cdot \Sigma A^{\sigma}_{CH} + 2.08$$

or $-8.054x + 32.308x = 2.08$, so that $x = 0.086$. This error, which positive, is made in the calculation of the total σ-electronic charge of the three C–H bonds of the methyl group. For one bond the error is $\frac{x}{3} = 0.029$. As the σ-electronic charge of a C–H bond of a methyl group of a hydrocarbon is $1 + \frac{4}{3 + E_C}$ and we assumed in the original calculation that $E_C = 1.19$, it follows that

$$1 + \frac{4}{3 + 1.19} - 0.029 = 1 + \frac{4}{3 + y}$$

in which y is the required electronegativity of the α-carbon of 1-butyne. From this we find that $y = E_{C_\alpha} = 1.32$.* Using this value for the electronegativity of the α-methylene carbon in the calculation of the electronic charges in 1-pentyne and substituting the calculated values in Equation 4, we find that the error Δ_H is no longer + 2.86, but 1.40. An analogous, though somewhat more complex, calculation of the electronegativity of the β-methylene carbon in this compound gives $E_{C_\beta} = 1.25$.**

We have therefore obtained proof of the enhanced electronegativity of atoms directly attached to a more electronegative atom and of reduction in electronegativity as these atoms become further removed from the more electronegative atom.

Dipole Moments. In establishing the relation between electronic charges of bonds, on the one hand, and energies, force constants, characteristic frequencies, and lengths of bonds on the other, we started from the idea that these properties of bonds are mainly determined by the electronic charges of the bonds. However, we can sometimes state beforehand that this is not so, and our calculations will then provide only a rough estimate. Such calculations of dipole moments, which are carried out by an unusual method, yield very important results.

We will illustrate the method of calculating dipole moments for the case of propyne (see figure). We shall first calculate the dipole moment that arises from the fact that the σ-electronic charge of C–H bond is less than 2 electrons, whereas that of a $C-C^{3\pi}$ bond is greater than 2 electrons. One should imagine that this comes about by the transposition of a certain charge $\frac{1}{3}q$ from the middle of each of the three C–H bonds to the middle of the $C-C^{3\pi}$ bond. The vector sum of the three dipole moments arising in this way is directed along the axis $C-C^{3\pi}-C^{3\pi}$ and, as will be seen from the figure, is equal to $q\left(\frac{1}{2} l_{CH} \cdot \cos\alpha + \frac{1}{2} l_{CC^{3\pi}}\right)$, in which l_{CH} and $l_{CC^{3\pi}}$ are the C–H and $C-C^{3\pi}$ bond lengths. The transposed charge is the excess over one electron which the $C-C^{3\pi}$ bond obtained from four electrons of a C atom, i.e.

---

* Strictly speaking, the value of E_{C_α} must be lower than this, for we are assuming that the electronegativity of carbon in a methyl group is 1.19, and, as we shall see later, this is not true. By assuming that overestimation of the summated σ-electronic charge of C–H bonds is due solely to underestimation of the value of E_{C_α}, we now overestimate the latter in our calculation.

** The heats of formation of 1-heptyne and higher normal homologs are at present calculated by the usual additive scheme with addition of 4.95 kcal/mole for each methylene group [8]. This is equivalent to assigning a value of 1.19 to the electronegativities of carbon atoms from γ–C, onward. This is evidently not true for γ-C, and it is probably not true for several more successive carbon atoms.

$$q = \frac{4 \cdot E_{C^{2\pi}}}{3 + E_{C^{2\pi}}} - 1 = \frac{3(E_{C^{2\pi}} - 1)}{3 + E_{C^{2\pi}}}.$$

The dipole moment of the methyl group in propyne is therefore

$$\mu_{CH_3C^{2\pi}} = \frac{3(E_{C^{2\pi}} - 1)}{2(3 + E_{C^{2\pi}})} (l_{CH} \cos\alpha + l_{CC^{2\pi}}).$$

The dipole moment calculated from this equation will be expressed in electron-angstroms; for conversion into debye units it must be multiplied by 4.8.

Diagram used in the calculation of the dipole moment of propyne. (The middles of the bonds are marked by short lines perpendicular to the bonds. The arrows indicate the transposition of electronic charges.)

In the general case – in place of $C^{2\pi}$ we may have any other atom X – the dipole moment arising owing to the transposition of σ-electronic charges from C–H bonds of the methyl group to the bond C–X is expressed (in debyes) by the equation

$$\mu_{CH_3X} = \frac{7.2(E_X - 1)}{3 + E_X} (l_{CH} \cdot \cos\alpha + l_{CX}). \qquad (5)$$

The dipole moments of monohalomethanes listed in Table 6 were calculated directly from this equation. In propyne, in accordance with the previous calculations, $E_{C^{2\pi}} = 1.77$. The angle α is the supplement of the tetrahedral angle 109°28'. Hence $\alpha = 70°32'$ and $\cos\alpha = 0.3333$. Data tables give $l_{CH} = 1.097$ and $l_{CC^{2\pi}} = 1.460$. Substituting these values in Equation 5 we obtain $\mu_{CH_3C^{2\pi}} = 2.13$ D.

The calculation of the dipole moments arising from the transposition of electronic charge from the middle of the acetylenic bond $C^{2\pi}-C^{2\pi}$ to the $C-C^{2\pi}$ and $C^{2\pi}-H$ bonds is still simpler. The excess above one electron that the $C^{2\pi}-H$ bond obtains from the four valence electrons of the $C^{2\pi}$ atom is equal to $\frac{4 \cdot E_H}{E_H + E_{C^{2\pi}}} - 1$, and the distance by which this charge is transposed is $\frac{1}{2} l_{C^{2\pi}H} + \frac{1}{2} l_{C^{2\pi}C^{2\pi}}$. Multiplication of the charge by this distance and the product by 4.8 gives the required dipole moment in debyes.

In the general case, for the structural element $X-C^{2\pi}-Y^{2\pi}$, in which $Y^{2\pi}$ may be $C^{2\pi}$ in an acetylenic bond or $N^{2\pi}$ in a nitrile bond, the dipole moment due to the passage of charge q from the bond $C^{2\pi}-Y^{2\pi}$ to the bond $X-C^{2\pi}$ is expressed in debyes by the equation

$$\mu_{Y^{2\pi}C^{2\pi}X} = 2{,}4\left(\frac{4E_X}{E_X+E_{Y^{2\pi}}}-1\right)(l_{XC^{2\pi}}+l_{C^{2\pi}Y^{2\pi}}). \qquad (6)$$

The dipole moments of hydrogen cyanide and cyanogen chloride (Table 6) were calculated from this equation.

TABLE 6

* The formulas are written so that the calculated dipole moment is in the direction of the arrow, i.e., its negative end is to the right of the center of gravity of the positive charges of the molecule.

** Bond lengths l and experimental values of dipole moment p_{expt} are taken from the review of Gordy and coworkers [9] or, when there are no data in this, from the latest edition of Landolt-Börnstein [4]. The values of l in this table and in Table 3 are sometimes slightly different; for Table 3 other sources were used.

*** $\Delta_p = p_{calc} - p_{expt}$.

Substituting the values of $\underline{l}$ and E for propyne in this equation, we obtain $\mu_{CC^{sp}} = 4.54$ D and $\mu_{C^{sp}H} = 2.41$ D. Of the component moments, $\mu_{CH_3C^{sp}}$ and $\mu_{C^{sp}H}$ are directed in one direction, and $\mu_{CC^{sp}}$ – in the opposite direction. Hence, taking the directions of the individual dipoles into account, for the resultant dipole moment of propyne we obtain

$$p = \mu_{CH_3C^{sp}} - \mu_{CC^{sp}} + \mu_{C^{sp}H} = 2.13 - 4.54 + 2.41 = 0.00.$$

Similar, sometimes somewhat more complicated, calculations are required to obtain the other dipole moments given in Column 4 of Table 6.

As p_{calc} is very greatly dependent on E (for the first six examples $\frac{dp}{dE} = 3$, on the average), the electronegatives that were assumed in the calculation of a given value of $\underline{p}$ are given in Column 6 of Table 6. The upper of the bracketed values corresponds to the Gordy scale, and lower to the Nekrasov scale (see Communication 1).

As will be seen from the first six examples, p_{expt} and p_{calc} are close in value. It follows that the dipole moments of polyatomic molecules arise mainly from the nonintegral character of the electronic charges of the separate bonds. It is natural to expect that, in such molecules, p_{calc} will be less than p_{expt}, for a part of the over-all dipole moment of the molecule is due to the displacement of charges along individual bonds. In cases in which one of the tabulated values of p_{calc} is less and the other is greater than p_{expt}, it must be considered that the electronegativity corresponding to the second value of p_{calc} is the less probable.

The calculated and experimentally determined dipole moments of propyne and hydrogen cyanide also stand in the correct relationship. In spite of the considerable difference between the experimental values of the dipole moments of chloroacetylene and cyanogen chloride, the values of Δ_p for the two compounds are very close to one another. This suggests that the source of the anomaly (the high value of Δ_p and its positive charge) is the chlorine atom, the free electron pair of which is probably greatly displaced in the direction of the highly electronegative carbon atom C^{sp}. If this is so, then for the analogous bromine and iodine compounds Δ_p should be still greater. For bromoacetylene Δ_p is in fact greater than for chloroacetylene.

* * *

The other electrical properties and many of the other physical characteristics of molecules and individual bonds are also determined – mainly or in high degree – by the distribution of electronic charges among the bonds. For these, therefore, relationships can be established in the same way as we have established relationships for heats of formation, characteristic frequencies, bond lengths, and dipole moments. For example, for the calculation of molecular refractions we may propose an additive scheme similar to that for heats of formation, though it is true that it would be applicable to a more limited range of compounds. However, there is no need to discuss these matters, for, as far as the physical properties of molecules are concerned, we have illustrated the basic ideas of the theory.

SUMMARY

1. Simple semiempirical equations are proposed for the relation between force constants and characteristic frequencies of bonds on the one hand and total (σ- + π-) electronic charges of bonds on the other. These equations are checked by calculation of the total electronic charges of ethylene and acetylene. The electronegativity of acetylenic carbon is determined.

2. It is shown that it is possible to calculate π-electronic charges of bonds by two methods which give closely agreeing results – from bond lengths and from electronegativities.

3. An additive scheme is proposed for the calculation of heats of formation of unsaturated hydrocarbons from their elements; the scheme is analogous to that already proposed for saturated hydrocarbons. The separate π-electronic energies of C–C and C–H bonds are calculated. Electronegativities are calculated for carbon atoms in the α- and β-positions with respect to the acetylenic bond of normal 1-alkynes.

4. It is shown that dipole moments of polyatomic molecules are generally determined by the nonintegral character of the electronic charges of individual bonds. It is possible to estimate electronegativities of atoms from dipole moments.

SYNTHESIS OF ORGANOSILICON COMPOUNDS CONTAINING CARBONYL AND CARBOXYL GROUPS

A. D. Petrov, E. A. Chernyshev, and M. Bisku

Organosilicon compounds containing carbonyl and carboxyl groups have generally been synthesized by the use of organometallic compounds, but papers have appeared recently on the synthesis of organosilicon acids by addition of silanes containing silicon-attached hydrogen to unsaturated esters with subsequent hydrolysis [1], the preparation of aldehydes and ketones by oxo synthesis with the aid of vinyl- and allyl-silanes [2], acylation of aromatic compounds with acid chlorides and fluorides in presence of $AlCl_3$ [3, 4], $SnCl_4$ [4], or BF_3 [5], and oxidation of p-ethylphenylsilanes [6].

We decided to try some new possible methods of preparing these compounds. As our first method we chose the known reaction of Kharasch for preparing aliphatic acid chlorides by reaction between oxalyl chloride $(COCl)_2$ and hydrocarbons in presence of a peroxide [7]. As organosilicon components for the reaction we used tetraethylsilane and chloro(ethyl)silanes. With $(C_2H_5)_4Si$ the reaction went satisfactorily and 3-(triethylsilyl)propionyl chloride was obtained in 32.2% yield on the amount of tetraethylsilane that reacted:

Apart from this product, small amounts of chlorotriethylsilane, dichlorodiethylsilane, and trichloroethylsilane were obtained.

Chlorotriethyl- and dichlorodiethyl-silanes also gave 3-substituted propionyl chlorides, but in lower yield. It must be mentioned that, in general, the yields of the acid chlorides were only 2-5% when reckoned on the amounts of reactants taken. In the case of trichloroethylsilane, the yield of acid chloride was so low that we did not succeed in isolating it.

As we wished to synthesize organosilicon acid chlorides having the functional group in the α-position, we brought $(C_2H_5)_3SiH$ and $HSiCl_3$ into reaction. In these cases, however, acid chlorides were not isolated and chlorotriethylsilane and silicon tetrachloride, respectively, were obtained in quantitative yields.

As our second method of synthesizing carbonyl-containing organosilicon compounds we selected the addition to vinylsilanes of aldehydes, and also of $HCCl_3$ and CCl_4, having in view the possibility of hydrolyzing the resulting (polychloroalkyl)silanes into acids. In the literature there is only a brief mention of the addition of butyraldehyde to trimethylvinylsilane without any indication of the yield of ketone [8]. We found that addition of butyraldehyde to triethylvinylsilane proceeds readily (60.2% yield), and with benzaldehyde the reaction again went satisfactorily. It is clear that this reaction can be used as a preparative method for obtaining organosilicon ketones in which the keto group is in the γ-position. Addition of $HCCl_3$ and CCl_4 to triethylvinylsilane in presence of a peroxide also went in good yield. Apart from the formation of the monomeric product, telomerization occurred with formation of an appreciable amount of high-boiling products containing Si and Cl. Unfortunately, we were unable to convert the resulting polychloroalkylsilanes by known methods [9, 10] into acids, for under the action of concentrated sulfuric acid at 100° quantitative carbonization occurred.

EXPERIMENTAL

1. Reaction of Tetraethylsilane and Chloroethylsilanes with $(COCl)_2$

A mixture of 91.5 g (0.635 mole) of $(C_2H_5)_4Si$ and 78.9 g (0.635 mole) of $(COCl)_2$ was prepared in a round-bottomed flask, and 1.5 g of freshly recrystallized benzoyl peroxide was added. Reaction began almost immediately, and the temperature of the mixture rapidly rose to 50°. The mixture was then heated at 70-90° for ten hours on each of three days, two further 1.5-g portions of benzoyl peroxide being added—one on the second, and one on the third day. Fractionation gave 11.3 g of oxalyl chloride, b.p. 64-66°; 0.7 g of trichloroethylsilane, b.p. 98-99° and n_D^{20} 1.4275; 0.9 g of dichlorodiethylsilane, b.p. 129° and n_D^{20} 1.4323; 2.8 g of chlorotriethylsilane, b.p. 143-144° and n_D^{20} 1.4315; 77.6 g of tetraethylsilane, b.p. 152-152.5° and n_D^{20} 1.4270; 7.4 g of benzoyl chloride, b.p. 75-77° (7 mm) and n_D^{20} 1.5528; and 6.4 g of 3-(triethylsilyl)propionyl chloride, b.p. 86-87.5° (5 mm); n_D^{20} 1.4449; d_4^{20} 0.9453; found MR 57.99; calculated MR 57.9. The yield, calculated on the amount of tetraethylsilane that reacted, was 32.2%.

Found %: C 52.52; 52.58; H 9.13; 9.04; Cl 16.07; 16.22; Si 13.52; 13.44 $C_9H_{19}SiOCl$.
Calculated %: C 52.42; H 9.22; Cl 16.99; Si 13.59

The reactions of $(COCl)_2$ with chlorotriethylsilane, dichlorodiethylsilane, and trichloroethylsilane were carried out under the same conditions. In the first two cases, apart from unchanged reactants and chloroethylsilanes, we isolated, respectively:

a) 3-(chlorodiethylsilyl)propionyl chloride, b.p. 87-88° (3.5 mm); n_D^{20} 1.4735; d_4^{20} 1.1321; found MR 52.82; calculated MR 53.03; the yield on the amount of $(C_2H_5)_3SiCl$ that reacted was 24.1%;

Found %: C 39.90; 39.92; H 6.96; 6.99, Cl 32.69; 33.06 $C_7H_{14}SiOCl_2$. Calculated %: C39.25; H 7.00; Cl 33.17

b) 3-(dichloroethylsilyl)propionyl chloride, b.p. 93-95° (6 mm); n_D^{20} 1.4820; d_4^{20} 1.2738; found MR 48.78; calculated MR 48.27; the yield on the amount of $(C_2H_5)_2SiCl_2$ that reacted was 11.7%;

Found %: C 31.01; 30.99; H 4.19; 4.38; Cl 43.54; 43.10; Si 12.55; 12.65 $C_5H_9SiOCl_3$.
Calculated %: C 30.72; H 4.13; Cl 44.55; Si 12.80

In the reactions of $(COCl)_2$ with $HSiCl_3$ and $(C_2H_5)_3SiH$, apart from unchanged reactants, in the first case was isolated $SiCl_4$ (71%), and in the second $(C_2H_5)_3SiCl$ (65%). The yields are based on the amount of the silane that reacted.

2. Reaction of Aldehydes with Triethylvinylsilane

A. Butyraldehyde. A mixture of 30.5 g (0.21 mole) of triethylvinylsilane and 62 g (0.87 mole) of butyraldehyde was prepared in the apparatus described above. It was heated at the boil for 50 hours, and at regular intervals 0.5-g portions of benzoyl peroxide were added so that 6 g was added in all. The boiling point of the mixture rose from 82° at the beginning to 121° at the end of the reaction. Fractionation gave 52.1 g of butyraldehyde, b.p. 74-76° and n_D^{20} 1.4834; 8.6 g of triethylvinylsilane, b.p. 145-146° and n_D^{20} 1.4332; and 19.9 g of 1-(triethylsilyl)-3-hexanone, b.p. 103.5° (3 mm); n_D^{20} 1.4560; d_4^{20} 0.8668; found MR 67.01; calculated MR 67.34; m.p. of semicarbazone 139°. The yield was 60.2% on the amount of triethylvinylsilane that reacted and 43.3% on the amount taken.

Found %: C 66.96; 67.20; H 12.10; 11.95 $C_{12}H_{26}SiO$. Calculated %: C 67.28; H 12.20

B. Benzaldehyde. The reaction conditions were the same. The reactants were 10 g (0.70 mole)* of triethylvinylsilane and 35.5 g (2.8 moles)* of benzaldehyde. The boiling point of the mixture rose from 156° to 177°. Fractionation gave 4.3 g of 3-(triethylsilyl)propiophenone, b.p. 168-170° (5 mm); n_D^{20} 1.5155; d_4^{20} 0.9746; found MR 76.71; calculated MR 76.36; m.p. of 2,4-dinitrophenylhydrazone 153°. The yield was 35% on the amount of triethylvinylsilane that reacted and 23% on the amount taken.

Found %: C 72.32; 72.38; H 9.80; 9.54 $C_{15}H_{24}SiO$. Calculated %: C 72.58; H 9.68

3. Reaction of CCl_4 and of $CHCl_3$ with Triethylvinylsilane

A. $CHCl_3$. The reaction conditions were the same. The reactants were 14.2 g (0.1 mole) of triethylvinylsilane and 46.8 g (0.4 mole) of $CHCl_3$. In the course of 30 hours 3 g of benzoyl chloride was added. The boiling

* Here, as elsewhere in the text, there are discrepancies between grams and moles of the given substances. These have not been corrected in translation — Publisher's note.

point of the mixture rose from 80° to 120°. Fractionation gave 12.8 g (48%) of triethyl(3, 3, 3-trichloropropyl) silane, b.p. 115-117° (3 mm); n_D^{20} 1.4785; d_4^{20} 1.0857; found MR 68.00; calculated MR 67.90. Yield 48%.

Found %: C 41.19; 41.03; H 7.01; 7.03; Cl 39.54; 39.48; Si 10.94; 10.74 $C_9H_{19}SiCl_3$.
Calculated %: C 41.60; H 7.32; Cl 40.50; Si 10.78

B. CCl_4. The reaction conditions were the same. Reaction was between 14.2 g (0.1 mole) of triethylvinylsilane and 29.1 g (0.4 mole) of CCl_4. In the course of 50 hours 5.5 g of benzoyl chloride was added. The boiling point of the mixutre rose from 84° to 103°. Fractionation gave 12.9 g (43.5%) of triethyl(1, 3, 3, 3-tetrachloropropyl)silane, b.p. 137-139° (5 mm); n_D^{20} 1.4974; d_4^{20} 1.2134; found MR 69.77; calculated MR 70.18.

Found %: C 36.47; 36.29; H 5.58; 5.77; Cl 47.78; 47.52; Si 9.58; 9.74 $C_9H_{18}SiCl_4$. Calculated %: C 36.88; H 6.13; Cl 47.57; Si 9.52

SUMMARY

1. Kharasch's addition reaction of aldehydes, $CHCl_3$, and CCl_4 was carried out with triethylvinylsilane, and his method of replacing hydrogen by the chloroformyl group was applied to tetraethylsilane and the chloro-(ethyl)silanes.

POLYENIC COMPOUNDS

COMMUNICATION 2. POLYENIC COMPOUNDS CONTAINING HETEROCYCLIC SUBSTITUENTS

B. M. Mikhailov and G. S. Ter-Sarkisyan

In the preceding communication [1], which was devoted to the synthesis of hexatriene hydrocarbons, it was shown that phenyl- and 1-naphthyllithiums add to 3-methyl-6-phenyl-3, 5-hexadien-2-one at the 1, 2-positions of the conjugated system with formation of the corresponding tertiary alcohols, whereas addition of 9-fluorenyllithium occurs at the 1, 6-positions of the conjugated system and results in the formation of an unsaturated ketone. In continuation of these investigations we have now studied the reactions of the same ketone with 2-pyridylmethyllithium and with 2-quinolylmethyllithium.

An analogy might be expected between the behavior of the metal derivatives of 2-picoline, quinaldine, and fluorene toward unsaturated ketones, for these heterocyclic compounds and fluorene behave very similarly in many chemical reactions. Investigation showed, however, that 2-pyridyl- and 2-quinolyl-methyllithiums behave like aryllithiums toward 3-methyl-6-phenyl-3, 5-hexadien-2-one, i.e., 1, 2-addition to the conjugated system occurs with formation of the corresponding tertiary alcohols, 2, 3-dimethyl-6-phenyl-1-(2-pyridyl)-3, 5-hexadien-2-ol (I) and 2, 3-dimethyl-6-phenyl-1-(2-quinolyl)-3, 5-hexadien-2-ol (II).

Our measurements of electrical conductivity of ethereal solutions of 2-pyridylmethyllithium, 2-quinolylmethyllithium, and 9-fluorenyllithium showed that both heterocyclic organolithium compounds have negligible conductivity, whereas the conductivity of 9-fluorenyllithium approaches that of triphenylmethyllithium. Hence, the heterocyclic organolithium compounds are only extremely slightly ionized in ethereal solution and must be regarded as homopolar compounds, whereas in 9-fluorenyllithium the carbon-metal bond is heteropolar. There can be no doubt that the difference between the behavior of 9-fluorenyllithium on the one hand and that of aryllithiums and heterocyclic organolithium compounds on the other toward unsaturated ketones is to be explained by the difference in the nature of the carbon-metal bonds in these compounds.

Dehydration of the tertiary alcohols containing heterocyclic substituents gave the corresponding hexatriene derivatives, 2, 3-dimethyl-6-phenyl-1-(2-pyridyl)-1, 3, 5-hexatriene (III) and 2, 3-dimethyl-6-phenyl-1-(2-quinolyl)-1, 3, 5-hexatriene (IV); in neither case was the formation of stereoisomers observed.

When an attempt was made to dehydrate 2, 3-dimethyl-6-phenyl-1-(2-pyridyl)-3, 5-hexadien-2-ol by heating it for 90 minutes at 150-160°, decomposition occurred with formation of 2-picoline and 3-methyl-6-phenyl-3, 5-hexadien-2-one, which was characterized as its 2, 4-dinitrophenylhydrazone. Similar decomposition

has been observed previously by Arens and coworkers [2] for the tertiary alcohol that they obtained from β-ionone and 4-methyl-2-pyridyllithium.

Apart from the above-described reactions, we investigated the reaction of 2-pyridylmethyllithium, and also of 2-quinolylmethyllithium, with cinnamaldehyde. It was found that in this case reaction proceeds readily with formation of 4-phenyl-1-(2-pyridyl)-3-buten-2-ol (V) and 4-phenyl-1-(2-quinolyl)-3-buten-2-ol (VI), which were obtained in satisfactory yields and without admixture of dehydration products.

When heated with glacial acetic acid, these alcohols lost water and were converted into the corresponding butadiene derivatives, 1-phenyl-4-(2-pyridyl)-1, 3-butadiene (VII) and 1-phenyl-4-(2-quinolyl)-1, 3-butadiene (VIII).

Some of these compounds have been prepared previously by other methods. Thus, 1-phenyl-4-(2-quinolyl)-1, 3-butadiene has been prepared by heating cinnamaldehyde with quinaldine and anhydrous zinc chloride [3-5] and also by the condensation of these reactants in presence of piperidine acetate [5]; in neither case was the yield high.

Späth and coworkers [6] tried to obtain the above-mentioned butenols by heating a mixture of equimolecular amounts of cinnamaldehyde and 2-picoline or quinaldine at 150-160° for 15-16 hours. In the case of 2-picoline they obtained the alcohol in admixture with the dehydration product, and in the case of quinaldine they could not isolate any butenol at all. The authors state that their 1-phenyl-4-(2-pyridyl)-1, 3-butadiene was a yellow substance. It is true that this substance remains yellow, even after several recrystallizations, and that under ultraviolet radiation it acquires a green fluorescence. However, by chromatography on alumina we succeeded in isolating 1-phenyl-4-(2-pyridyl)-1, 3-butadiene in the form of colorless crystals with a blue fluorescence.

When 4-phenyl-1-(2-pyridyl)-3-buten-2-ol was heated at 150-160°, decomposition was again observed, the products being 2-picoline and cinnamaldehyde.

EXPERIMENTAL

2, 3-Dimethyl-6-phenyl-1-(2-pyridyl)-3, 5-hexadien-2-ol (I). 2-Picoline (9.3 g, i.e., 0.1 mole) was added to a solution of phenyllithium prepared from 15.7 g (0.1 mole) of bromobenzene and 1.4 g of lithium in 100 ml of ether. The resulting solution of 2-pyridylmethyllithium was cooled, and after one hour an ethereal solution of 3-methyl-6-phenyl-3, 5-hexadien-2-one [7] was added; a crystalline precipitate rapidly began to form. The reaction mixture was stirred at room temperature for 90 minutes and was then set aside overnight. On the next day the precipitate was filtered off, treated with water, again filtered off, and dried. The product, amounting to 17.4 g (69.4%), was 2, 3-dimethyl-6-phenyl-1-(2-pyridyl)-3, 5-hexadien-2-ol, m.p. 72-81°. After being crystallized from ethanol, the substance was obtained in colorless crystals, m.p. 86-87°.

Found %: C 81.47; H 7.57; N 5.08 $C_{19}H_{21}ON$. Calculated %: C 81.68; H 7.53; N 5.02

2, 3-Dimethyl-6-phenyl-1-(2-pyridyl)-1, 3, 5-hexatriene (III). Dry hydrogen chloride was passed into a cooled (ice water) ethereal solution of 1 g of 2, 3-dimethyl-6-phenyl-1-(2-pyridyl)-3, 5-hexadien-2-ol until the precipitate solidified. The precipitate was filtered off, neutralized with ammonia, washed with water, and dried. The product, m.p. 97-99°, amounted to 0.9 g—an almost quantitative yield. After being crystallized from ethanol and subjected to chromatography on alumina, 2, 3-dimethyl-6-phenyl-1-(2-pyridyl)-1, 3, 5-hexatriene was obtained in the form of slightly yellowish crystals, m.p. 98-99°.

Found %: C 87.02; H 7.36; N 5.35 $C_{19}H_{19}N$. Calculated %: C 87.32; H 7.32; N 5.36

2, 3-Dimethyl-6-phenyl-1-(2-quinolyl)-3, 5-hexadien-2-ol (II). An ethereal solution of 3-methyl-6-phenyl-3, 5-hexadien-2-one was added over a period of one hour to a cooled solution of 2-quinolylmethyllithium prepared from 12.5 g (0.087 mole) of quinaldine and an equimolecular amount of phenyllithium. Toward the end of the addition the ketone was precipitated as yellow crystals. The reaction mixture was stirred for 3.5 hours at room temperature and then left overnight. On the next day the mixture was cooled with ice water, the ethereal solution was decanted, and the precipitate was decomposed with alcohol. The alcoholic solution was cooled with a cooling mixture and the precipitate that formed was filtered off, washed with water, and dried in a vacuum desiccator. In this way 11.7 g of 2, 3-dimethyl-6-phenyl-1-(2-quinolyl)-3, 5-hexadien-2-ol, m.p. 80-87°, was obtained, and by dilution of the alcoholic mother liquor with water a further 4.8 g of the same substance was obtained. The total yield was 16.5 g (59%). After being crystallized from ethanol, 2, 3-dimethyl-6-phenyl-1-(2-quinolyl)-3, 5-hexadien-2-ol was obtained as yellowish crystals, m.p. 88-90°.

Found %: C 83.83; H 6.93; N 4.25 $C_{23}H_{23}ON$. Calculated %: C 83.86; H 7.04; N 4.25

2, 3-Dimethyl-6-phenyl-1-(2-quinolyl)-1, 3, 5-hexatriene (IV). 2, 3-Dimethyl-6-phenyl-1-(2-quinolyl)-3, 5-hexadien-2-ol (3 g) was dehydrated under the conditions used in the previous dehydration experiment. The product, amounting to 2.4 g (85.6%), melted at 121-132°. After being crystallized from benzene and subjected to chromatography on alumina from a mixture of benzene and petroleum ether, 2, 3-dimethyl-6-phenyl-1-(2-quinolyl)-1, 3, 5-hexatriene was obtained in lemon-yellow crystals, m.p. 141-142°.

Found %: C 88.70; H 6.69; N 4.46 $C_{23}H_{21}N$. Calculated %: C 88.70; H 6.80; N 4.50

4-Phenyl-1-(2-pyridyl)-3-buten-2-ol (V). Cinnamaldehyde (11.9 g, i.e., 0.09 mole) was added to a cooled solution of 2-quinolylmethyllithium prepared as described above. The mixture was then stirred for 1 hour at room temperature and decomposed with water. In order to dissolve the precipitate that formed, ether was added. The ether layer was separated, solvent was distilled off, and the residue was steam-distilled to remove any unchanged reactants. The residual oil was extracted with benzene, solvent was distilled off, and the residue was treated with a 1:1 mixture of benzene and petroleum ether. The resulting crystalline precipitate was filtered off (12.6 g) and crystallized from aqueous methanol. In this way 4.8 g of 4-phenyl-1-(2-pyridyl)-3-buten-2-ol, m.p. 76-78°, was obtained, and from the mother liquor a further 4.5 g of the same substance, m.p. 74-78°, was obtained. The total yield was 9.3 g (45%). After being recrystallized from a mixture of benzene and ethanol, 4-phenyl-1-(2-pyridyl)-3-buten-2-ol was obtained as colorless crystals, m.p. 82-83° (the literature [6] gives 82-83°).

1-Phenyl-4-(2-pyridyl)-1, 3-butadiene (VII). A solution of 1 g of 4-phenyl-1-(2-pyridyl)-3-buten-2-ol in 4 ml of glacial acetic acid was boiled for five minutes with 0.5 ml of concentrated sulfuric acid, after which the solution was cooled, diluted with water, and neutralized with ammonia. The precipitate was filtered off, washed with water, and dried. The product was 0.88 g—an almost quantitative yield—of 1-phenyl-4-(2-pyridyl)-1, 3-butadiene, m.p. 110-116°. After being crystallized from a mixture of benzene and ethanol and then subjected to chromatography on alumina, 1-phenyl-4-(2-pyridyl)-1, 3-butadiene was obtained in colorless crystals, m.p. 123-124°; it showed blue fluorescence.

In the literature [6], this substance is described as yellow plates, m.p. 123-124°.

4-Phenyl-1-(2-quinolyl)-3-buten-2-ol (VI). An ethereal solution of 8.6 g (0.065 mole) of cinnamaldehyde was added to a cooled solution of 2-quinolylmethyllithium prepared from 10 g (0.07 mole) of freshly distilled quinaldine and an equimolecular amount of phenyllithium. Toward the end of the addition of cinnamaldehyde, the solution cleared and a little crystalline precipitate formed. The reaction mixture was boiled for one hour, and on the next day it was decomposed with water. The precipitate was filtered off (4.6 g, m.p. 125-131°). The ethereal and aqueous solutions were separated, ether was distilled off, and the residual oil was cooled with a cooling mixture. A further 1.4 g of substance, m.p. 124-130°, was precipitated. The total yield was 6 g (33.5% on the amount of cinnamaldehyde taken). After being crystallized from a mixture of benzene and ethanol, 4-phenyl-1-(2-quinolyl)-3-buten-2-ol was obtained as fine colorless crystals, m.p. 142°.

Found %: C 83.06; H 6.21; N 5.13 $C_{19}C_{17}ON$. Calculated %: C 82.88; H 6.22; N 5.09

1-Phenyl-4-(2-quinolyl)-1, 3-butadiene (VIII). 4-Phenyl-1-(2-quinolyl)-3-buten-2-ol (1 g) was dehydrated in the manner described above. The product, amounting to 0.74 g (83%), melted at 114-117°. After being crystallized from a mixture of benzene and ethanol and then subjected to chromatography on alumina from a 1:1 mixture of benzene and petroleum ether, 1-phenyl-4-(2-quinolyl)-1, 3-butadiene was obtained in light yellow crystals, m.p. 118-119° (the literature [6] gives 119°); it showed blue fluorescence.

SUMMARY

1. In the reactions of 2-pyridylmethyllithium and of 2-quinolylmethyllithium with 3-methyl-6-phenyl-3, 5-hexadien-2-one, the corresponding tertiary alcohols were formed. Dehydration of these gave 2, 3-dimethyl-6-phenyl-1-(2-pyridyl)-1, 3, 5-hexatriene and 2, 3-dimethyl-6-phenyl-1-(2-quinolyl)-1, 3, 5-hexatriene.

2. Reaction of 2-pyridylmethyllithium and of 2-quinolylmethyllithium with cinnamaldehyde gave the butenols 4-phenyl-1-(2-pyridyl)-3-buten-2-ol and 4-phenyl-1-(2-quinolyl)-3-buten-2-ol. Dehydration of these gave butadiene derivatives.

SYNTHESIS OF STEROID COMPOUNDS AND RELATED SUBSTANCES

COMMUNICATION 38. ANALOGS OF DOISYNOLIC ACID NOT CONTAINING A B RING

I. N. Nazarov and S. I. Zavyalov

In a previous investigation [1] we synthesized some tricyclic ketones of the types (I) and (II), which are structurally related to homoestrone with its B ring removed.

The present paper describes further synthetic work on structural analogs of steroid hormones.

By treatment with paraform and dimethylamine hydrochloride, 4'-methoxyacetophenone (III) was converted in good yield into the hydrochloride of 3-dimethylamino-4'-methoxypropiophenone (IV) [2], which reacted with 1, 3-cyclohexanedione in presence of alkali with formation of the triketone (V). Attempts to cyclize

this product with the object of obtaining the oxygen-containing steroid analog (VI) were not successful, for treatment of the triketone (V) with phosphoric oxide or sulfuric acid did not yield any individual products, and treatment with boiling acetic anhydride in presence of sodium acetate gave the enol acetate (VII). When treated with alkali for a short time, this ester was hydrolyzed into the original triketone (V).

Reaction of 4'-methoxyacetophenone with acetylene by the method developed in our laboratory [3] gave the acetylenic alcohol (VIII), which was converted into the ethylenic alcohol (IX) when partially hydrogenated over a palladium catalyst. Dehydration of the ethylenic alcohol under various conditions (with the aid of potassium hydrogen sulfate, p-toluenesulfonic acid, or magnesium sulfate) was accompanied by much polymerization, and the highest yield of the diene (X) that we were able to attain was 35%. This diene readily underwent diene synthesis with maleic anhydride, and the adduct obtained (XI) was quantitatively hydrolyzed by alkali into the dicarboxylic acid (XII).

It was found that the ethylenic alcohol (IX) could be used directly in the diene condensation instead of the diene (X); dehydration of (IX) then occurred in the reaction itself. Thus, heating of the ethylenic alcohol (IX) with maleic anhydride or methacrylic acid in boiling xylene gave the corresponding adduct (XI) or (XIII) in a yield of 33% or 38%, respectively.

As in the condensation with maleic anhydride the above-mentioned dicarboxylic acid (XII) is formed as well as the adduct (XI); the total yield in this reaction attains 50%.

When boiled with aqueous-alcoholic alkali, the bicyclic ester (XIII) is converted into the acid (XIV), which we prepared also by another method. Condensation of 2-methoxy-1, 3-butadiene (XXII) with methyl methacrylate and subsequent hydrolysis of the adduct (XXI) gave, as already described [4], methyl 1-methyl-4-oxo-1-cyclohexanecarboxylate (XX). Reaction of this product with p-methoxyphenylmagnesium bromide and vacuum-distillation of the reaction product gave a mixture of the above bicyclic ester (XIII) and the corresponding acid (XIV), probably formed by scission of the intermediate lactone (XVIII).

When treated with aluminum chloride in boiling xylene, the acid (XIV) was demethylated with formation of the bicyclic phenol (XV), which may be regarded as an analog of doisynolic acid (XVI) in which the B ring is missing. It must be pointed out that the previously described [5] phenolic acid (XVII), which was prepared by another method, possesses estrogenic activity.

EXPERIMENTAL

Preparation of the Triketone (V). A mixture of 4.2 g of the hydrochloride of 3-dimethylamino-4'-methoxypropiophenone (IV) (m.p. 180-181°) [2], 3 g of 1, 3-cyclohexanedione (m.p. 104-105°) [6], and a solution of 1 g of potassium hydroxide in 20 ml of water was heated for 30 minutes in a boiling water bath. When cool, the solution was treated with 2 g of sodium carbonate, filtered, and acidified to Congo red with concentrated hydrochloric acid. Addition of ether to the precipitated oil caused it to crystallize, and 2.5 g (33%) of the triketone (V), m.p. 119-120° (from aqueous methanol), was obtained.

Found %: C 70.37; 70.23; H 6.51, 6.62 $C_{16}H_{18}O_4$. Calculated %: C 70.1; H 6.5

Reaction of the Triketone (V) with Acetic Anhydride. A mixture of 3 g of the triketone (V), 0.03 g of sodium acetate, and 24 ml of acetic anhydride was refluxed for three hours. Acetic acid and excess of acetic anhydride were removed, and the residue was treated with 1 g of sodium carbonate in 15 ml of water and then extracted with chloroform. The chloroform extract gave 1.5 g (44%) of the enol acetate (VII), b.p. 228-231° (1 mm) and n_D^{20} 1.5620.

Found %: C 68.19; 68.36; H 6.34; 6.39 $C_{18}H_{20}O_5$. Calculated %: C 68.3; H 6.3

Hydrolysis of the Enol Acetate (VII). A mixture of 1.5 g of the enol acetate (VII) and a solution of 0.4 g of potassium hydroxide in 10 ml of water was stirred at 60-70° until the oil dissolved (about 45 minutes). The cooled solution was acidified with hydrochloric acid, and 0.9 g (69%) of the triketone (V), m.p. 119-120°, was precipitated.

2-p-Methoxyphenyl-3-buten-2-ol (IX). 2-p-Methoxyphenyl-3-butyn-2-ol (VIII) (30 g; m.p. 35°) [3] was hydrogenated as a solution in 50 ml of dry dioxane in presence of a palladium catalyst supported on calcium carbonate (5% Pd). After the absorption of 4025 ml (18°, 755 mm) of hydrogen, i.e., one molecular equivalent, the test for an acetylene became negative and hydrogenation was discontinued. The product, amounting to 22 g (70%) was 2-p-methoxyphenyl-3-buten-2-ol (IX), b.p. 109-110° (2 mm); n_D^{20} 1.5393; d_4^{20} 1.056; found MR 52.82; calculated MR 52.1.

Found %: C 74.16; 74.10; H 7.99; 8.07 $C_{11}H_{14}O_2$. Calculated %: C 74.20; H 7.89

2-p-Methoxyphenyl-1, 3-butadiene (X). A mixture of 5 g of 2-p-methoxyphenyl-3-buten-2-ol (IX) and 5 mg of potassium hydrogen sulfate was heated under a residual pressure of 5 mm of nitrogen at a bath temperature of 100°. The product was dried with calcium chloride and distilled under a reduced pressure of nitrogen. The product, amounting to 1.5 g (35%), was 2-p-methoxyphenyl-1, 3-butadiene (X), b.p. 80° (3 mm); n_D^{20} 1.5554; d_4^{20} 0.934.

Found %: C 82.20; 81.97; H 7.63; 7.69 $C_{11}H_{12}O$. Calculated %: C 82.45; H 7.50

Condensation of 2-p-Methoxyphenyl-1, 3-butadiene with Maleic Anhydride. 1. A mixture of 1.7 g of 2-p-methoxyphenyl-1, 3-butadiene (X), 1 g of maleic anhydride, and 6 ml of dry benzene was refluxed for one hour. Solvent was removed, and 2.5 g (95%) of the adduct (XI), m.p. 124-125° (from a mixture of benzene and heptane), was obtained.

Found %: C 70.17; 69.93; H 5.69; 5.59 $C_{15}H_{14}O_4$. Calculated %: C 69.99; H 5.45

2. A solution of 1.8 g of 2-p-methoxyphenyl-3-buten-2-ol (IX) and 0.8 g of maleic anhydride in 16 ml of xylene was refluxed for 30 minutes. The residue remaining after removal of xylene was treated with 3 g of sodium carbonate in 20 ml of water, and the aqueous solution was filtered. Acidification of the solution to Congo red with 1:1 hydrochloric acid resulted in a precipitate of 0.4 g of the dicarboxylic acid (XII), m.p. 208-210° (from aqueous methanol).

Titration equivalent found: 140 $C_{15}H_{16}O_5$. Titration equivalent calculated: 138

Found %: C 65.11; 65.14; H 5.93; 5.91 $C_{15}H_{16}O_5$. Calculated %: C 65.22; H 5.88

The neutral product, after being recrystallized from a mixture of benzene and heptane, gave 0.8 g of the above-described adduct (XI), m.p. 124-125°. Conversion of the adduct (XI) into the dicarboxylic acid (XII) was effected in quantitative yield by a short hot treatment with dilute caustic alkali solution.

Preparation of Methyl 4-p-Methoxyphenyl-1-methyl-3-cyclohexene-1-carboxylate (XIII). A mixture of 2.2 g of 2-p-methoxyphenyl-3-buten-2-ol (IX), 3 g of methyl methacrylate, and 15 ml of xylene was refluxed for four hours. Solvent was removed, and vacuum-distillation of the residue gave 1.2 g (37%) of methyl 4-p-methoxyphenyl-1-methyl-3-cyclohexene-1-carboxylate (XIII), b.p. 158-166° (1 mm) and n_D^{20} 1.5549.

Found %: C 73.54; 73.48; H 7.35; 7.46 $C_{16}H_{20}O_3$. Calculated %: C 73.8; H 7.7

Hydrolysis of Methyl 4-p-Methoxyphenyl-1-methyl-3-cyclohexene-1-carboxylate (XIII). A mixture of 1 g of methyl 4-p-methoxyphenyl-1-methyl-3-cyclohexene-1-carboxylate (XIII) and a solution of 0.5 g of sodium hydroxide in 10 ml of 50% aqueous alcohol was refluxed for four hours. The mixture was cooled, diluted with 10 ml of water, and acidified with concentrated hydrochloric acid. A precipitate of 0.5 g (53%) of 4-p-methoxyphenyl-1-methyl-3-cyclohexene-1-carboxylic acid (XIV), m.p. 132-133° (from heptane), was obtained.

Titration equivalent found: 245 $C_{15}H_{18}O_3$. Titration equivalent calculated: 246

Found %: C 73.40; 73.05; H 7.29; 7.30 $C_{15}H_{18}O_3$. Calculated %: C 73.15; H 7.31

Reaction of p-Methoxyphenylmagnesium Bromide with Methyl 1-Methyl-4-oxo-1-cyclohexanecarboxylate (XX). The Grignard reagent prepared from 7 g of p-bromoanisole and 0.8 g of magnesium in 50 ml of ether was added dropwise to a stirred ice-cooled solution of 4.4 g of methyl 1-methyl-4-oxo-1-cyclohexanecarboxylate (XX) (b.p. 115-117° (14 mm); n_D^{20} 1.4618) [4] in 30 ml of ether. The mixture was allowed to stand for one hour at room temperature and was then decomposed with ice and dilute (1 : 1) hydrochloric acid. The ether layer was washed with sodium carbonate solution, and ether was evaporated off. Vacuum distillation of the residue gave 1.6 g of methyl 4-p-methoxyphenyl-1-methyl-3-cyclohexene-1-carboxylate (XII), b.p. 159-164° (1 mm) and 1.7 g of the acid (XIV), b.p. 185-200° (1 mm), m.p. 132-133° (from heptane).

Demethylation of 4-p-Methoxyphenyl-1-methyl-3-cyclohexene-1-carboxylic acid (XIV). A mixture of 0.4 g of 4-p-methoxyphenyl-1-methyl-3-cyclohexene-1-carboxylic acid (XIV), 1 g of aluminum chloride, and 5 ml of xylene was refluxed for 5 minutes. The mixture was cooled and treated with ice and dilute hydrochloric acid. The precipitate formed was dissolved in sodium carbonate solution, and the resulting solution was boiled with activated charcoal and acidified with dilute hydrochloric acid. There was a precipitate of 0.12 g (33%) of 4-p-hydroxyphenyl-1-methyl-3-cyclohexene-1-carboxylic acid (XV), m.p. 167-168° (from water).

Found %: C 72.35; 72.17; H 6.74; 6.78 $C_{14}H_{16}O_3$. Calculated %: C 72.4; H 6.8

SUMMARY

1. Reaction between the hydrochloride of 3-dimethylamino-4'-methoxypropiophenone (IV) and 1, 3-cyclohexanedione in presence of alkali gave the bicyclic triketone (V), which was converted into the corresponding enol acetate (VII) when boiled with acetic anhydride in presence of sodium acetate.

2. It was shown that 2-p-methoxyphenyl-1, 3-butadiene (X) readily undergoes diene condensation with maleic anhydride and with methyl methacrylate with formation of the normal adducts (XI) and (XIII). It was found that in these reactions it is possible to use 2-p-methoxyphenyl-3-buten-2-ol directly, as it is readily dehydrated under the conditions of the experiment.

3. Reaction between p-methoxyphenylmagnesium bromide and methyl 1-methyl-4-oxo-1-cyclohexanecarboxylate (XX) gave a mixture of 4-p-methoxyphenyl-1-methyl-3-cyclohexene-1-carboxylic acid (XIV) and the corresponding ester (XIII), the products being identical with those obtained previously by diene condensation of 2-p-methoxyphenyl-1, 3-butadiene (X) with methyl methacrylate.

4. Demethylation of 4-p-methoxyphenyl-1-methyl-3-cyclohexene-1-carboxylic acid (XIV) by the aid of aluminum chloride in boiling xylene gave the bicyclic phenol (XV), which is of interest for tests on estrogenic activity.

α-KETO EPOXIDES AND THEIR REACTIONS

COMMUNICATION 7. GEOMETRIC ISOMERISM IN THE α-KETO DIEPOXIDE SERIES

I. N. Nazarov and A. A. Arkhem

In a previous communication [1] we showed that aliphatic divinyl ketones are smoothly oxidized by alkaline hydrogen peroxide to the corresponding α-keto epoxides:

In the case of unsymmetrically substituted divinyl ketones the α-keto diepoxides may be obtained in the form of cis and trans isomers.

Weitz and Scheffer [2] were the first to suggest that 3, 3"-p-phenylenebis[23-epoxypropiophenone] (I), which they prepared, could exist in the form of three geometric isomers: cis-cis, cis-trans, and trans-trans. However, they did not isolate any of these isomers in the pure state.

(I)

Somewhat earlier, Bodfon [3] condensed 2, 3-epoxy-3-m-nitrophenylpropiophenone with 2-bromoacetophenone and isolated two isomeric keto diepoxides (II), m.p. 170° and 207°, although other keto epoxides of this series had been obtained in one form only.

(II)

Apart from geometric isomerism, in this case the author admitted the possibility of physical isomerism—so-called monotropy. These are the only examples in the literature of cis-trans isomerism in the α-keto diepoxide series. Very little study has been devoted also to the stereochemistry of the oxidation of α, β-unsaturated ketones with alkaline hydrogen peroxide. Lutz [4] showed recently that oxidation of isomeric chalcones with alkaline hydrogen peroxide gave the corresponding α-keto epoxides only in the trans configuration. However, it is known also that dypnone (III), which is a chalcone derivative, gives two isomeric α-keto epoxides, m.p. 94° and 164°, under these conditions [5]:

(III)

As Cromwell and Setterquist [6] showed, the α- and β-forms of 2, 3-epoxy-3-o-nitrophenylpropiophenone, m.p. 111° and 175°, which were obtained previously by Bodfon [7] are geometric isomers. They [6] synthesized the α-form of Bodfon's keto epoxide (m.p. 111°) by oxidation of 2-nitrochalcone with alkaline hydrogen peroxide:

m.p. 111-112°

The isomerization of the α-form into the β-form in presence of sodium ethoxide, which was first observed by Bodfon [3], is explained by Cromwell and Setterquist [6] as follows:

trans (α) form cis (β) form

We studied the oxidation of 1, 5-diphenyl-3-pentadienone (IV), m.p. 112-113°, with alkaline hydrogen peroxide. The dienone was prepared by the alkaline condensation of benzaldehyde with acetone [8] and—on analogy with 4-phenyl-3-buten-2-one and chalcone, for which the trans configurations have been rigorously proved [4]—probably has a trans-trans configuration.

By the oxidation of 1, 5-diphenyl-3-pentadienone (IV) with alkaline hydrogen peroxide in dioxane, we obtained a quantitative yield of a crystalline α-keto diepoxide (V) in the form of a mixture of geometric isomers, from which fractional crystallization gave two individual isomers, m.p. 99° and 119°:

(IV) (V)

In addition we obtained an appreciable amount of an intermediate fraction, m.p. 86-110°, which we did not succeed in resolving into individual isomers. It should be noted that Weitz and Scheffer [2], in their attempt at oxidizing 1, 5-diphenyl-3-pentadienone (IV) with alkaline hydrogen peroxide, did not succeed in isolating the keto diepoxide (V).

Our result indicates that, in the oxidation of 1, 5-diphenyl-3-pentadienone (IV) with alkaline hydrogen peroxide in dioxane, inversion of geometric configuration probably occurs, since at least two isomers of the α-keto diepoxide (V) are formed; this is in complete agreement with the ionic mechanism of this reaction [9].

Oxidation of 1-cyclohexen-1-yl propenyl ketone (VI) with alkaline hydrogen peroxide gave the keto diepoxide (VII) in a yield of about 70%. This again appears to exist in two geometric forms (liquid and solid):

(VI) (VII)

Hydrolysis of the crystalline keto diepoxide (VII) with boiling water gave a crystalline dihydroxychromanone (VIII), and hydrolysis of the liquid diepoxide (VII) gave the chromanone (VIII) in the form of a viscous, difficulty crystallizable sirup:

(VII) (VIII)

Oxidation of the methoxy ketone (IX) with alkaline hydrogen peroxide gave the keto epoxide (X) in high yield:

(IX) (X)

It should be noted that the rate of oxidation of the dienone (VI) with alkaline hydrogen peroxide is appreciably greater than the rate of oxidation of the methoxy ketone (IX).

EXPERIMENTAL

α-Keto Diepoxide (V)

A solution of 105 g of 1, 5-diphenyl-3-pentadienone (IV) (m.p. 109-110°) in 1200 ml of dioxane was prepared in a 2-liter three-necked flask fitted with mechanical stirrer, thermometer, and two dropping funnels. The solution was stirred and cooled with ice water while, over a period of five minutes, 100 ml of 18% hydrogen peroxide and 40 ml of 4 N NaOH were added simultaneously from the dropping funnels. The oxidation reaction was accompanied by slight evolution of heat, and the temperature of the reaction mixture was maintained at not above 20° by cooling. After one hour the whole of the hydrogen peroxide had reacted. The solution was neutralized with 100 ml of 10% sulfuric acid, and the whole was diluted with an equal volume of water. The crystalline precipitate was filtered off, washed on the filter with ethanol, and recrystallized from dioxane. The product, amounting to 95 g, consisted of colorless crystals, m.p. 110-118°.

Repeated fractional crystallization of these crystals from petroleum ether (b.p. 80-100°) gave: a) 18 g of the high-melting isomer of the keto diepoxide (V) in the form of glistening silvery leaves, m.p. 119-119.5°;

Found %: C 76.60; 76.62; H 5.19; 5.28 $C_{17}H_{14}O_3$. Calculated %: C 76.69; H 5.26
Found: M 208; 211 (in benzene) $C_{17}H_{14}O_3$. Calculated: M 266

we were unable to recrystallize the 2, 4-dinitrophenylhydrazone because it resinified when heated in alcoholic solution; and b) 5 g of the low-melting isomer of the keto diepoxide (V) in the form of glistening needles, m.p. 99.5°;

Found %: C 76.31; 76.59; H 5.32; 5.28 $C_{17}H_{14}O_3$. Calculated %: C 76.69; H 5.26

In addition, we obtained an intermediate fraction (70 g, m.p. 86-100°) consisting of a mixture of isomers of the diepoxide (V).

Found %: C 77.11; 77.10; H 5.44; 5.33 $C_{17}H_{14}O_3$. Calculated %: C 76.69; H 5.26

A mixture of the two pure isomers melted at 84-96°.

α-Keto Diepoxide (VII)

Over a period of two hours, 104 g of the dienone (VI) (b.p. 80° (1.5 mm); n_D^{24} 1.5100) [10] and 50 ml of 8 N NaOH were added simultaneously from two dropping funnels to a solution of 250 ml of 24% hydrogen peroxide in 750 ml of dioxane with vigorous stirring and cooling with ice and salt. The oxidation continued for about 5.5 hours and was accompanied by evolution of heat. When reaction was complete, 15 g of hydrogen peroxide remained in the reaction mixture, the excess added being about 13 g. The solution was neutralized with 130 ml of 10% sulfuric acid, hydrogen peroxide was decomposed with manganese dioxide, and the precipitate of sodium sulfate was filtered off. Most of the dioxane was distilled off under reduced pressure (about 100 mm), distillation being continued until the liquid formed two layers.

The product was extracted with ether, and the extract was dried with anhydrous sodium sulfate. Vacuum-fractionation gave 60 g of the diepoxide (VII) in the form of a colorless liquid, b.p. 105-107° (2.5 mm). Repeated chilling of this gave 12 g of the solid isomer of the keto diepoxide (VII), m.p. 54.5° (from petroleum ether).

Found %: C 65.99; 65.83; H 7.93; 7.86 $C_{16}H_{14}O_3$. Calculated %: C 65.93; H 7.89

Repeated fractionation of the liquid fraction gave 35 g of the liquid diepoxide (VII), b.p. 105° (2 mm); n_D^{20} 1.4840; d_4^{20} 1.1281; found MR 46.18; calculated MR 46.48.

Found %: C 65.74; 65.77; H 7.83; 7.81 $C_{16}H_{14}O_3$. Calculated %: C 65.93; H 7.89

Hydrolysis of the Keto Diepoxide (VII)

a) A mixture of 5 g of the keto diepoxide (VII) (m.p. 54.5°) and 100 ml of water was boiled until complete dissolution occurred (15 hours). The solution was evaporated under reduced pressure, and the thick sirupy residue was dissolved in dry chloroform. The solution yielded 3.7 g of crystals of the dihydroxychromanone (VIII), which melted at 81-82° after three recrystallizations from ether.

Found %: C 60.22; 60.19; H 8.17; 8.20 $C_{16}H_{16}O_4$. Calculated %: C 60.00; H 8.00

b) A mixture of 20 g of the keto diepoxide (VII) (b.p. 105-107° (2.5 mm); n_D^{20} 1.4840) and 200 ml of water containing 5 ml of concentrated hydrochloric acid was heated in a boiling water bath for 2.5 hours. When the reaction mixture was cooled, about 5 g of a thick sirup settled on the bottom of the flask. The product was extracted with ether, and the extract was dried with anhydrous sodium sulfate. Vacuum fractionation gave about 13 g of the dihydroxychromanone (VIII) in the form of a thick colorless sirup, b.p. 105-106° (1 mm) and n_D^{20} 1.5060, which gradually congealed into a paste; we did not succeed in crystallizing it.

Keto Epoxide (X)

With continuous stirring, 50 ml of 24% hydrogen peroxide and 15 ml of 4 N NaOH were added to a solution of 45.5 g of the methoxy ketone (IX) (b.p. 100-103° (2 mm); n_D^{20} 1.4880) [10] in 350 ml of methanol cooled to −7° with ice and salt. The oxidation reaction proceeded with slight evolution of heat. After 2.5 hours from the

start of reaction, 4 g of hydrogen peroxide remained in the reaction mixture (the excess added was about 3.5 g). The reaction products were isolated in the usual way. Two vacuum fractionations gave about 30 g of the keto epoxide (X) in the form of a colorless liquid, b.p. 90° (1.5 mm); n_D^{20} 1.4720; d_4^{20} 1.0314; found MR 53.75; calculated MR 53.29.

Found %: C 68.56; 68.71; H 9.41; 9.19 $C_{12}H_{18}O_3$. Calculated %: C 68.87; H 9.09

The high carbon content is probably to be explained by admixture of unchanged methoxy ketone, although reoxidation of the analyzed fraction did not affect the analytical results.

SUMMARY

1. In the oxidation of 1,5-diphenyl-3-pentadienone (IV) and of 1-cyclohexen-1-yl propenyl ketone (VI) with alkaline hydrogen peroxide, in each case two geometric isomers of the corresponding α-keto diepoxide were isolated.

2. It is suggested that the hydrogen peroxide oxidation reaction is accompanied by inversion of the configuration of the original α, β - unsaturated ketone.

STEREOCHEMISTRY OF CYCLIC COMPOUNDS

COMMUNICATION 15. CONDENSATION OF 2-METHOXY-1, 3-BUTADIENE WITH MALEIC AND CITRACONIC ANHYDRIDES AND WITH THE METHYL ESTERS OF FUMARIC AND MESACONIC ACIDS

I. N. Nazarov and V. F. Kucherov

2-Alkoxy-1, 3-butadienes are notable in that, as a result of diene condensation and hydrolysis of the adducts formed, they can give substituted cyclic ketones, many of which are not readily accessible. As a result, 2-alkoxy-1, 3-butadienes have been used frequently in diene condensations, and the literature contains reports of their reactions with acrolein [1, 2], crotonaldehyde [3], methyl vinyl ketone [3], acrylonitrile [4], maleic and citraconic anhydrides [5], maleic and fumaric esters [7], and p-benzoquinone [8, 9].

Work in our laboratory [10] has shown that 2-methoxy-1, 3-butadiene is able to condense also with α, β-unsaturated cyclic ketones with formation of the corresponding bicyclic ketones, mainly of para structure:

We considered that it would be of interest to use 2-methoxy-1, 3-butadiene in condensations with anhydrides and esters of some unsaturated cis- and trans-dicarboxylic acids with the object of obtaining stereoisomeric oxo-1, 2-cyclohexanedicarboxylic acids.

According to the literature [5, 6] 2-methoxy-1, 3-butadiene readily reacts with maleic anhydride; reaction in boiling benzene gives a yield of about 65% of the cis methoxy anhydride (I), which is hydrolyzed by 3% hydrochloric acid into the cis-oxocyclohexanedicarboxylic acid (II), identical with a product obtained previously [11]. With diazomethane the keto acid (II) gave the liquid cis keto diester (III), the semicarbazone of which was found to be different from that obtained by Petrov and Sopov [7]; it melted at 186-187°. Vacuum distillation of the cis keto acid (II) gave the corresponding cis keto anhydride (IV), but when this was obtained by treatment with acetyl chloride at the boil, its formation was accompanied by formation of isomers of lactone character which we did not succeed in isolating in the pure state.

The condensation of 2-methoxy-1, 3-butadiene with methyl fumarate went much better: reaction at 230° for three hours gave the trans methoxy diester (V) [7] in a yield of about 80%. Hydrolysis of the trans methoxy diester (V) with 10% potassium hydroxide solution gave the trans keto acid (VI), m.p. 204-205°, and with diazomethane this gave the trans keto diester (VII), which formed a semicarbazone of m.p. 179-180°.

The melting point of our trans acid (VI) was 15° higher than the value reported in the literature [7]. The trans keto acid (VI), unlike the cis isomer (II), readily gave the trans keto anhydride (VIII) with boiling acetyl chloride. When heated, this anhydride was completely isomerized into the stable cis keto anhydride (IV).

Heating of 2-methoxy-1, 3-butadiene with citraconic anhydride for six hours at 100° gave a good yield of the cis methoxy anhydride (IX), possibly contaminated with a little of the meta isomer (X). However, hydrolysis of the adduct with 3% hydrochloric acid resulted in the isolation of only one individual cis keto acid (XI), m.p. 143°, with a para arrangement of carbonyl and methyl groups, and not meta – the arrangement previously assigned arbitrarily to this compound [8].

The incorrectness of the earlier view was proved by studying the reactions of the cis keto acid (XI) and the condensation of 2-methoxy-1, 3-butadiene with mesaconic ester. It was found that, when boiled with acetyl chloride, the cis keto acid (XI) readily gave the cis keto anhydride (XII), and by the action of diazomethane it gave the cis keto diester (XIII), which was characterized as the semicarbazone, m.p. 182°.

The isomeric trans keto diester (XV), the semicarbazone of which melted at 202°, was prepared by acid hydrolysis of the adduct (XIV) formed in high yield by condensing 2-methoxy-1, 3-butadiene with mesaconic ester (240° for four hours).

Hydrolysis of the trans keto diester (XV) with 20% potassium hydroxide solution also gave only one individual trans keto acid (XVI), m.p. 178°. When heated in a vacuum, this acid was converted in good yield into the isomeric cis keto anhydride (XII), which proved that the isomeric keto acids (XI) and (XVI) are sterically different. The structure of these stereoisomers as 1-methyl-4-oxo-1, 2-cyclohexanedicarboxylic acid follows from the fact that the semicarbazone prepared from the diethyl ester of the trans keto acid (XVI) had the same melting point as that described previously [12] and differed greatly from the known semicarbazone of diethyl trans-1-methyl-5-oxo-1, 2-dicarboxylate [13].

These results show that the condensation of 2-methoxy-1, 3-butadiene with citraconic and mesaconic anhydrides gives mainly adducts of para structure, as in the case of the diene condensations of various 2-substituted dienes with unsymmetrical dienophiles [14].

EXPERIMENTAL

Condensation of 2-Methoxy-1, 3-butadiene with Maleic Anhydride

2-Methoxy-1, 3-butadiene (15 ml) [10] was added to a solution of 20 g of freshly distilled maleic anhydride in 100 ml of dry benzene. The mixture was set aside for two days at room temperature and was then refluxed for five hours. The solution was decanted from the polymer that formed, benzene was distilled off, and the residue was vacuum-distilled. The product, in yield of 24 g (64%), was the cis methoxy anhydride (I), b.p. 130-132° (3 mm) and n_D^{20} 1.5070.

Found %: C 59.59; 59.49; H 5.68; 5.89 $C_9H_{10}O_4$. Calculated %: C 59.34; H 5.53

cis Keto Diester (III). A mixture of 10 g of the cis methoxy anhydride (I) and 30 ml of 3% hydrochloric acid was boiled for 90 minutes and then evaporated to small bulk under reduced pressure. The product gradually crystallized out; it was filtered off and washed with a little cold water (6.2 g, m.p. 160-163°). Evaporation of the aqueous mother liquor gave a further 2 g of the same acid, m.p. 160-162°. Crystallization from water gave pure cis keto acid (II), m.p. 167-168°, which is in accord with data in the literature [7, 11].

After treatment with ethereal diazomethane and vacuum-distillation of the product, 5 g of the cis keto acid (II) gave 4.7 g of the cis keto diester (III), b.p. 130-131° (1.5 mm) and n_D^{20} 1.4740.

Found %: C 56.24; 56.27; H 6.55; 6.51 $C_{10}H_{14}O_5$. Calculated %: C 56.06; H 6.59

The semicarbazone prepared in the usual way from the cis keto ester (III) melted constantly at 186-187° after crystallization from methanol. Petrov and Sopov give m.p. 138-139° for this semicarbazone [7].

Found %: N 15.25; 15.24 $C_{11}H_{19}O_5N_3$. Calculated %: N 15.50

Clemmensen reduction of the cis keto ester (III) gave a good yield of the known cis-1, 2-cyclohexanedicarboxylic acid, m.p. 191-192°, undepressed by admixture of a known sample.

cis Keto Anhydride (IV). The cis keto dicarboxylic acid (II) (2 g) was heated at 210° in a vacuum for 15 minutes and was then distilled at 2 mm. The viscous product (1.3 g) crystallized when treated with benzene, and recrystallization from benzene gave 1.1 g of the cis keto anhydride (IV), which melted constantly at 127-128°.

Found %: C 57.27; 57.09; H 5.17; 5.06 $C_8H_8O_4$. Calculated %: C 57.14; H 4.80

Condensation of 2-Methoxy-1, 3-butadiene with Dimethyl Fumarate

A mixture of 18 g of dimethyl fumarate, 30 g of 2-methoxy-1, 3-butadiene (threefold excess), and 100 ml of dry benzene was heated at 230-235° for three hours. Vacuum fractionation gave 23 g (80%) of the adduct, b.p. 120-125° (2 mm). Redistillation under reduced pressure gave 20.8 g of the trans methoxy diester (V), b.p. 112-113° (1 mm) and n_D^{20} 1.4780, which gradually solidified and then melted at 65-66°, which is in accord with data in the literature [7].

trans Keto Acid (VI). A mixture of 6 g of the trans methoxy diester (V) and 50 ml of 10% potassium hydroxide solution was boiled for 90 minutes until solution was complete. The product was treated with active charcoal, filtered, and acidified with hydrochloric acid. The solution was evaporated under reduced pressure, and the residue was treated with acetone. The acetone solution was evaporated to low bulk, and after several days 2.7 g of the trans keto acid (VI), m.p. 196-198°, separated. After crystallization from a little water the melting point was 204-205°. According to Petrov and Sopov [7], the trans keto acid (VI) melts at 188-190°.

Found %: C 51.83; 51.84; H 5.52; 5.38 $C_9H_{10}O_5$. Calculated %: C 51.81; H 5.41

trans Keto Diester (VII). The trans keto acid (VI) (2.3 g) was treated with diazomethane in ether. Ether was distilled off, and the residue crystallized when treated with petroleum ether. The product (2.3 g) was the trans keto diester (VII), m.p. 53-55°. After being crystallized from a mixture of diethyl ether and the petroleum ether it melted at 55-56°, which is in accord with data in the literature [7]. The semicarbazone, prepared in the usual way, melted at 179-180° after crystallization from methanol. Clemmensen reduction of the trans keto diester (VII) gave the known trans-1, 2-cyclohexanedicarboxylic acid, m.p. 218-220°.

trans Anhydride (VIII). A mixture of 3 g of the trans keto acid (VI) and 25 ml of acetyl chloride was boiled until solution was complete (four hours), and acetyl chloride was then distilled off. The residue gradually crystallized when it was allowed to stand with benzene. The product (1.7 g) was the trans anhydride (VIII), m.p. 151-153°, raised to 155-156° by recrystallization from benzene.

Found %: C 57.12; 57.06; H 4.82; 4.73 $C_9H_8O_4$. Calculated %: C 57.14; H 4.80

Thermal Isomerization of the trans-Keto Acid (VI)

The trans keto acid (VI) (2 g) was heated at 210° for 15 minutes and then vacuum-distilled. Crystallization from benzene gave 1.1 g of the cis keto anhydride (IV), m.p. 125-127°, undepressed by admixture of the sample described above.

Condensation of 2-Methoxy-1, 3-butadiene with Citraconic Anhydride

A mixture of 11 g of citraconic anhydride, 13.2 g of 2-methoxy-1, 3-butadiene, and 50 ml of benzene was heated in a sealed tube at 100° for six hours. Vacuum fractionation gave 14 g of the adduct (IX), b.p. 135-142° (5 mm) and n_D^{20} 1.4930. Redistillation through a column gave 11 g of the cis methoxy anhydride (IX), b.p. 133-135° (3 mm); n_D^{20} 1.4945.

Found %: C 61.38; 61.46; H 6.42; 6.33 $C_{10}H_{12}O_4$. Calculated %: C 61.25; H 6.27

cis-1-Methyl-4-oxo-1, 2-cyclohexanedicarboxylic Acid (XI)

A mixture of 10 g of the cis methoxy anhydride (IX) and 20 ml of 3% hydrochloric acid was boiled for two hours. Water was distilled off under reduced pressure, and the residue was dissolved in benzene. The solution was dried with sodium sulfate, and benzene was distilled off down to low bulk. After several days, 6.5 g of the crystalline cis keto acid (XI), m.p. 132-136°, separated. After crystallization from a mixture of benzene and ether it melted at 142-143°.

Found %: C 53.86; 53.88; H 6.13; 5.97 $C_9H_{12}O_5$. Calculated %: C 53.99; H 6.04

cis Keto Anhydride (XII). A mixture of 0.5 g of the cis keto acid (XI) and 5 ml of acetyl chloride was boiled until solution was complete, and volatile substances were distilled off under reduced pressure. Treatment of the residue with petroleum ether gave 0.3 g of the cis keto anhydride (XII), m.p. 135-140°, which melted constantly at 145-146° after crystallization from benzene.

Found %: C 59.42; 59.10; H 5.80; 5.86 $C_9H_{10}O_4$. Calculated %: C 59.33; H 5.55

cis Keto Diester (XIII). A suspension of 4.5 g of the cis keto acid (XI) in ether was treated with a slight excess of ethereal diazomethane. After removal of ether, the liquid product was vacuum-distilled and gave 5.3 g of the cis keto diester (XIII) as a viscous liquid, b.p. 149-150° (3 mm) and n_D^{20} 1.4730.

Found %: C 57.72; 57.50; H 6.78; 7.03 $C_{11}H_{16}O_5$. Calculated %: C 57.88; H 7.06

After crystallization from methanol the semicarbazone, prepared in the usual way, melted at 162-164°.

Found %: N 14.91; 14.92 $C_{10}H_{19}O_3N_3$. Calculated %: N 14.77

Clemmensen reduction of the cis keto diester (XIII) gave a good yield of cis-1-methyl-1, 2-cyclohexanedicarboxylic acid, m.p. 156-157°, undepressed by admixture of a known sample.

Condensation of 2-Methoxy-1, 3-butadiene with Dimethyl Mesaconate

A solution of 10 g of dimethyl mesaconate and 16 g of 2-methoxy-1, 3-butadiene (a threefold excess) in 30 ml of dry benzene was heated in a steel ampoule at 235-240° for four hours. Benzene was distilled off, and vacuum-distillation of the residue gave 9.9 g of adduct, b.p. 125-135° (4 mm). Redistillation through a column gave 8.9 g of the trans methoxy diester (XIV), b.p. 124-126° (3 mm) and n_D^{22} 1.4780.

Found %: C 59.84; 59.87; H 7.57; 7.70 $C_{10}H_{16}O_5$. Calculated %: C 59.80; H 7.49

trans Keto Diester (XV). A mixture of 6 g of the trans methoxy diester (XIV) and 25 ml of 3% hydrochloric acid was stirred at 40° for three hours, water was distilled off under reduced pressure, the residue was carefully extracted with ether, and the ethereal solution was washed with a little cold water and dried with sodium sulfate. Vacuum distillation gave 4.4 g of the trans keto diester (XV), b.p. 145-146° (3 mm); n_D^{22} 1.4720.

Found %: C 57.87; 57.90; H 7.00; 7.12 $C_{11}H_{16}O_5$. Calculated %: C 57.88; H 7.08

After crystallization from 70% methanol, the semicarbazone prepared from the trans keto diester (XV) melted at 200-201°.

Found %: N 14.53; 14.84 $C_{12}H_{19}O_5N_3$. Calculated %: N 14.77

Clemmensen reduction of the trans keto diester gave pure trans-1-methyl-1, 2-cyclohexanedicarboxylic acid, which showed no depression of melting point in admixture with a known sample.

trans-1-Methyl-4-oxo-1, 2-cyclohexanedicarboxylic Acid (XVI)

A mixture of 3 g of the trans keto diester (XV) and 20 ml of 20% potassium hydroxide solution was boiled for three hours, treated with active charcoal, filtered, and acidified with hydrochloric acid. Water was distilled off under reduced pressure, and the dry residue was carefully extracted with ether. The extract was dried with sodium sulfate, ether was distilled off to low bulk, and the residue was diluted with a little petroleum ether. After several days, 1.15 g of crystals, m.p. 158-165°, formed. On standing, the mother liquor gave a further 0.4 g of crystals, m.p. 150-160°. Two recrystallizations from water gave 1.1 g of the trans keto acid (XVI), m.p. 176-178°.

Found %: C 53.92; 53.88; H 5.96; 5.94 $C_9H_{12}O_5$. Calculated %: C 53.99; H 6.04

Boiling with ethanol in benzene solution in presence of a little sulfuric acid converted the trans keto acid (XVI) into its diethyl ester, b.p. 130-132° (2 mm), semicarbazone m.p. 141-142°, which corresponds to data in the literature [12]. The semicarbazone of the isomeric diethyl trans-1-methyl-5-oxo-1, 2-cyclohexanedicarboxylate melts at 158° [13].

Thermal Isomerization of the trans Keto Acid (XVI)

The trans keto acid (XVI) (0.5 g) was heated under reduced pressure at 210° for 20 minutes. Crystallization from benzene gave 0.3 g of the cis keto anhydride (XII), m.p. 144-145°, undepressed by admixture of the sample obtained previously (above).

SUMMARY

1. A study was made of the condensations of 2-methoxy-1, 3-butadiene with maleic and citraconic anhydrides and with fumaric and mesaconic esters. The corresponding cis- and trans-4-oxo-1, 2-cyclohexanedicarboxylic acids, their anhydrides, and their methyl esters are described.

2. It was shown that, in the condensation of 2-methoxy-1, 3-butadiene with citraconic anhydride and mesaconic ester, mainly para-adducts are formed, and these were characterized by their derivatives.

MECHANISM OF HYDRATION AND DEHYDRATION REACTIONS IN PRESENCE OF ZINC HALIDES

A. B. Kuchkarev and N. I. Shuikin

Processes of hydration and dehydration are extensively used in the industry of organic synthesis and preparative chemistry for the preparation of substances of great practical importance, particularly alcohols and unsaturated hydrocarbons. These reactions proceed successfully only in presence of catalysts. The catalysts most frequently used are sulfuric and phosphoric acids, alumina, thoria, and various salts [1]. It is to be noted that, in spite of the great practical importance of hydration and dehydration reactions, their mechanisms have not been adequately elucidated. There are various schemes in the literature for the course of these reactions in presence of certain protonic acids [2], but there are substantially no soundly based data on the mechanisms of these reactions in presence of aprotonic acids. We must point out also that metal halides have long been used as hydrating and dehydrating agents; and among these the most extensively used is zinc chloride.

Dehydration of Alcohols

Many investigators [3-5] have studied the dehydration of various alcohols with the aid of zinc chloride, and, on the basis of their experimental results, they have explained the mechanism of the reaction of alcohols with zinc chloride in various ways. Kondakov [6] considers that zinc chloride acts exclusively as a water-eliminating agent and does not admit the possibility of the formation of intermediate compounds. Liebmann [7] also regards zinc chloride as a water-eliminating agent. According to these views, the reaction of zinc chloride with alcohols is expressed in the following scheme:

$$C_nH_{2n+1}OH \xrightarrow{ZnCl_2} C_nH_{2n} + H_2O;$$

$$2C_nH_{2n+1}OH \xrightarrow{ZnCl_2} (C_nH_{2n+1})_2O + H_2O.$$

Other authors, however, hold a different view of the mechanism of reactions of zinc chloride with alcohols. Thus, going back to Williamson [8], we find that in his theory of the formation of ethers he considered that zinc chloride reacts like sulfuric acid with alcohols, forming intermediate zinc alkoxides, which then give ethers:

$$2C_2H_5OH + ZnCl_2 = (C_2H_5O)_2Zn + 2HCl;$$

$$2C_2H_5OH + 2HCl = 2C_2H_5Cl + 2H_2O;$$

$$(C_2H_5O)_2Zn + 2C_2H_5Cl = 2C_2H_5 \cdot O \cdot C_2H_5 + ZnCl_2.$$

The same view was developed later by Walter [9], who observed the formation of mixed zinc alkoxides in the reaction of zinc chloride with alcohols:

$$i\text{-}C_5H_{11}OH + ZnCl_2 \rightarrow i\text{-}C_5H_{11}OZnCl + HCl.$$

At high temperature the mixed zinc alkoxide decomposed into various new substances:

From the products of this reaction Walter succeeded in isolating an oily compound, to which he ascribed the formula $C_5H_{11}OZnCl$, although there was a great discrepancy between the found and calculated values for the zinc, carbon, and hydrogen contents. After an investigation of the decomposition products of aluminum and zinc alkoxides, Tishchenko [10] concluded that reaction between alcohols and zinc chloride proceeds as follows:

$$ZnCl_2 + 2ROH \rightarrow Zn(OR)_2 + 2HCl;$$

$$2ROH + 2HCl \rightarrow 2RCl + 2H_2O.$$

The author considered that the alkyl chloride reacts with the zinc alkoxide with formation of an ether,

$$Zn(OR)_2 + 2RCl \rightarrow ZnCl_2 + 2R_2O.$$

and olefins are formed by decomposition of the zinc alkoxide. Favorsky [11] pointed out the resemblance between the mechanisms of the reactions of sulfuric acid and zinc chloride with α-glycols and assumed the formation of mixed zinc alkoxides as intermediate products.

There is, therefore, a divergence of opinion on the mechanism of the dehydration of alcohols in presence of zinc chloride, and it is difficult to judge which of the suggested schemes is the correct one. The views of authors of the first group, which assume that zinc chloride is merely a water-removing agent, are not in accord with the experimental facts and, in our opinion, must be regarded as doubtful. The various schemes proposed by authors of the other group, which assume the formation of intermediate compounds in the course of the dehydration of alcohols under the action of zinc chloride, have the drawback of being based on indirect experimental facts. For example, when reaction between zinc chloride and alcohols was carried out at high temperatures (350-400°) in iron vessels [3, 4], there were by-products in the formation of which iron and its oxide probably played a major part. However, in the establishment of the mechanism of the action of zinc chloride on alcohols the effect of these factors was not taken into consideration by earlier investigators.

With the object of elucidating the nature of the catalytic effect of zinc halides in the course of hydration and dehydration, we undertook an investigation of the reactions of alcohols and olefins with zinc chloride and bromide [12]. Taking into account the importance of studying intermediate products for the establishment of reaction mechanisms, we first tried to determine the conditions for the formation of the products which, as we showed, are formed in the reaction between zinc halides and alcohols. We studied the action of anhydrous zinc

chloride and bromide on methyl, ethyl, propyl, isopropyl, butyl, isobutyl, isopentyl, benzyl, cyclohexyl, and other alcohols. Experiments were carried out in glass apparatus with various proportions of reactants under various conditions of temperature. After prolonged trials, we succeeded in isolating complex compounds of zinc chloride and bromide with alcohols. It was found that in these complexes zinc chloride and bromide are combined with alcohols in various proportions, which depend on reaction conditions and the identity of the alcohol. Compounds of zinc chloride and bromide of composition $ZnX_2 \cdot ROH$ and $ZnX_2 \cdot 2ROH$ were obtained, and sometimes compounds of other compositions were formed [13]. For example, study of the fusion diagram of the system zinc chloride–cyclohexanol confirmed the formation of the compound $ZnCl_2 \cdot 2C_6H_{11}OH$. These complexes are viscous oily liquids that are heavier than water. They are very hygroscopic and readily liquefy in the air. They are readily soluble in many organic solvents (benzene, toluene, acetone, alcohol, ether), but are almost insoluble in petroleum ether. Their solutions have acid properties and are electrically conducting. Thus, the molecular conductivity of zinc chloride in absolute methanol at 75° was found [14] to be 2.88 at 2.778 moles/liter, 1.49 at 4.884 moles/liter, and 0.560 at 5.84 moles/liter.

A study of the pH of aqueous and alcoholic solutions of zinc chloride and some other metal halides showed [15] that change in the concentration of the halide has a great effect on pH. It should be noted that, in solutions of $ZnCl_2$ and $CaCl_2$ in absolute ethanol, the quinhydrone electrode did not show a salt error. This indicates that these salts interact completely with the alcohol with formation of complex compounds. Benzene solutions of the crystalline complexes formed by zinc chloride and bromide with cyclohexanol, 2-methyl-2-butanol, tert-butyl alcohol, and some other alcohols show acid reactions to various indicators (4-phenylazo-1-naphthylamine, Methyl orange, Dimethyl yellow, litmus).

The acid properties of zinc chloride and bromide complexes are shown clearly also in their effects on alkylation, acylation, esterification, and addition reactions, which generally go very well in presence of acid catalysts (H_2SO_4, H_3PO_4, HF, etc.). Thus, good yields of carboxylic esters and acetals are obtained in presence of zinc halide complexes [16]. According to Meerwein, the acid properties of concentrated aqueous zinc chloride solutions are to be explained by the formation of complex compounds which have the properties of acids. The author measured the acidity of concentrated aqueous zinc chloride solutions by their catalytic activity on the inversion of sugar [17].

Thus, all these facts confirm the view that the appearance of acid functions in alcoholic solutions of zinc halides is due to the formation of complex acids. It is probable that complex-formation between zinc halides and alcohols proceeds by interaction between the electron-acceptor zinc ion and the electron-donor oxygen atom of the alcoholic hydroxyl:

In our opinion, the possibility that the complex has a cyclic structure cannot be excluded:

The possibility of the formation of such cyclic intermediate complexes in the course of reaction was pointed out by Shilov [18] in explaining the mechanism of addition to unsaturated molecules.

In alcoholic solutions of zinc chloride, the latter does not dissociate into chloride and zinc ions [19]. The electrical conductivity of these solutions must be attributed to hydrogen ions from the alcoholic hydroxyl. This is in accord with the fact that the alcohols themselves, particularly the lower ones, have acidic, although very weakly acidic, properties. Methanol, for example, has an ionization constant of 10^{-16}. It is clear that the formation of new bonds with the oxygen atom will weaken the bond between the oxygen and hydrogen of the hydroxy group, so that the complexes formed will behave like the usual mineral acids:

$$2ROH + ZnCl_2 \rightleftarrows H_2\left[\begin{matrix} RO \\ RO \end{matrix}\!\!>\!ZnCl_2\right] \rightleftarrows 2H^+ + \left[\begin{matrix} RO \\ RO \end{matrix}\!\!>\!ZnCl_2\right]$$

We also studied the behavior of these complexes toward heat. We found that, unlike the compounds formed by $CaCl_2$, $MgCl_2$, and $CdCl_2$ with alcohols, the molecular compounds of zinc halides, depending on the nature of the complexed alcohol and the temperature of treatment, break down with formation of various new compounds. For example, when methanol and ethanol complexes of zinc chloride are heated at 200-230°, gaseous and liquid products are formed. The gaseous decomposition products from the methanol complex were found to contain 10-12% of unsaturated hydrocarbons. The liquid products consisted mainly of dimethyl ether and the original alcohol; no aldehydes or other compounds were detected.

The decomposition of the ethanol complex began at 170° with formation of diethyl ether, the original alcohol, and gases containing 90% of ethylene. No aldehydes, hydrogen, or saturated hydrocarbons were detected among the decomposition products. In the breakdown of complexes of propyl alcohol (decomposition temperature 200°), butyl alcohol (decomposition temperature 185°), isopropyl alcohol (decomposition temperature 160°), and hexyl alcohol (decomposition temperature 170°), mainly unsaturated hydrocarbons, their polymers, and small amounts of the original alcohol and water were formed. Aldehydes, hydrogen, and saturated compounds were again absent in the decomposition products.

When heated to 140-145°, the crystalline complex of cyclohexanol and zinc chloride decomposed into cyclohexene (85% yield), cyclohexene dimer, high-boiling products, and water. Zinc bromide complexes gave similar results. It should be noted that slow dropwise addition of various alcohols to zinc chloride heated to 300° in a hard-glass flask results in the formation of products similar to those obtained by the decomposition of zinc halide complexes.

Hence, at relatively low temperatures, zinc halides form complex compounds of acidic character with alcohols, their general formula being $ZnX_2 \cdot nROH$. Under more severe conditions of temperature complex-formation is accompanied by decomposition of the complexes into ethers, unsaturated hydrocarbons, the original alcohols, and water. No aldehydes, hydrogen, alkyl halides, or saturated hydrocarbons are formed.

Hence, the reaction of dehydration of alcohols in presence of zinc halides can be represented as the formation in the first place of an intermediate compound ($ZnX_2 \cdot nROH$), which then, depending on the identity of the alcohol and the conditions of heating, decomposes with formation of various substances. The course of the reaction can be represented as follows:

$$ZnX_2 + nROH \underset{k_2}{\overset{k_1}{\rightleftarrows}} ZnX_2 \cdot n\,ROH \xrightarrow{k_3} C_nH_{2n},\ ROR,\ H_2O$$

and other products.

The final results of the dehydration reaction depend on the values of the rate constants k_1, k_2, and k_3.

It should be noted that, according to some authors [20], at first ethers are formed and, under given reaction conditions, these then decompose in presence of catalysts into olefins. On the other hand, other investigators [21] consider that ethers are not intermediaries in the formation of olefins.

The results of our investigations on the dehydration of alcohols with the aid of zinc halides show that olefins can arise both directly in the decomposition of intermediate complexes, and also as a result of the breakdown of ethers formed in the course of the dehydration. For example, the dehydration of lower alcohols (CH_3OH, C_2H_5OH) with $ZnCl_2$ and $ZnBr_2$ is accompanied by simultaneous formation of ethers and olefins. Moreover, in the dehydration of alcohols of higher molecular weight we were unable to isolate any appreciable amount of the corresponding ethers from the reaction products: the ethylenic hydrocarbons were almost always formed in quantitative yield. Similar results were obtained also in the thermal decomposition of the individual zinc halide complexes. For example, when heated above their melting points, the crystalline complex compounds of $ZnCl_2$ and $ZnBr_2$ with tertiary alcohols (tert-butyl alcohol, 2-methyl-2-butanol) decomposed quantitatively into the corresponding olefins.

The formation of ethers in the dehydration of alcohols depends mainly on the nature of the latter. Generally speaking, ethers are obtained in good yield only in the dehydration of lower alcohols. The reaction probably goes as follows:

$$CH_3OH + ZnCl_2 \rightleftarrows [ZnCl_2 \cdot OCH_3]\,H \rightleftarrows [ZnCl_2 \cdot OCH_3]^- + \overset{+}{H}.$$

Alcohols, being amphoteric compounds, can ionize as acids or as bases. In an acid medium they behave as bases, i.e., give carbonium and hydroxyl ions:

$$CH_3OH \rightleftarrows \overset{+}{CH_3} + \overline{OH}$$

$$\overset{+}{H} + \overline{OH} \rightleftarrows H_2O.$$

The carbonium ion then reacts with the anion of the acidic complex with formation of a new intermediate compound which then decomposes with formation of an ether:

$$[ZnCl_2 \cdot OCH_3]^- + \overset{+}{CH_3} \rightleftarrows [ZnCl_2 \cdot OCH_3]\,CH_3$$
$$[ZnCl_2 \cdot OCH_3]\,CH_3 + HOH \rightarrow CH_3OCH_3 + ZnCl_2 \cdot H_2O.$$

This scheme explains to some extent why reaction with lower alcohols (methanol, ethanol) proceeds with a comparatively high yield of ether. This is probably to be explained by the fact that in the case of methanol and ethanol we are dealing with the most active alcohols, which dissociate more strongly than their higher homologs. In the case of the higher alcohols their complexes decompose under certain temperature conditions directly into the corresponding unsaturated hydrocarbons and hydroxohalozinc acids:

$$ZnX_2 + n\,C_nH_{2n+1}OH \rightleftarrows [ZnX_2 \cdot (C_nH_{2n+1}O)_n]\,H_n.$$

in which n is the number of alcohol molecules (usually two):

$$[ZnX_2(C_nH_{2n+1}O)_n].H_n \rightleftarrows nC_nH_{2n} + [ZnX_2 \cdot (OH)_n]\,H_n.$$

Thus, the dehydration of 2-methyl-2-butanol in presence of zinc chloride proceeds as follows:

$$ZnCl_2 + 2C_5H_{11}OH \rightleftarrows [ZnCl_2 \cdot (C_5H_{11}O)_2]\ H_2 \rightleftarrows$$
$$\rightleftarrows 2C_5H_{10} + [ZnCl_2 \cdot (OH)_2]\ H_2$$
$$\downarrow\uparrow$$
$$ZnCl_2 + 2H_2O.$$

As will be seen from this scheme, as pentene and water are removed from the sphere of reaction, equilibrium is moved to the right, and zinc chloride enters into reaction with the alcohol.

It is probable, therefore, that acidic complexes between zinc halides and alcohols play the same part in the dehydration reaction that alkyl hydrogen sulfates play in dehydration with sulfuric acid, forming, like alkyl hydrogen sulfates, ethers under some conditions and unsaturated hydrocarbons under others.

Hydration of Olefins

We must point out that there are contradictory views on the mechanism of addition of water to unsaturated hydrocarbons in presence of zinc halides as catalysts. In the opinion of some investigators [22], in the hydration reaction zinc halides activate the double bonds of unsaturated compounds. According to the results of other investigations [23], hydration proceeds under the action of hydrohalic acid formed by the hydrolysis of zinc halide.

In order to determine the part played by zinc halides in the hydration reaction, we first studied the possibility of the formation of intermediate complexes between olefins and zinc halides. Kondakov [22] unexpectedly discovered molecular compounds of pentenes with $ZnCl_2$. For this purpose he used pure $ZnCl_2$ and various pentene isomers obtained from fermentation amyl alcohol. On the basis of his analyses he attributed the composition $C_5H_{10} \cdot 2ZnCl_2$ to the compound. Kondakov noted that, in the reaction between moist 2-methyl-2-butene and $ZnCl_2$, the formation of the crystalline product was accelerated. However, he did not admit the possibility of the participation of water in the composition of these substances; he considered that water simply played the part of solvent.

In our opinion, it is here impossible to neglect the fact that zinc chloride reacts more vigorously with water than with unsaturated hydrocarbons. As is well known, zinc chloride combines with water with evolution of a considerable amount of heat, whereas we have found that well dried unsaturated hydrocarbons do not react with anhydrous $ZnCl_2$. For example, we left a mixture of dry 2-methyl-2-butene and anhydrous zinc bromide in sealed tubes for several months, and no addition products were formed. It is evident that, when water is present in the reaction medium, zinc chloride will in the first place react with the water.

Hence, it is very probable that water participates directly as a reactant in complex-formation between ethylenic hydrocarbons and zinc halides. We succeeded in isolating crystalline complexes of zinc chloride and bromide with various unsaturated hydrocarbons, using moist olefins of zinc halides for this purpose. The following compounds were isolated:

$$C_5H_{10} \cdot 2ZnCl_2 \cdot H_2O,\ C_5H_{10} \cdot 2ZnBr_2 \cdot H_2O \text{ and } (C_5H_{10})_2 \cdot ZnBr_2 \cdot 2H_2O.$$

The last of these complexes was prepared by reaction of dry 2-methyl-2-butene with previously prepared zinc bromide hydrate $ZnBr_2 \cdot 2H_2O$.

Hence, the formation of complexes of unsaturated hydrocarbons with zinc halides depends on the presence of a definite amount of moisture in the reaction medium. Our observations confirm Meerwein's suggestion about the existence of hydroxochlorozinc acids of general formula $[(ZnCl_2) \cdot nH_2O]$ [17]. Thus, unsaturated hydrocarbons react not with anhydrous zinc halides, but with various hydroxochloro- and hydroxobromo-zinc acids with formation of hygroscopic crystalline complexes. Investigation of the properties of these compounds showed that they are acidic in character: their solutions in absolute benzene show an acidic reaction to 4-phenylazo-1-naphthylamine. When treated with water, these compounds decompose into the corresponding alcohols and hydroxochloro- or hydroxobromo-zinc acids.

It was further established that the product obtained by reaction of zinc bromide with 2-methyl-2-butanol was identical, both in composition and in properties, to the substance obtained from the hydroxobromozinc acid

$[ZnBr_2 \cdot (OH)_2]H_2$ and 2-methyl-2-butene. The two preparations had the same melting point (63°) and had acidic properties. When treated with water they both gave 2-methyl-2-butanol. This crystalline substance, therefore, is the intermediate complex common to the reactions of hydration of 2-methyl-2-butene and the dehydration of 2-methyl-2-butanol. In its general form, the reaction can be represented by the scheme:

$$[ZnBr_2 \cdot (OH)_2]H_2 + 2C_nH_{2n} \rightleftharpoons [ZnBr_2 (C_nH_{2n+1}O)_2]H_2 \rightleftharpoons 2C_nH_{2n+1}OH + ZnBr_2.$$

As will be seen from this scheme, an equilibrium exists between the hydration and dehydration reactions. Depending on the conditions, equilibrium is displaced either in the direction of dehydration of the alcohol or in the direction of hydration of the olefin.

Hence, the hydration of 2-methyl-2-butene in presence of a zinc halide proceeds according to the scheme:

$$ZnBr_2 + 2H_2O \rightleftharpoons [ZnBr_2(OH)_2]H_2 \quad (1)$$

$$[ZnBr_2 \cdot (OH)_2]H_2 + 2C_5H_{10} \rightleftharpoons [ZnBr_2 \cdot (OH)_2]H_2 \cdot 2C_5H_{10}. \quad (2)$$

$$[ZnBr_2 \cdot (OH)_2]H_2 \cdot 2C_5H_{10} \xrightarrow{2HOH} 2C_5H_{11}OH + [ZnBr_2 \cdot (OH)_2]H_2. \quad (3)$$

It is possible that addition of the hydroxobromozinc acid to 2-methyl-2-butene gives the following complex:

Thus, the hydration of unsaturated hydrocarbons in presence of zinc halides proceeds in two stages. In the first stage hydroxohalozinc acids add to unsaturated hydrocarbons, the process being analogous to the addition of mineral acids. In the second stage, on addition of water, the addition compounds decompose like alkyl hydrogen sulfates with formation of the corresponding alcohols and hydroxo acids. From the point of view of electronic theory, the reaction can be represented as follows:

If we denote $(CH_3)_2\overset{+}{C} \cdot CH_2 \cdot CH_3$ by $\overset{+}{R}$, then

SUMMARY

1. It is shown that, in the hydration of olefins and dehydration of alcohols in presence of zinc halides as catalysts, intermediate complexes are formed which later decompose, in a manner dependent on conditions, with formation of the final reaction products.

2. Both in the reaction of zinc halides with alcohols and in the reaction between hydroxchalozinc acids and the unsaturated hydrocarbons corresponding to these alcohols, the same intermediate complexes are formed. This indicates the existence of a state of equilibrium between the reactions of hydration of olefins and dehydration of alcohols. On the basis of these data and of a detailed investigation of the composition of complexes formed by zinc halides with alcohols and unsaturated hydrocarbons, a possible mechanism is proposed for hydration and dehydration reactions in presence of zinc halides as catalysts.

3. Comparison between hydration and dehydration reactions catalyzed by zinc halides, on the one hand, and by mineral acids, on the other, shows that they are very similar in mechanism.

4. On the basis of theoretical considerations and of a study of the properties of the intermidiate zinc halide compounds, a possible structure is proposed for the intermediate complexes.

OXIDATION-REDUCTION SYSTEMS FOR THE INITIATION OF FREE-RADICAL PROCESSES

COMMUNICATION 1. REVERSIBLE SYSTEMS IN WHICH ORGANIC HYDROPEROXIDES, DIENOLS, AND SALTS OF METALS OF VARIABLE VALENCE TAKE PART

G. P. Belonovskaya, B. A. Dolgoplosk, and E. I. Tinyakova

Oxidation-reduction systems have recently received considerable application for the initiation of free-radical processes, particularly polymerization processes in aqueous emulsions. The present investigation is devoted to a study of the mechanism of the action of reversible oxidation-reduction systems consisting of organic hydroperoxides, traces of iron or copper salts, and dienols (dihydroxymaleic and ascorbic acids) that are well known as components of natural biochemical oxidation-reduction systems. The systems that we developed were found to be extremely effective for the initiation of polymerization in aqueous emulsions.

Mechanism of the Action of the System

In order to determine by what mechanism the system acts and the parts played by individual reactions in the initiation of the polymerization process, it was considered to be necessary to study the kinetics of the interaction of the components in media of water and aqueous emulsions.

a) Kinetics of the Reactions of Dihydroxymaleic and Ascorbic Acids with Cumene Hydroperoxide. The kinetics of the reactions were studied in aqueous solutions in an atmosphere of nitrogen completely freed from oxygen; the concentrations of oxidizing and reducing agents were equimolecular and were about 0.15%. The kinetics of the process were characterized by following the changes in the contents of hydroperoxide (b) and dienol (a) in the reaction mixture. In a study of the effect of pH on the rate of reaction of cumene hydroperoxide with dihydroxymaleic acid it was shown that a minimum rate is found when reaction occurs at a pH of about 7; lowering or raising of pH leads to increased rate of reaction. In the case of ascorbic acid, reaction proceeds most slowly in acid and neutral media. The results of the experiments are shown in Figures 1-5.

In absence of metal salts, reaction between dihydroxymaleic or ascorbic acid and the hydroperoxide in an acid medium proceeds comparatively slowly (Curve 1, Figures 1 and 2) and scarcely goes at all at -15° and at -35° (Curve 1, Fig. 3). At pH 10.5 reaction between the hydroperoxide and ascorbic acid proceeds at an appreciable rate even in absence of iron or copper salts (Curve 1, Fig. 4). Even in this case, lowering of temperature to -15° and -35° leads to the complete cessation of the process (Fig. 5).

In all pH regions, reaction between the components is considerably accelerated by the introduction of salts of metals of variable valence into the system in very low concentration. In an acid medium iron salts are the more effective, and in an alkaline medium copper salts have the greater effect. As Figures 1-5 show, by varying the concentration of the metal salt we may regulate reaction rate over a wide range. Thus, at pH 3 (created by the dihydroxymaleic acid itself) and 0°, reaction is greatly accelerated by the introduction of only 0.5 mole % of Mohr's salt, (based on the amount of the hydroperoxide) (Curve 2, Fig. 1); in presence of 10 mole % of Mohr's salt, dihydroxymaleic acid almost disappears from the system in 15 minutes (Curve 3, Fig. 1). The case of ascorbic acid (Fig. 2) is similar, but metal salts are effective in considerably lower concentrations than in the dihydroxymaleic acid system.

The accelerating effect of metal salts is particularly notable at -15° and -35°, i.e., under the conditions under which cumene hydroperoxide scarcely reacts at all with dienols; with lowering of temperature the effective concentration of metal salt increases. The same situation is found also with dihydroxymaleic acid in an alkaline

Fig. 1. Kinetics of reaction of dihydroxymaleic acid (DMA) with cumene hydroperoxide as function of concentration of metal salt at 0° and pH 3: 1) no metal salt added; 2) Mohr's salt 0.5 mole % on hydroperoxide; 3) Mohr's salt 10 moles % on hydroperoxide; 4) $CuSO_4 \cdot 5H_2O$ 0.7 mole % on hydroperoxide.

Fig. 2. Kinetics of reaction of ascorbic acid (AA) with cumene hydroperoxide as function of concentration of metal salt at 0° and pH 3: 1) no metal salt added; 2) Mohr's salt 0.1 mole % on hydroperoxide; 3) Mohr's salt 0.5 mole % on hydroperoxide; 4) $CuSO_4 \cdot 5H_2O$ 0.7 mole % on hydroperoxide.

medium at -15° (Fig. 5). For the attainment of the necessary reaction rate, the concentration of copper salt must be raised to 0.2-0.4% on the amount of hydroperoxide.

The kinetics of the consumption of the hydroperoxide are almost always closely similar to those of the consumption of dienol, which is in accord with the overall equation:

However, since the products of the oxidation of dienols have fairly high reducing properties in alkaline media, their participation in reactions with metal salts and with the hydroperoxide results in departures from this stoichiometrical relation (Fig. 4). That such departures are likely to occur follows also from the complex character of the reaction, with participation of free radicals in the intermediate stages.

b) Reactions of Cumene Hydroperoxide and Dihydroxymaleic Acid with Iron Salts. In order to determine the kinetics of the oxidation of Fe^{2+} into Fe^{3+} by cumene hydroperoxide, solutions of the hydroperoxide and of Mohr's salt were cooled to 0° and mixed. Test samples were taken immediately and after five minutes, and these were analyzed for unchanged ferrous iron and for the sum of ferric iron and hydroperoxide. For the study of the reduction of Fe^{3+} into Fe^{2+} by dihydroxymaleic acid, equivalent amounts of ferric ammonium alum and

Fig. 3. Kinetics of reaction of ascorbic acid (AA) with cumene hydroperoxide in presence of iron salts in an acid medium (pH 3) at -15° and -35°: 1) no metal salt added (-15° and -35°); 2) Mohr's salt 0.2 mole % on hydroperoxide at -15°; 3) Mohr's salt 0.4 mole % on hydroperoxide at -15°; 4) Mohr's salt 2.0 moles % on hydroperoxide at -35°.

Fig. 4. Kinetics of reaction of ascorbic acid (AA) with cumene hydroperoxide in an alkaline medium (pH 10.5) in presence of iron salts at 0°: 1) no metal salt added; 2) Mohr's salt 0.1 mole % on hydroperoxide; 3) Mohr's salt 0.5 mole % on hydroperoxide; 4) $CuSO_4 \cdot 5H_2O$ 0.5 mole % on hydroperoxide; $CuSO_4 \cdot 5H_2O$ 0.7 mole % on hydroperoxide.

dihydroxymaleic acid were separately dissolved in 0.1 N HCl at 0° and mixed. Test samples were taken immediately and after 5 and 10 minutes, and these were analyzed for unchanged dihydroxymaleic acid and ferric iron. Fig. 6 represents graphically the reactions between cumene hydroperoxide and ferrous salts (Curve 2), between dihydroxymaleic acid and a ferric salt (Curve 3), and between the hydroperoxide and dihydroxymaleic acid (Curve 1).

Comparison of the curves in Fig. 6 shows that oxidation and reduction of iron salts by the hydroperoxide and by dihydroxymaleic acid (Curves 2 and 3) proceed almost instantaneously at 0°. However, direct reaction between the hydroperoxide and dihydroxymaleic acid is very slow. Hence, in this system, ferric salts are considerably more vigorous oxidizing agents than the hydroperoxide. It is known that the reduction of ferric iron by ascorbic acid is instantaneous [1]. It must be stated also that at 0° the ferric salts that are formed have no direct effect on the decomposition of the hydroperoxide; this reaction proceeds at an appreciable rate only above 50°.

c) Mechanism of the Action of the System in the Polymerization Process. The results obtained in our study of the kinetics of individual reactions permit us to arrive at a conclusion about the mechanism of action of the oxidation-reduction system taken as a whole. When the hydroperoxide, dienol, and salt of a metal of variable valence are present simultaneously, the leading role is taken by processes that are very fast, i.e., the alternating reactions of reduction of Fe^{3+} by the dienol and oxidation of Fe^{2+} by the hydroperoxide. In the system consisting of the hydroperoxide, hydroxymaleic (or ascorbic) acid, and an iron salt, a reversible cycle of

Fig. 5. Kinetics of reaction of dihydroxymaleic acid (DMA) with cumene hydroperoxide in an alkaline medium (pH 11) at ~15°: 1) no metal salt added; 2) $CuSO_4 \cdot 5H_2O$ 0.2 mole % on hydroperoxide; 3) $CuSO_4 \cdot 5H_2O$ 0.4 mole % on hydroperoxide; 4) $CuSO_4 \cdot 5H_2O$ 0.8 mole % on hydroperoxide.

transformations arises, the operation of which is ensured by the presence of only traces of the metal salt.

As is well known [2, 3], Process I – the oxidation of ferrous salts by hydroperoxides – can be used effectively for the initiation of free-radical processes.

Fig. 6. Kinetics of reactions in aqueous solutions at 0° in an acid medium: 1) cumene hydroperoxide + dihydroxymaleic acid; 2) cumene hydroperoxide + Fe^{2+}; 3) dihydroxymaleic acid + Fe^{2+}.

Process II – the reduction of ferric iron by dienols in aqueous solution – cannot be used for the initiation of polymerization, which indicates that the reaction is more complex than could be foreseen from the bimolecular scheme

If we take account of the tendency of dienols to form complex compounds with heavy-metal salts, the reaction can be represented as follows, without intermediate free-radical stages:

As one of us and Kropacheva [4] showed, in those cases in which the reducing agent for the ferric salts is a substance that does not form complexes with ferric iron, the reduction of Fe^{3+} to Fe^{3+} can be used for the initiation of polymerization.

A system of dienol and hydroperoxide without iron salts does not initiate polymerization at low temperature in acid media, which is in accord with the absence of interaction between the components of the system. From this it becomes clear that, in the given reversible cycle of transformations, initiation of polymerization can be associated only with Process I, i.e., with reaction between ferrous salts and the hydroperoxide. The role of the dienol in this cycle is merely that of reducing ferric salts to ferrous.

The same oxidation-reduction changes occur when copper salts are used.

In our study of Reaction II we showed experimentally that the reduction of copper salts by dihydroxymaleic and ascorbic acids at 0° proceeds further than the reduction of iron salts (as far as metallic copper). As will be shown below, reaction between the dienol and the hydroperoxide in presence of copper salts can be used effectively for the initiation of polymerization in an alkaline medium.

The views that we have discussed about the mechanism of the action of these systems are in accord with the fact, which we have established, of the impossibility of forming a reversible system based on stannous salts, which are readily oxidized by the hydroperoxide into the stannic form, but cannot be regenerated, under the conditions studied, by reduction with the dienol.

The systems studied are very close to biochemical systems in composition. The establishment of the possibility of the initiation of free-radical processes with the aid of these systems is an indirect confirmation of earlier suggestions by various authors [5] concerning the probable development of biochemical oxidation-reduction processes through a free-radical stage.

Initiation of Polymerization in an Aqueous Emulsion

In aqueous emulsions, one component of the system (the hydroperoxide) is in the hydrocarbon phase, and and the other two (the dienol and the metal salt) are in the aqueous phase. The reaction between the hydroperoxide and the ferrous salt, which proceeds at the interface, determines the general kinetics of the process. In a water-hydrocarbon emulsion reaction is considerably slower than in a homogeneous aqueous medium, and this creates the necessary conditions for the application of the reaction for the initiation of polymerization.

In full accord with our results on the kinetics of reactions between the components in aqueous solutions, a system consisting of the hydroperoxide and the dienol without metal salt does not initiate polymerization below 0°. For example, in presence of the binary system of ascorbic acid and cumene hydroperoxide in an acid medium at -15° (sodium di-tert-butylnaphthalenesulfonate being used as emulsifier), no polymerization occurs. Addition of Mohr's salt in a concentration of 0.02 mole % on the amount of hydroperoxide results in effective initiation of the polymerization process. By varying the concentration of metal salt we may vary the rate of reaction between the components of the system and the related rate of polymerization.

It should be noted that, as might be expected, the system containing ascorbic acid is effective for polymerization in presence of much lower amounts of iron salt than those required in the dihydroxymaleic acid system. For example, the polymerization of butadiene at -15° in presence of the ascorbic acid system proceeds effectively when the concentration of Mohr's salt is 0.02 mole % on the hydroperoxide (50% yield of polymer in 16.5 hours), whereas under the same conditions in presence of the dihydroxymaleic acid system and 0.82 mole % of Mohr's salt a yield of 60% is attained only after 40 hours.

It is an important fact that increase in the content of metal salt above a certain value can lead not to acceleration of the polymerization process, but to retardation and, in certain cases, complete inhibition. The

Fig. 7. Kinetics of the polymerization of butadiene (1 and 2) and of the consumption of ascorbic acid (3 and 4): 1 and 3) Mohr's salt 0.02 mole % on hydroperoxide; 2 and 4) Mohr's salt 0.07 mole % on hydroperoxide.

retardation of polymerization with increase in the iron concentration above a certain limit is associated with rapid consumption of components of the system. Here, probably, lies the source of the inhibiting action, noted by many investigators, of salts of copper and other metals for the initiation of polymerization by peroxides.

The effect of iron concentration on the relation between the kinetics of polymerization and the interaction of the components of the system is seen clearly in Fig. 7, which relates to the polymerization of butadiene in an acid medium.

In presence of 0.02 mole % of Mohr's salt the consumption of the components proceeds in a uniform manner (Curve 1, Fig. 7). This corresponds to a uniform process of polymerization (Curve 3). Increase in the concentration of Mohr's salt to 0.07 mole % affects the kinetics of both processes substantially (Curves 2 and 4). Polymerization, which is very fast at first, then comes almost to a stop (Curve 2), this behavior being associated with the rapid consumption of components of the oxidation-reduction system, as can be seen from Curve 4.

Fig. 8. Kinetics of the polymerization of a mixture of butadiene and styrene in an emulsion (1) and kinetics of the decomposition of dihydroxymaleic acid in its reaction with the hydroperoxide in an aqueous medium (2) as functions of the pH of the medium at 0°.

Fig. 9. Kinetics of the polymerization of a mixture of butadiene and styrene in an alkaline medium in presence of a system containing dihydroxymaleic acid and a copper salt: 1) 5°, $CuSO_4 \cdot 5H_2O$ 0.2 mole % on hydroperoxide; 2) 15°, $CuSO_4 \cdot 5H_2O$ 0.5 mole % on hydroperoxide.

The direct connection between the kinetics of the interaction of the components of the system in aqueous solutions and the kinetics of polymerization in emulsions is shown quite clearly by a study of the effect of the pH of the medium on the polymerization process. As is shown in Fig. 8, the curve for the rate of emulsion polymerization as a function of the pH of the medium has the same character as the curve for the rate of interaction of the components of the system in aqueous solutions and passes through a minimum in the neutral range (Fig. 8).

In an alkaline medium, as would be expected from the kinetics of the interaction of components of the system, emulsion polymerization proceeds most efficiently in presence of very small amounts of copper salts (Fig. 9). Taking this case as our example, we have shown that copper salts, which were previously regarded as inhibitors of polymerization processes, may act in certain concentrations as extremely effective activators for these processes.

EXPERIMENTAL

a) Determination of the Dienols and the Hydroperoxide. Dihydroxymaleic and ascorbic acids were determined by titration with 0.1 N iodine in presence of starch. The applicability of this method was previously checked for media of water and aqueous emulsions. Cumene hydroperoxide was also determined iodometrically. For the determination of the hydroperoxide in dilute aqueous solutions containing 0.1-0.15% of the hydroperoxide, the following analytical procedure was adopted: 2 g of crystalline potassium iodide and 5 ml of 60% sulfuric acid were added to 30-40 ml of the aqueous solution of cumene hydroperoxide. The flask was closed with a ground-in stopper moistened with potassium iodide solution, and the contents were carefully mixed until the potassium iodide had dissolved completely. The mixture was set aside in the dark for one hour, and the iodine liberated was titrated with 0.05 N thiosulfate solution in presence of starch. When cumene hydroperoxide and dihydroxymaleic or ascorbic acid were both present in the solution, the dienol was first determined in a sample by titration with iodine, and then the cumene hydroperoxide was determined. The dienol was thus determined almost quantitatively, and the titration for the hydroperoxide gave 96-97% of the true value.

TABLE 1

Determination of Cumene Hydroperoxide and Dihydroxymaleic Acid when Simultaneously Present in Aqueous Solutions

No.	Amount introduced		Amount found (%)

1	0.0410	—	99.4	—
2	—	0.0400	—	99.5
3	0.0430	0.0400	100.4	96.5
4	0.0430	0.0400	99.5	96.0
5	0.0500	0.0450	100.8	97.3

Table 1 gives the results of analyses of artificial mixtures.

b) Determination of Ferrous and Ferric Salts in Presence of the Hydroperoxide and Dienol. In our study of the oxidation of Fe^{2+} into Fe^{3+} by cumene hydroperoxide, the Fe^{2+} concentration was determined by titration with 0.1 N $K_2Cr_2O_7$ and the sum of the amounts of Fe^{3+} formed and unused hydroperoxide was determined by reaction with HI and subsequent titration with 0.1 N thiosulfate. The results given in Table 2 show that the iodometric method gives adequate accuracy both in the determination of each of the components separately and in the determination of the overall content of hydroperoxide $+Fe^{3+}$

In presence of dihydroxymaleic acid and its decomposition products ferric iron cannot be determined by the usual iodometric method. In a study of the kinetics of the reduction of Fe^{3+} to Fe^{2+} by dihydroxymaleic acid, ferric iron has been determined by titration with 0.1 N $K_4Fe(CN)_6$ [6]. This method enables us to determine ferric iron in presence of dihydroxymaleic acid and gives values of 97-99% of the true value. The content of dihydroxymaleic acid was determined by titration with iodine in 0.1 N HCl. Under these conditions Fe^{2+} is not oxidized by iodine.

TABLE 2

Verification of the Procedure for the Simultaneous Determination of Hydroperoxide and Ferric Iron in Artificial Mixtures

No.	Amount introduced into mixture (g)		Amount found (%)	
	Hydroperoxide	Fe^{+++} (ferric ammonium alum)	Hydroperoxide	Fe^{+++}
1	—	0.0426	—	99.3
2	—	0.0400	—	98.5
3	0.0548	—	99.2	—
4	0.0650	—	100.2	—
5	0.0300	0.0250	100.7	Total content of Fe^{+++} + hydroperoxide
6	0.0300	0.0250	99.5	
7	0.0300	0.0250	100.1	

c) Experimental Procedure. The kinetics of the interaction of the components of the system were studied in aqueous solutions for equimolecular proportions of hydroperoxide and dienol at concentrations of about 0.15%. A solution of the hydroperoxide in water or in aqueous glycerol was introduced into the vessel, which was blown out with nitrogen and cooled to the temperature of the experiment. Dihydroxymaleic or ascorbic acid, dissolved in the minimum amount of water, was then introduced into the vessel, and a test sample was taken for the determination of hydroperoxide and dienol concentrations. When reaction was carried out in presence of a metal salt, this was introduced into the apparatus as an aqueous solution. The experiments were carried out at 0°, -15°, and -35°. The temperature of the thermostat was maintained constant within ± 0.5°.

SUMMARY

1. A study was made of the mechanism of the action of reversible oxidation-reduction systems consisting of an organic hydroperoxide, a dienol, and an iron or copper salt.

2. It was shown that it is possible to use these systems for the initiation of polymerization at low temperatures.

CHLOROMETHYLATION OF TOLUENE

I. N. Nazarov and A. V. Semenovsky

Chloromethylation of toluene has recently attracted attention as a possible basis for the preparation of terephthalic acid, a raw material for the manufacture of the synthetic fiber Terylene. Unlike the chloromethylation of benzene, which has been studied in detail [1], the chloromethylation of toluene has not received adequate attention in the literature, and on the question of the direction of the reaction, i.e., the relative amounts of the isomers formed, the data are very contradictory. Thus, in 1920 in work on chloro- and bromo-methylation with the aid of bishalomethyl ethers, Stephen and others [2] found that the entry of chloro- and bromo-methyl groups into monosubstituted benzenes occurs exclusively in the para-position.

In 1923, Blanc [3], who developed the well known method of chloromethylation with paraform and hydrogen chloride, reported that toluene gives the para-isomer. Later, papers [4-7] appeared which indicate the formation of a mixture of ortho- and para-isomers in the chloromethylation of toluene, but only in one of these [6] was the composition of the mixture of α-chloroxylenes (here obtained both by Stephen's method and by Blanc's method) determined.

The relative amounts of isomers were determined by thermal analysis of the mixture of alcohols obtained by hydrolysis of the mixture of α-chloroxylenes. It was found that the mixture prepared by Stephen's method contained 53.2% of the ortho-isomer, and the mixture prepared by Blanc's method contained 41.7% of the ortho-isomer. Nevertheless, a paper appeared in 1951 [8] which reported that Blanc chloromethylation of toluene gives α-chloro-p-xylene. In 1953 there appeared a report [9] of the formation of a mixture of 64% para-, 34.7% ortho-, and 1.3% meta-isomer by the chloromethylation of toluene in acetic acid. In the same year it was reported [10] that the content of para-isomer can be raised to 80% by chloromethylation in concentrated hydrochloric acid in absence of catalyst. Finally, after we had completed the present investigation, there appeared a paper [11] in which it was shown viscosimetrically that a mixture of α-chloro-o- and α-chloro-p-xylenes is formed in approximately equal proportions in the chloromethylation of toluene.

The present investigation on the chloromethylation of toluene is concerned mainly with orientation. We considered two of the various methods of chloromethylating toluene: 1) the method, already used for benzene, of treatment with paraform and hydrogen chloride in presence of anhydrous zinc chloride in excess of the hydrocarbon as solvent; and 2) treatment with paraform or formaldehyde in concentrated hydrochloric acid in absence of zinc chloride.

As a result of many experiments on the chloromethylation of toluene by the first method we found that the best result (71.5% yield) is attained by carrying out the reaction under the conditions recommended by Lock [12] for the chloromethylation of benzene, but with a smaller amount of catalyst (zinc chloride). Increase in the amount of zinc chloride without change in the other conditions leads to increase in the yield of ditolylmethane (see table).

Addition of anhydrous aluminum chloride to the zinc chloride also results in greater amounts of ditolylmethane and resinous residue. Addition of thionyl chloride results in almost complete absence of α-chloroxylenes and the formation of much ditolylmethane (49.1%) and products of higher molecular weight. A similar result is obtained when zinc chloride is completely replaced by thionyl chloride.

Addition of various amounts of phosphorus trichloride and phosphoric oxide again did not result in increased yield of α-chloroxylenes. Apart from the amount and composition of the catalyst, the temperature of the reaction

TABLE

Amount of $ZnCl_2$ (g) for 200 g of toluene and 15 g (0.5 mole) of paraform	7.5	8.5	10.0	13.0
Amount of ditolylmethane (g)	7.8	9.6	12.5	24.9

mixture and the duration and efficiency of stirring greatly affect the chloromethylation process. Rise in temperature and increase in the duration of reaction resulted in an increase in the amount of by-products formed. Use of carbon tetrachloride instead of toluene as solvent did not lead to increased yield of the desired product. It follows from these considerations that a reduction in the amount of by-products may be expected if the chloromethylation reaction is carried out in absence of zinc chloride and other catalysts that can promote Friedel-Crafts side reactions. We therefore studied the chloromethylation of toluene in concentrated hydrochloric acid, in absence of zinc chloride. When the reaction was carried out under the recommended conditions, i.e., passage of hydrogen chloride for 25 hours through a vigorously stirred mixture of toluene, paraform, and concentrated hydrochloric acid at 55°, the product of the chloromethylation of toluene was obtained in 70.5% yield without an appreciable amount of by-products. It was found that the 25-hour passage of hydrogen chloride is unnecessary for the success of the process, a passage of 1.5-2 hours, for the more rapid depolymerization of the paraform and raising of the hydrochloric acid concentration, being adequate. The yield of chloromethylation product was then 56.4% on the amount of toluene taken and 71.3% on the amount that reacted. In all cases the chloromethylation product was a liquid distilling at 92-94° (21 mm) which could not be resolved by fractionation through a 15-plate column.

The main purpose of the present investigation was the determination of the composition of the mixture of isomeric α-chloroxylenes obtained by the chloromethylation of toluene. The presence of a mixture of isomeric α-chloroxylenes in the product of the chloromethylation of toluene was indicated immediately by various facts. For example, by oxidation of the chloromethylation product with chromic anhydride in acetic acid, only terephthalic acid in a yield of only 41.2% was obtained, for under these conditions chromic anhydride oxidizes the ortho-isomer completely with rupture of the benzene ring. Hydrolysis of the chloromethylation product does not give the crystalline p-methylbenzyl alcohol (m.p. 58-59°), but a liquid mixture of isomeric methylbenzyl alcohols, from which only by freezing could the para-isomer of m.p. 58-59° be isolated (yield about 30%).

The quantitative determination of the proportions of the isomeric α-chloroxylenes in the products of the chloromethylation of toluene was carried out by comparing the amount of terephthalic acid formed by chromic anhydride oxidation of pure p-methylbenzyl alcohol with the amount formed similarly from the mixture of methylbenzyl alcohols obtained by hydrolysis of the chloromethylation product of toluene. Thus, by the oxidation of pure p-methylbenzyl alcohol, terephthalic acid is obtained in 81.2% yield, and in the oxidation under strictly analogous conditions of the mixture of methylbenzyl alcohols obtained by hydrolysis of the chloromethylation product of toluene (or in the oxidation of the actual chloromethylation products), the yield of terephthalic acid is only 39.2%. It follows from these results that chloromethylation of toluene gives a mixture of α-chloroxylenes containing 48.3% of the para-isomer and 51.7% of the ortho-isomer. Isophthalic acid, which corresponds to the meta-isomer, was not detected in any of the experiments.

Similar results were obtained by oxidation of the mixture of methylbenzyl alcohols obtained after freezing out a definite amount of the para-isomer (48.6% of para- and 51.4% of ortho-isomer). These calculations are based on the well known experimental fact—which we have verified—that in oxidation with chromic anhydride only the para- and meta-isomers give the corresponding benzenedicarboxylic acids (terephthalic and isophthalic acids) in good yield (80-85%), whereas the ortho-isomer is completely broken down in this oxidation and does not give phthalic acid. A series of experiments on oxidation with different excesses of chromic anhydride gave agreeing results. Our results are in close accord with results on the mixture of α-chloroxylenes obtained by the physical methods of thermal analysis (53.2% of ortho-isomer) [6] and viscometry (about 50% of ortho-isomer) [11].

With the object of directly determining the ortho-isomer in the chloromethylation products of toluene, the mixture of α-chloroxylenes was oxidized to benzenedicarboxylic acids with dilute nitric acid at 200° [13]. The total yield of dicarboxylic acids was 81%, from which phthalic acid was isolated in 32% yield and terephthalic acid in 49% yield.

Unlike chromic anhydride, dilute nitric acid oxidizes also the ortho-isomer at high temperatures (about 200°), with fairly smooth formation of phthalic acid:

Oxidation of the mixture of α-chloroxylenes with boiling dilute nitric acid gave the corresponding mixture of toluic acids, from which, by crystallization of the calcium salts [14], o- and p-toluic acids were isolated. Oxidation of the resulting mixture of toluic acids with chromic anhydride gave terephthalic acid in an amount corresponding to the content of para-isomer in the original mixture of α-chloroxylenes (about 48%).

The method that we used for establishing the proportions of isomers obtained in the chloromethylation of toluene makes it possible rapidly to obtain results on the composition of the mixture, for, having once made a comparative oxidation with the pure para-isomer, in further work we need only determine the yield of terephthalic acid obtained directly by oxidation of the mixture of α-chloroxylenes. It was thus shown that in the chloromethylation of toluene by paraform or formaldehyde in a medium of concentrated hydrochloric acid, and also in presence of a catalyst, the same mixture of α-chloroxylenes – 48% of para- and 52% of ortho-isomer – is always obtained. An attempt was made to alter the proportions of the isomers in favor of the para-isomer. With this object toluene was chloromethylated in presence of other catalysts, such as $AlCl_3$, $SnCl_4$, $SiCl_4$, H_2SO_4. It was found that replacement of zinc chloride in this way does not affect the relative amounts of isomers to any practical extent, while at the same time it lowers the yield of α-chloroxylenes (to about 40% for $SnCl_4$ and $SiCl_4$, and still lower in the other cases). This result agrees with conclusions arrived at in a recent paper [11].

EXPERIMENTAL

Chloromethylation of Toluene in presence of Zinc Chloride in Excess of the Hydrocarbon

A mixture of 200 g of toluene, 15 g (0.5 mole) of paraform, and 8.5 g of anhydrous zinc chloride was prepared in a three-necked flask fitted with reflux condenser, thermometer, tube for passage of gas, and an efficient stirrer. A rapid stream of hydrogen chloride was passed for 20 minutes through the vigorously stirred mixture; the reaction temperature rose to 50°. After the passage of hydrogen chloride, the mixture was stirred for one hour at 50°. The toluene layer was then washed carefully: first with water, then with sodium bicarbonate solution, and again with water. The solution was dried with calcium chloride, and toluene was distilled off. The mixture of α-chloro-o- and α-chloro-p-xylenes, amounting to 50 g (71.5%), boiled at 78-80° (10 mm). In addition, 9.6 g of ditolylmethanes, b.p. 140-145° (7 mm), was obtained.

Chloromethylation of Toluene in Concentrated Hydrochloric Acid in absence of Zinc Chloride

Hydrogen chloride was passed for 25 hours into a vigorously stirred mixture of 138 g of toluene, 58.5 g of paraform, and 180 ml of concentrated hydrochloric acid at 55°. The organic layer was carefully washed with water and sodium bicarbonate solution, and was dried over calcium chloride. Fractionation gave a little unchanged toluene and 148.7 g of a mixture of α-chloro-o- and α-chloro-p-xylenes, b.p. 96-97° (26 mm). The yield was 70.5% on the amount of toluene that reacted.

Hydrolysis of a Mixture of α-Chloro-o- and α-Chloro-p-xylenes

The above-described mixture of α-chloroxylenes (30 g), water (100 ml), and chalk (15 g) were introduced into a three-necked flask fitted with reflux condenser and stirrer. The contents of the flask were stirred vigorously and boiled for 25 hours. The resulting mixture of methylbenzyl alcohols was extracted with dichloroethane and dried over potassium carbonate. Vacuum distillation of the product gave 19.7 g (77%) of a mixture of o- and p-methylbenzyl alcohols, b.p. 120-122°(24 mm). By repeated freezing, 5.4 g of pure p-methylbenzyl alcohol was isolated from this mixture; after being recrystallized from water it melted at 58-59°.

When the α-chloroxylenes were hydrolyzed with sodium or potassium carbonate, a fraction of b.p. 170-173° (5 mm) was obtained. From this bis(p-methylbenzyl) ether, m.p. 58-60° [15], was isolated.

Oxidation of α-Chloroxylenes and Methylbenzyl Alcohols with Chromic Anhydride

a) A mixture of 4.1 g of the above-described mixture of α-chloro-o- and α-chloro-p-xylenes, 30 g of chromic anhydride, 90 ml of water, 90 ml of acetic acid, and 30 ml of sulfuric acid was refluxed until exothermic oxidation set in. When spontaneous heating ceased, the reaction mixture was boiled further for one hour. After cooling, filtration, and drying of the crystals that separated, 2 g (41%) of terephthalic acid was obtained; its dimethyl ester melted at 141-142°, and in admixture with a known sample there was no depression of melting point.

Other oxidation experiments were carried out under strictly identical conditions, and the following results were obtained:

b) By oxidation of 3.56 g of pure p-methylbenzyl alcohol, m.p. 58-59°, 3.93 g (81.2%) of terephthalic acid was obtained.

c) By oxidation of 3.56 g of the mixture of methylbenzyl alcohols corresponding to the original mixture of α-chloroxylenes, 1.90 g (39.2%) of terephthalic acid was obtained.

d) By oxidation of 3.56 g of the mixture of methylbenzyl alcohols remaining after the pure para-isomer had been frozen out, 1.11 g (22.9%) of terephthalic acid was obtained.

e) By oxidation of 3.97 g of the mixture of toluic acids obtained by oxidation of the original mixture of α-chloroxylenes with dilute nitric acid (see below), 1.90 g (39.2%) of terephthalic acid was obtained.

In all these experiments the terephthalic acid obtained was identified by its dimethyl ester, m.p. 141-142°, undepressed by admixture of a known sample.

Esterification of Terephthalic Acid

A mixture of 1 g of terephthalic acid, 15 ml of methanol, and 1.5 g of concentrated sulfuric acid was refluxed for ten hours. The crystals that precipitated on cooling were filtered off and recrystallized from methanol. The product, amounting to 1 g (91%), was dimethyl terephthalate, m.p. 141-142°, undepressed by admixture of a known sample.

Oxidation of the Mixture of α-Chloroxylenes with Dilute Nitric Acid at 200°

A mixture of 3.5 g of the α-chloroxylene mixture and 84 ml of 10% nitric acid was introduced into a 200-ml rotating autoclave. Agitation was continued for 90 minutes at 200°. The autoclave was cooled, and 2.02 g of water-insoluble terephthalic acid was isolated and identified as its dimethyl ester, m.p. 141-142°. Evaporation of the mother liquor and recrystallization of the residue from 5% hydrochloric acid gave 1.3 g of phthalic acid, the anilide of which melted at 209-210° and showed no depression of melting point in admixture with a known sample. The total yield of acids was 3.32 g (81%).

Oxidation of the Mixture of α-Chloroxylenes to Toluic Acids

The mixture of α-chloroxylenes (50 g) was refluxed with 1700 ml of 5% nitric acid for 50 hours. The crystals of toluic acids which precipitated on cooling were filtered off, recrystallized from water, and dried in a desiccator. The yield was 37.1 g (76.6%).

The mixture of toluic acids was separated with the aid of their calcium salts, which were obtained by the action of calcium hydroxide. When boiled with water, the calcium salt of o-toluic acid passed into solution and the calcium salt of p-toluic acid remained and was filtered off. The filtrate was evaporated to dryness and the residue was crystallized twice from alcohol, thus giving the calcium salt of o-toluic acid. The calcium salts obtained were treated with dilute hydrochloric acid, and the free toluic acids were recrystallized from water and dried in a vacuum desiccator. In this way, from 5 g of the above-described mixture of toluic acids, 0.5 g of pure o-toluic acid, m.p. 102-103°, and 0.9 g of p-toluic acid, m.p. 179-180°, were isolated. Neither showed depression of melting point in admixture with a known sample.

SUMMARY

The chloromethylation of toluene was investigated in detail, and it was shown by the oxidation method that the reaction gives a mixture of α-chloro-o-xylene and α-chloro-p-xylene in almost equal proportions. The relative amounts of these products are almost independent of reaction conditions (catalyst, temperature, solvent, etc.).

SYNTHESIS AND REACTIONS OF OXYGEN-CONTAINING ORGANOSILICON COMPOUNDS

COMMUNICATION 3. SYNTHESIS AND SOME REACTIONS OF VINYL ETHERS OF 3-(TRIMETHYLSILYL)- AND 3-(DIETHYLMETHYLSILYL)-1-PROPANOL

M. F. Shostakovsky, I. A. Shikhiev, and N. V. Komarov

Vinyl ethers of organic [1] and organosilicon [2] alcohols are of great theoretical and practical interest at the present time. In previous investigations we synthesized 3-(trimethylsilyl)-1-propanol [2] and carried out some of its reactions [3]. We showed also that reaction of vinyl ethers with silanols [4] and organosilicon alcohols [5] gave the corresponding organosilicon acetals, whereas reaction with organic acids [1] gave partial acylals.

With the object of studying the reactivities and proving the structures of the vinyl ethers of organosilicon alcohols that we have prepared, in the present investigation we have converted them into organosilicon acetals and acylals and made a comparative study of the properties of these derivatives. The reactions proceeded as follows:

in which R = CH_3; C_2H_5; C_3H_7-i

The structure of one of the acetals (IV) was proved by its synthesis by two different methods:

It should be noted that the chemistry and reactivities of organosilicon acetals have not been discussed in the literature, and there is no information at all about organosilicon acylals. We consider that the mechanism of the formation of organosilicon acetals and acylals from vinyl ethers of organosilicon alcohols and organic alcohols and acids is analogous to that of the formation of the corresponding organic acetals and acylals [1] and can be represented as follows:

The organosilicon acetals and acylals that we obtained are pleasant-smelling colorless liquids, insoluble in water and more stable than their organic analogs. As is well known [6], organic acetals are readily hydrolyzed in presence of traces of mineral acid, but hydrolysis of the corresponding organosilicon acetals proceeds only to the extent of 5-12% under these conditions. Organosilicon acylals are also more stable and more difficultly hydrolyzable by mineral acids than their organic analogs; more severe conditions are necessary for the complete hydrolysis of organosilicon acetals and acylals.

EXPERIMENTAL

1. Synthesis of 3-(Diethylmethylsilyl)-1-propanol

With cooling and vigorous stirring, 126 g (2.85 moles) of dry ethylene oxide was added to the Grignard reagent prepared from 34.5 g (1.42 moles) of magnesium and 213.5 g of (chloromethyl)diethylmethylsilane, b.p. 155° (752 mm) and n_D^{20} 1.4405. The reaction temperature was maintained below 9°. When addition was complete, the reaction mixture was stirred further for 2.5 hours and then set aside overnight. On the next day the mixture was heated for eight hours at 35°, and the complex was then decomposed, first with moist ether, and then with 10% hydrochloric acid. The ether layer was separated, and the aqueous layer was extracted twice with ether. The ether layer and the extracts were washed with 1% aqueous sodium carbonate and with water, dried over calcined potassium carbonate, and distilled. Two distillations gave 97.2 g of a substance having b.p. 98° (10 mm); n_D^{20} 1.4452; d_4^{20} 0.8489; found MR 50.28; calc. for $C_9H_{20}SiO$ MR 50.35; found M 169.0; 164.8; calculated M 160.3.

Found %: C 60.24; 60.18; H 12.52; 12.74; Si 18.29 $C_9H_{20}SiO$. Calculated %: C 59.94; H 12.57; Si 17.5

These results correspond to 3-(diethylmethylsilyl)-1-propanol. The average yield in a series of experiments was 42%.

2. Synthesis of the Vinyl Ether of 3-(Diethylmethylsilyl)-1-propanol

A 500-ml rotating steel autoclave was loaded with 3-(diethylmethylsilyl)-1-propanol (55 g) and 7.5% potassium ethoxide solution (1.054 g of potassium). The air in the autoclave was displaced by acetylene, and the autoclave was then filled with acetylene at a pressure of 18 atm and was heated for five hours at 170-180°. The autoclave was cooled to room temperature, and a second portion of acetylene was introduced, this operation being repeated until acetylene ceased to be absorbed. The contents of the autoclave—64.5 g of a dark-brown liquid of pleasant ethereal odor—were transferred to a Favorsky flask, distilled under reduced pressure, and treated with sodium to remove unchanged alcohol. Fractionation of the product gave the following fractions:

Fraction I. b.p. 75-83° (9 mm); 4.8 g; n_D^{20} 1.4385

Fraction II. b.p. 83-85° (9 mm); 28.3 g; n_D^{20} 1.4415

Fraction III. b.p. 85-88° (9 mm); 14.7 g; n_D^{20} 1.4420

Residue in still 2.1 g

Fractions II and III were combined, treated with sodium, and distilled. The product amounted to 41.5 g and had b.p. 82-83° (8 mm); n_D^{20} 1.4415; d_4^{20} 0.8326; found MR 59.80; calc. for $C_{10}H_{22}SiO$ MR 59.36.

Found %: C 64.05; 64.20; H 12.11; 11.95; Si 15.80; 15.98 $C_{10}H_{22}SiO$. Calculated %: C 64.45; H 11.00 Si 15.06

These results correspond to the vinyl ether of 3-(diethylmethylsilyl)-1-propanol. The average yield in a series of experiments was 68%. This substance is a colorless mobile liquid of very pleasant odor, insoluble in water, but readily soluble in organic solvents. It decolorizes bromine water, readily polymerizes in presence of traces of 5% ferric chloride solution, and gives other reactions characteristic of vinyl ethers, which are being studied.

3. Hydrolysis of the Vinyl Ether of 3-(Diethylmethylsilyl)-1-propanol

A weighed sample of the ether and 20 ml of 2% H_2SO_4 were sealed in 150-ml tube and heated in a boiling water bath for six hours. When cool, the contents were transferred quantitatively to a 200-ml measuring flask and made up to volume with distilled water. The contents of the flask were well mixed, and the acetaldehyde content was determined [6]: 15 ml of 0.1 N bisulfite solution was added to 50 ml of the solution under test, the mixture was well stirred, and after 15 minutes the excess of bisulfite was titrated with 0.1 N iodine.

Triplicate results for the content of the vinyl ether of 3-(diethylmethylsilyl)-1-propanol in our preparation were 96.21%, 95.80%, and 95.85%.

4. Synthesis of Acetaldehyde 3-(Diethylmethylsilyl)propyl 3-(Trimethylsilyl)propyl Acetal

Concentrated hydrochloric acid (0.02 ml) was added to a vigorously stirred mixture of 7.45 g (0.04 mole) of the vinyl ether of 3-(diethylmethylsilyl)-1-propanol (b.p. 82-83° (8 mm); n_D^{20} 1.4415) and 5.28 g (0.04 mole) of 3-(trimethylsilyl)-1-propanol (b.p. 79-80° (24 mm); n_D^{20} 1.4296) at 18°. The temperature of the reaction mixture rose to 53°, and the mixture was then heated at 65° for 30 minutes. It was set aside overnight, and was then neutralized with potassium carbonate and fractionated:

Fraction I. b.p. 50-100° (2 mm); n_D^{20} 1.4401; 1.1 g

Fraction II. b.p. 101-131° (2 mm); n_D^{20} 1.4418; 2.4 g

Fraction III. b.p. 132-133° (2 mm); n_D^{20} 1.4429; 7.36 g

Residue in still, b.p. 133° (2 mm); 1.5 g

Redistillation of Fractions II and III gave 8.65 g (69%) of a substance of b.p. 131-132° (2 mm); n_D^{20} 1.4428; d_4^{20} 0.8582; found MR 98.39; calc. for $C_{16}H_{36}Si_2O_2$ MR 99.01.

Found %: C 59.93; 59.87; H 11.93; 12.04; Si 17.37; 17.00 $C_{16}H_{36}Si_2O_2$. Calculated %: C 60.30; H 12.02; Si 17.63

These results correspond to acetaldehyde 3-(diethylmethylsilyl)propyl 3-(trimethylsilyl)propyl acetal.

5. Synthesis of Acetaldehyde 3-(Diethylmethylsilyl)propyl 3-(trimethylsilyl)propyl Acetal

Reaction under similar conditions between 6.32 g (0.04 mole) of the vinyl ether of 3-(trimethylsilyl)-1-propanol (b.p. 61° (18 mm); n_D^{20} 1.4265) and 6.40 g (0.04 mole) of 3-(diethylmethylsilyl)-1-propanol (b.p. 98-99° (10 mm); n_D^{20} 1.4430) gave 7.95 g (62.5%) of a substance having b.p. 140-141° (3 mm); n_D^{20} 1.4425; d_4^{20} 0.8589; found MR 98.26; calc. for $C_{16}H_{36}Si_2O_2$ MR 99.01. In physicochemical constants this substance is identical with the 3-(diethylmethylsilyl)propyl 3-(trimethylsilyl)propyl acetal obtained in the previous experiment by another route.

The other organisilicon acetals (Tables 1 and 2) were prepared under similar conditions by the same procedure.

6. Synthesis of Acetic Ester of 1-[3-(Trimethylsilyl)propoxy]ethanol

A mixture of 4.95 g (0.03 mole) of the vinyl ether of 3-(trimethylsilyl)-1-propanol (b.p. 61° (18 mm); n_D^{20} 1.4265) and 1.8 g (0.03 mole) of glacial acetic acid was prepared in a three-necked 25-ml flask fitted with thermometer, mercury-sealed stirrer, and reflux condenser. The mixture was stirred for three hours at room temperature and no signs of reaction were observed. It was then heated at 65° for 30 hours (until the sharp odor of acetic acid disappeared). Vacuum distillation then gave the following fractions:

Fraction I. b.p. 25-95° (13 mm); n_D^{20} 1. 3820; 0.7 g

Fraction II. b.p. 96-101° (13 mm); n_D^{20} 1.4212; 0.8 g

Fraction III. b.p. 102-104° (13 mm); n_D^{20} 1.4219; 3.5 g

Residue in still, b.p. 104° (13 mm); n_D^{20} 1.4335; 1.4 g

Fraction I was not investigated. Redistillation of Fractions II and III gave 3.9 g (59.5%) of a substance having b.p. 92-93° (8 mm); n_D^{20} 1.4218; d_4^{20} 0.9027; found MR 61.44; calc. for $C_{10}H_{22}SiO_3$ MR 61.60.

Found %: C 55.36; 55.27; H 10.35; 10.34; Si 12.61; 12.84 $C_{10}H_{22}SiO_3$. Calculated %: C 54.97; H 10.11; Si 12.85

* Described in a previous communication [3].

These results correspond to the acetic ester of 1-[3-(trimethylsilyl)propoxy]ethanol.

Two other organosilicon partial acylals were prepared similarly; their physicochemical constants are given in Table 1. The extent of the hydrolysis of acetals and acylals by 2% sulfuric acid under various conditions was determined by the bisulfite method [6], and the results are given in Table 2.

SUMMARY

1. The vinyl ether of 3-(diethylmethylsilyl)-1-propanol was synthesized by a modification of the Favorsky-Shostakovsky method.

2. A study was made of the reactions of the vinyl ethers of 3-(trimethylsilyl)- and 3-(diethylmethylsilyl)-1-propanol with water, organic and organosilicon alcohols, and organic acids.

3. 3-(Diethylmethylsilyl)-1-propanol, its vinyl ether, four organosilicon acetals, and three acylals were prepared for the first time.

4. It was shown that, under similar conditions, the vinyl ether of 3-(diethylmethylsilyl)-1-propanol and organosilicon acetals and acylals are hydrolyzed with greater difficulty than their organic analogs.

BRIEF COMMUNICATIONS

KINETICS AND CHEMISTRY OF THE POLYCONDENSATION ESTERS OF α-AMINO ACIDS

COMMUNICATION 4. COPOLYCONDENSATION OF GLYCINE ETHYL ESTER AND N-CARBOXYGLYCINE ANHYDRIDE

K.T. Poroshin, T.D. Kozarenko and Yu.I. Khurgin

The condensation of anhydrides of α-(carboxyamino) acids with esters of amino acids was applied by Wessely and Sigmund [1] and Bailey [2] in the preparation of di- and tri-peptides. The lowness of the yield of peptides of the required structure and the formation of by-products (piperazinediones and higher peptides) considerably limited the extension of this method.

In our investigation we have carried out the copolycondensation of glycine ethyl ester and N-carboxyglycine anhydride, in which we expected that a process of mutual initiation would occur. The primary process (1) is initiation of the breakdown of the anhydride of the α-(carboxyamino) acid by the amino group of the corresponding amino acid. The formation of a peptide chain by reaction of the anhydride of the carboxyamino acid is accompanied by liberation of carbon dioxide, which acts as an initiator for the polycondensation of the ester of the amino acid (2). Process 2 is accompanied by liberation of alcohol, which forms a second initiator for the polycondensation of the anhydride of N-carboxyglycine (3). Copolymerization is characterized by increase in the concentration of initiators and can therefore be regarded as an autocatalytic process. The scheme of mutual initiation can be represented as follows:

We investigated the chemical compositions of copolycondensation products obtained under identical conditions of temperature (40° for four hours) with different relative concentrations of glycine ethyl ester and N-carboxyglycine anhydride, which will be expressed as ratios of molar concentrations of anhydride and ester (A/E). Chromatographic investigation of the copolycondensation products showed that peptide esters were formed in the course of the reaction, but no free peptides were detected, which suggests that the peptide chain grows at the amino end.

EXPERIMENTAL

The copolycondensation of glycine ethyl ester and N-carboxyglycine anhydride was carried out both in the mass — by dissolving the appropriate proportion of one monomer in the other — and also in dry dioxane solution. For reaction in the mass the reaction vessel was kept in a thermostat at 40 ± 0.1° for four hours, and for copolycondensation in solution reaction was for 12 hours at the same temperature.

Mass copolycondensation was carried out for values of A/E of 0.02, 0.04, 0.067, 0.08, 0.168 and 0.233, and

Chromatographic separation on paper of products of the copolycondensation of glycine ethyl ester and N-carboxyglycine anhydride in the system butyl alcohol + acetic acid + water (4 : 1 : 5) after threefold development: 1) mixture of glycine and the di-, tri-, tetra-, penta- and hexa-peptides of the glycine series; 2) product of the copolycondensation of glycine ethyl ester and N-carboxyglycine anhydride (A/E 0.08; 40°; 4 hours); 3) product of the polycondensation of glycine ethyl ester in presence of CO_2 [3] (CO_2/E 0.08; 40°; 4 hours).

for solution copolymerization the ratios were 0.1, 0.25, 0.45, 0.66, 1.0, 1.5, 2.0, 3.0 and 9.0.

At the end of reaction in the mass, the reaction mixture was cooled, and the solid part was ground with dry ether, filtered off, and again washed with ether.

The reaction products from the solution-copolymerization reaction were freed from dioxane at 40° under low pressure and then treated as in the first case.

The combined filtrate was analyzed for the content of unchanged glycine ethyl ester by the method desctibed previously [3]. The same filtrate was tested for N-carboxyglycine anhydride by the method of Berger, Sela and Katchalski [4]. Chromatographic investigation of the ethereal filtrate showed that it contained glycine ethyl ester and traces of glycylglycine ethyl ester. In no case was N-carboxyglycine anhydride detected. The polymer, which contained peptide ethers of various chain lengths, was investigated by the method of differential titration developed previously [5] for the contents of triglycine esters, the "tetrapeptide" fraction, and 2,5-piperazinedione [6]. The mass-copolycondensation products were investigated by partition chromatography on paper. The chromatograms were formed in the systems butyl alcohol + acetic acid + water (4 : 1 : 5) and phenol + water (4 : 1) on chromatographic paper supplied by the Leningrad factory Goznak.

In the first sytem the peptide esters can be readily separated. Free peptides and glycine have low R_F values and are not separated in this system. No peptides or glycine were detected in the condensation products. A chromatogram was taken also by Keil's method [7], and in this also no free peptides were detected. The chromatograms were color-developed by Rydon and Smith's method [8], the chlorinated chromatograms being treated in a solution of o-tolidine and KI [9] (see figure).

Investigation of the polymers obtained showed that they did not contain N-carboxyglycine anhydride. The content of tripeptide esters varied from 10.2% to 33.6%. The content of tetrapeptide and higher peptide esters varied from 20.10% to 48.35%. Piperazinediones were present in the polymers in amounts depending on A/E and varying from 16.10% down to scarcely detectable amounts.

SUMMARY

1. Copolycondensation of N-carboxyglycine anhydride and glycine ethyl ester was carried out in the mass and in solution for various relative amounts of monomers. The chemical compositions of the products were studied.

2. Copolycondensation proceeds under conditions of mutual initiation. No N-carboxyglycine or free peptides were detected in the copolycondensation products, but peptide esters and various amounts of piperazinediones were present.

3. It is suggested that the peptide chain grows from the amino end.

EFFECT OF PYRIDINE ON THE RATE AND SELECTIVITY OF THE HYDROGENATION OF DIPHENYLACETYLENE AND CYCLOPENTADIENE OVER RANEY NICKEL AND PLATINUM BLACK

L.Kh. Freidlin and B.D. Polkovnikov

It is known that pyridine acts not only as a catalyst poison in hydrogenation, but effects also the selectivity of the catalyst [1-3]. Thus, in pyridine solution in presence of palladium, triple bonds are hydrogenated only as far as the double-bond stage, whereas in alcohol and dioxane, reaction proceeds to the single-bond stage [4, 5].

It was considered to be of interest to study the effect of pyridine on the activity and selectivity of another catalyst for low-temperature hydrogenation – Raney nickel. With this object, in the present investigation we made comparative measurements of the rates of hydrogenation of diphenylacetylene and cyclopentadiene over Raney nickel in 96% ethanol and the same solvent with addition of 10% of pyridine, in cyclohexane and the same solvent with addition of 10% of pyridine, and in pyridine alone. Reaction was carried out in the liquid phase in a hydrogenation flask at 25° and atmospheric pressure. The experimental conditions, which are given in the table, ensured that reaction occurred in the kinetic region. The catalyst was prepared by leaching a 50% Ni-Al alloy with 20% sodium hydroxide for two hours at 100°. Electrolytic hydrogen was used.

Fig. 1. Hydrogenation of cyclopentadiene (3-9) and diphenylacetylene (1-2) over Raney nickel (1-7) and platinum black (8-9): 1, 4, 9) in ethanol; 2, 7, 8) in ethanol + 10% of pyridine; 3) in pyridine; 5) in cyclohexane; 6) in cyclohexane + 10% of pyridine.

TABLE

Effect of Pyridine on the Rate and Selectivity of the Hydrogenation of Diphenylacetylene and Cyclopentadiene in Presence of Raney Nickel and Platinum Black. Experimental Conditions: weight of nickel 0.4 g; volume of solvent 10 ml; rate of agitation 900 shakes per minute; length of sweep 127 cm

No.	Substance hydrogenated	Weight of substance (g)	Solvent	Consumption of hydrogen (ml)		Duration of reaction (minutes)	
				theoretical	actual	total	half-period
1	Diphenylacetylene	0.1700	Ethyl alcohol	48.6	47.8	7	1.1
2	Diphenylacetylene	0.2000	Alcohol-pyridine	57.6	28.5	19	19
3	Cyclopentadiene	0.1266	Pyridine	97.6	49.1	19	19

*In presence of platinum black.

First, hydrogenation of the triple bond of diphenylacetylene was studied. The results are given in the table and in Figure 1. Comparison of the kinetic curves 1 and 2 shows that addition of 10% of pyridine to alcohol or cyclohexane causes a great reduction in the rate of hydrogenation. Also, the volume of hydrogen consumed (28.5 ml) corresponds to hydrogenation of diphenylacetylene to stilbene (Experiment 2). Hence, in presence of pyridine Raney nickel loses the ability to hydrogenate an isolated C = C bond.

No one has studied the effect of pyridine on the rate and selectivity of the hydrogenation of conjugated double bonds. We recently showed that the conjugated double bonds of cyclopentadiene are hydrogenated successively over Raney nickel. It was natural to expect that, in presence of pyridine, cyclopentadiene would be selectively hydrogenated to cyclopentene in presence of nickel.

Figure 1 shows that the rate of addition of hydrogen in pyridine (Curve 3) is considerably lower than in alcohol (Curve 4) or in cyclohexane (Curve 5). The consumption of hydrogen by the sample of cyclopentadiene (0.002 mole) was 49.1 ml (Experiment 3), which corresponds to hydrogenation to cyclopentene. Further absorption of hydrogen was not observed even after addition of 5 ml of alcohol to the solution. In the mixed solvent cyclohexane-pyridine (Curve 6) the rate of hydrogenation of cyclopentadiene was still less than in pyridine. With addition of 5 ml of alcohol the reaction rate increased greatly, and on Curve 6 a sharp maximum appears. However, in this experiment also, cyclopentadiene was hydrogenated only as far as cyclopentene (Experiment 6). Analogous selectivity was observed in the hydrogenation of cyclopentadiene in the mixed solvent alcohol-pyridine (Curve 7, Experiment 5).

It might be expected that, over Raney nickel in presence of pyridine, a binary mixture of diphenylacetylene

Fig. 2. Hydrogenation of mixtures of cyclopentadiene and diphenylacetylene: 1) in alcohol + 10% pyridine; 2) in cyclohexane + 10% pyridine; 3) in alcohol; 4) in cyclohexane.

and cyclopentadiene would also be hydrogenated selectively, i.e., to a mixture of stilbene and cyclopentene. Judging from the consumption of hydrogen, this expectation is fully realized. The kinetic curves for the hydrogenation of binary mixtures are given in Figure 2. It will be seen that, in the mixed solvents alcohol-pyridine (Curve 1) and cyclohexane-pyridine (Curve 2), the rate of reaction is considerably lower than in alcohol (Curve 3) or in cyclohexane (Curve 4). The consumption of hydrogen in absence of pyridine (Experiments 8 and 10) is twice as great as in presence of pyridine (Experiments 9 and 11).

Over platinum black (0.046 g) the rate of hydrogenation of cyclopentadiene in the mixed solvent alcohol-pyridine (Curve 8, Figure 1) was again much lower than in alcohol (Curve 9, Figure 1). However, the consumption of hydrogen (96.5 ml) corresponded to exhaustive hydrogenation of cyclopentadiene to cyclopentane (Experiment 12).

SUMMARY

1. An investigation was made of the effect of pyridine on the rate and selectivity of the hydrogenation of diphenylacetylene and cyclopentadiene in presence of Raney nickel and platinum black.

2. It was found that, over Raney nickel in presence of pyridine, selective hydrogenation occurs: diphenylacetylene to stilbene and cyclopentadiene to cyclopentene.

This specificity of the poisoned catalyst may be used for the purpose of purifying industrial olefin fractions from diene and acetylene hydrocarbons, and also for the purpose of determining the contents of the latter in ethylenic hydrocarbons.

3. Unlike Raney nickel, platinum black promotes the hydrogenation of both double bonds of cyclopentadiene in presence of pyridine.

DETERMINATION OF SPECIFIC SURFACES OF THE COMPONENTS OF MIXED $MgO-Cr_2O_3$ CATALYSTS

A.M. Rubinshtein, V.A. Afanasyev and N.A. Pribytkova

It is generally known that most heterogeneous catalysts, particularly those of practical importance, are mixed catalysts, which include metals on inert or active carriers and various mixtures of oxides and other compounds. It has long been established that between activity and surface area there exists a relationship, which for some simple reactions over single-component catalysts is one of direct proportionality [1]. The specific surface has therefore become one of the most important characteristics of catalysts. Methods of determining specific surface from the adsorption isotherms of inert gases or organic vapors have been fairly fully developed. These methods, however, being based on physical adsorption, give the total surface of simple or mixed catalysts, whereas for mixed catalysts it is particularly important and interesting to know what fraction of the surface is contributed by each of the components.

To solve this problem the physical adsorption method must be combined with the measurement of specific chemisorption. This method of determining the specific surfaces of the components of binary catalysts has been applied in very few cases and, with one exception, only for metal-carrier systems, the total surface being most frequently determined from low-temperature adsorption of nitrogen, and the metal surface from data on the chemisorption of hydrogen (Pt) or of CO (Ni, Co, Fe). We are here referring to the determination of the surface of Pt in platinized charcoal [2-4], Co on kieselguhr [5], Ni on alumina [6], Pt on barium sulfate [7] and on silica [8], and Fe in the promoted catalyst for ammonia synthesis [9]. The above-mentioned exception, in which the surface occupied by an oxide was measured, is the determination of the distribution of the promoter (K_2O) in the iron catalyst for ammonia synthesis by measuring the physical adsorption and chemisorption of CO_2 [10]. These examples cover all the information in the literature of catalysis on the separate determination of the surfaces of the components of mixed catalysts.

These results enable us to conclude that the determination of the specific surface of reduced metal in a mixed catalyst by the method discussed does not present any substantial difficulties. This, however, cannot be said of oxide mixtures – not only the more complex ones, but even binary mixtures. Not a single example of such systems has been treated in the literature, but this is not because the problems are not of interest, but because it is extremely difficult to find a substance which, under some conditions or other, will be chemisorbed by only one of the components of a mixed catalyst. In our investigation, however, we have been able to find such a substance.

EXPERIMENTAL

By determining the specific surfaces of catalysts from adsorption isotherms of benzene vapor in a flow system at ordinary pressure [11] and comparing the results for binary catalysts based on magnesia with specific surfaces determined from the chemisorption of iodine from carbon tetrachloride solution [12], we found the system $MgO-Cr_2O_3$, in which only one component (MgO) chemisorbs iodine. We then carried out experiments on the separate determination of the specific surfaces of the components of this catalyst, and we prepared a series of catalysts with varying contents of the components. Some of these were prepared by coprecipitation with 10% ammonia from mixed solutions of magnesium and chromium nitrates at room temperature. The precipitate was washed, molded, dried at 110-120°, and calcined in the air at 425° for six hours for the conversion of hydroxides into oxides. Pure MgO and Cr_2O_3 were prepared similarly. Three catalysts were prepared by impregnating

TABLE

Catalyst	Composition (mole %)		S	S_I	S_{MgO}	$S_{Cr_2O_3}$	Method of preparation
	Cr_2O_3	MgO	(sq. m/g)

molded MgO with various amounts of chromium nitrate solution and then heating to effect thermal decomposition.

We described the procedure for determining specific surface by adsorption of benzene vapor in a flow system in a previous paper [11]. The determination of surface from the chemisorption of iodine by MgO catalysts [12] was carried out as follows. About one gram of catalyst was weighed accurately and transferred to a 200-ml flask with a ground stopper; 25 ml of 0.1 N iodine in CCl_4 was added, and the mixture was allowed to stand for 2.5 hours in the dark. The clear liquid, not containing any suspended particles of catalyst, was poured off carefully, and 10 ml was transferred to a flask; 15 ml of alcoholic KI (2 g of KI in 300 ml of C_2H_5OH and 84 ml of H_2O) was added, and the mixture was titrated with 1.0 N thiosulfate; no indicator was necessary. A control experiment was carried out with iodine solution without catalyst. The determination was repeated on several test samples of the same catalyst. The value of the specific surface, which is equal to the iodine value [12], was calculated from the formula:

$$S_I = \frac{a \cdot 2.5 \cdot T_{Na_2S_2O_3}}{A},$$

in which a is the difference between the volumes of thiosulfate solution required in the working and control titrations, $T_{Na_2S_2O_3}$ is the titer of the thiosulfate solution, and A is the weight of catalyst (g). Comparison of the values obtained by this method with those obtained from nitrogen adsorption isotherms [12] and from benzene vapor adsorption isotherms [11] showed close agreement of results.

By way of example we show the adsorption isotherms for benzene vapor on Catalysts 2 and 4 (see figure). The table gives the compositions and methods of preparation of the catalysts, the specific surfaces found by chemisorption of iodine (S_I) and from adsorption isotherms of benzene vapor (S), and also the specific surface contributed by each of the components of the catalyst (S with the appropriate subscript). These data show that Cr_2O_3, for which S = 32 sq. m/g, does not chemisorb iodine to an appreciable extent, so that its surface is not determined by the iodine method. On the basis of this observation we may suppose that adsorption of iodine under the given conditions makes it possible to determine the specific surface of magnesia, and $S - S_I$ will give the specific surface of Cr_2O_3 in the catalyst. As will be seen from the table, for all the mixed catalysts S_I is indeed less than S, and with increase of the proportion of Cr_2O_3 in the mixture it falls continuously, both in the impregnated and in the coprecipitated catalysts.

For the correct appraisal of the results it is important to note that they cannot depend on the character of the porosity since the area occupied by an iodine molecule on the catalyst surface (21 A^2 [12]) is less than the area occupied by a benzene molecule, which various data in the literature indicate to be 40 A^2. It is therefore impossible to explain the fact that S_I is less than S by the hypothesis that some of the pores are inaccessible to

iodine molecules, for iodine molecules are smaller than benzene molecules. The only explanation of the difference between S and S_I is that only part of the surface adsorbs iodine and this part is formed of MgO.

The data in the table show that impregnated catalysts have a lower S than precipitated, which is quite understandable in view of the mutual protective action from crystallization and sintering found in coprecipitated catalysts. Although this effect was absent in the impregnated catalysts, the value of S was greater than that of the original MgO as a result of the introduction of the second component.

Hence, a combination of the methods of chemisorption of iodine and of adsorption of benzene vapor enabled us to determine separately the specific surfaces of the components of a mixed oxide catalyst. We have shown previously that, apart from MgO, many oxides chemisorb iodine from its solution in CCl_4 [11]. We therefore consider our present results to be interesting in connection with the possibility of determining not only the total specific surface, but also the specific surface of Cr_2O_3 in various mixed catalysts containing other oxides instead of magnesia.

SUMMARY

A method is proposed for the separate determination of the specific surfaces of the components of MgO-Cr_2O_3 catalysts by a combination of two methods of determining specific surfaces: from isotherms for the physical adsorption of a vapor (benzene) and from the chemisorption of iodine from its solution in carbon tetrachloride.

SYNTHESIS OF C^{14}-LABELED TOLUENE

A.A. Korotkov and S.P. Mitsengendler

Several methods have been proposed for the synthesis of C^{14}-labeled toluene, and these consist of 3-4 stages and give yields of 30-50% on the original active preparation [1, 2]. It is clear that for this purpose we may use the method of methylation of benzene and its derivatives. In the methylation of benzene with dimethyl sulfate and other alkylating agents in presence of aluminum chloride, the yield of toluene, which is diluted with a large excess of benzene, is comparatively low (59% [3] and 32% [4]). In the methylation of bromobenzene (via phenylmagnesium bromide) with dimethyl sulfate, an excess of the latter is required and the yield of toluene does not exceed 41% on the amount of bromobenzene taken [5]. In the methylation of bromobenzene with methyl iodide in presence of sodium [6], equimolecular amounts of reactants are used, but the authors do not state the yield of toluene. We selected this method for the preparation of C^{14}-labeled toluene.

EXPERIMENTAL

1. Preparation of C^{14}-labeled Methyl Iodide. This was prepared from C^{14}-labeled methanol and hydriodic acid. With minor modifications, the microapparatus used for the preparation of methyl iodide from methyl formate (see figure) [7] was used for the synthesis.

Diagram of microapparatus for the preparation of methyl-C^{14} iodide: a) reaction flask; b) aqueous suspension of red phosphorus; c) calcium chloride tube; d) trap for the condensation of methyl-C^{14} iodide.

Methanol-C^{14} (0.3 g) was cooled to −70° and dissolved in 10 ml of hydriodic acid of sp. gr. 1.7. The solution was poured into the flask a. A feeble current of nitrogen was passed continuously through the reaction mixture, which was heated gradually in an oil bath so that it reached a temperature of 130° in 90 minutes. The methyl-C^{14} iodide formed was carried away by the current of nitrogen (condenser not in operation) and condensed in the trap d, which was cooled to −70°. The yield of methyl-C^{14} iodide was 85-90% on the amount of alcohol taken.

2. Alkylation of Bromobenzene with Methyl-C^{14} Iodide. A solution of 13.56 g (0.095 mole) of methyl-C^{14} iodide and 22.54 g (0.14 mole) of bromobenzene in 20 ml of ether was cooled and rapidly poured into a flask containing 8 g of sodium wire in 10 ml of ether. The flask was connected through a condenser to a trap surrounded by a cooling mixture (−70°) contained in a Dewar vessel. Reaction began after the mixture had been heated slowly (over 1-2 hours) to a feeble boil, and it came to an end after 6-8 hours. Gentle reaction was maintained by cooling the flask with water. The mixture was allowed to stand overnight, and ether, unchanged methyl-C^{14} iodide (fraction boiling up to 50°), and a wide fraction boiling up to 130° were distilled off.

Pure toluene (3-5 ml) was added to the dry residue, and this was distilled into the receiver containing the wide fraction. The total toluene-containing distillate was boiled for 3-4 hours with sodium and then fractionated

through a microcolumn.

From the original methyl-C^{14} iodide, total activity 165 microcuries, we obtained unchanged methyl-C^{14} iodide, activity 13.9 microcuries, and 21.35 g of toluene-C^{14}, activity 131.5 microcuries. The yield of toluene-C^{14} was therefore 80% on the original amount of methyl-C^{14} iodide and 87% on the amount that reacted. The constants of the toluene-C^{14} obtained: b.p. 109-110° (753 mm), d_4^{20} 0.8654; n_D^{20} 1.4967.

The activity measurements were made with a "B" apparatus with end-on counter.

Senior laboratory worker V.D. Prochukhan took part in the experimental work.

SUMMARY

C^{14}-labeled toluene was synthesized by the alkylation of bromobenzene with methyl-C^{14} iodide. The yield of toluene-C^{14} was 80% on the original amount of methyl-C^{14} iodide and 87% on the amount that reacted.

SYNTHESIS OF C^{14}-LABELED BENZENE

A.A. Korotkov and S.P. Mitsengendler

Several methods have been published for the preparation of benzene-C^{14} [1-3]. With the exception of Turner's method [3], these methods give comparatively low yields – 22-25% on the original amount of active carbon. For the synthesis of benzene-C^{14} we used the known reaction of condensation of acetylene to benzene [4-6], by which it is possible to obtain benzene-C^{14} in one stage. The most satisfactory method of carrying out this reaction was found to be Berl and Hofmann's method [5], in which 98-99% of the acetylene is utilized in the formation of an aromatic tar containing up to 40% of a benzene fraction.* The method consists in the passage of acetylene diluted with steam at high speed through a tube containing porcelain beads at 740°. The steam has the purpose of facilitating the removal of heat and so minimizing the destruction of the condensation products first formed and reducing coke formation.

EXPERIMENTAL

1. Preparation of Acetylene-C^{14}. Acetylene-C^{14} was prepared according to the scheme: $BaCO_3^* \rightarrow BaC_2^* \rightarrow H_2C_2^*$: barium carbide by the method developed by Keier [7]; and acetylene by decomposition of the carbide with water in the apparatus described by Cheronis [8], as modified in detail by us** (Figure 1). By this method the yield of acetylene was 72-80% on the amount of barium carbonate taken. The labeled acetylene (16-20 ml) was displaced from the system by 25 times its volume of acetylene-C^{12} into one of the gas burets of the apparatus for the condensation of acetylene to benzene (Figure 2).

Fig. 1.

2. Condensation of Acetylene-C^{14}. Acetylene-C^{14} (500 ml) having a total activity of 0.615 millicurie was passed at a rate of 4.5 liters/hour from the gas buret 1 through two successive vessels containing water in the water thermostat 4. Constancy of temperature (78 ± 0.5°) was attained by the use of boiling ethanol in the hollow walls of the thermostat. The gas mixture, containing 45% of water vapor, passed on to a quartz tube 5 (diameter 15 mm, length and volume of heated part 160 mm and 28 ml, respectively) heated to 740° and filled with 4-mm beads of white clay that had been fired at 1200°. The upper, entering end of the reaction tube was heated to 300° with an electric tube furnace, length 50 mm. The tar and steam condensed in the receiver 6 at −5° and in three successive traps at −15°.

The gas mixture (250 ml), consisting mainly of unchanged acetylene, passed to gas buret 2. In one cycle about 60% of the acetylene reacted. The gas mixture passing into the gas buret 2 was diluted to 500 ml with acetylene-C^{12} from the gas buret 3, and was again passed through the reactor. In this case the gas buret 1 served as a receiver for unchanged acetylene.

*Berl and Hofmann carried out the condensation of acetylene in a large apparatus capable of passing 60 liters of acetylene per hour. The authors did not isolate benzene and toluene from the fractions obtained.

**The wire-filled U-shaped trap for condensation of acetylene was replaced by a more compact bell-shaped trap in an aluminum jacket. The yield of acetylene was determined by the pressure change in the system.

Each cycle lasted 5-7 minutes. In the course of 11 cycles the acetylene-C^{14} reacted almost completely, the total consumption of acetylene being 2-3 liters (2.44 g). From this amount of acetylene about 2.5 ml (2.35 g) of an aromatic C^{14} tar was obtained (8% of the acetylene was consumed in the formation of coke and gaseous saturated hydrocarbons). In the course of the experiment, which lasted 65-70 minutes, only a very little coke was formed: it formed a thin covering on the beads and the walls of the quartz tube.

Fig. 2.

This acetylene condensation process was first tried out on acetylene-C^{12}. In this case the yield of tar was also 95-96%. For the determination of the yield and purity of the benzene, a fraction boiling up to 150° was distilled from the tar, purified from unsaturated compounds, and then fractionated through a microcolumn. From 13.3 g of the fraction (48%), 9.82 g of benzene was obtained (33.6% yield on the amount of acetylene taken). Apart from benzene, some toluene was isolated (3.2% yield on the amount of acetylene taken).* The constants of the benzene obtained were: b.p. 80° (757 mm); d_4^{20} 0.8771; n_D^{18} 1.5013.

3. Isolation of Benzene-C^{14} and Toluene-C^{14} from the Tar Obtained. After the experiment the reactor and trap were washed out with ether and the resulting solution was fractionated from a flask having a small Vigreux column (height 100 mm). Ether came over first, and then a fraction boiling up to 150°, which was collected in a small separating funnel. In order to separate benzene-C^{14} more completely from the tar, 2 ml of pure benzene, free from unsaturated compounds, was added to the residue in the distillation flask, and this was then distilled into the same separating funnel. The operation of washing the tar residue with benzene was repeated three times. The distillate was treated directly in the separating funnel with 75% sulfuric acid in 4-5 small portions. It was then washed with water and dried with fused calcium chloride (after removal of unsaturated compounds the hydrocarbon layer was reduced by 5% in volume). The dried solution was distilled over sodium from a flask having a small Vigreux column (height 100 mm). To the small residue in the flask, 2 ml of pure benzene was added, and this was distilled into the receiver for benzene-C^{14}. The operation was repeated 3-4 times until C^{14} was absent in the distillate.**

From the original acetylene-C^{14}, total activity 0.615 millicurie, 18.2 g of benzene-C^{14} was obtained, activity 0.183 millicurie, i.e., the yield of benzene-C^{14} was 29.8% on the amount of active carbon in the acetylene-C^{14} taken. The residue from the distillation of benzene was diluted with 1 ml of toluene, free from unsaturated compounds, and was distilled. The operation was repeated until C^{14} was absent in the distillate. We obtained 2.26 g of toluene having a total activity of 0.0078 millicurie, which corresponds to 1.26% on the amount of active carbon in the acetylene taken.

Laboratory worker A.P. Kudryavtsev took part in the experimental work.

*In Zelinsky's method [4] the yields of benzene and toluene are 23-25% and 4%, respectively.

**The activities of the preparations obtained were measured with a "B" apparatus with end-on counter.

SUMMARY

C^{14}-labeled benzene was synthesized by the condensation of acetylene-C^{14} diluted with steam at 740°, the time of contact being 3.5 seconds. The yield of benzene-C^{14} was 30% on the amount of active carbon taken.

ORGANOBORON COMPOUNDS

COMMUNICATION 14.* ACTION OF ORGANIC BASES ON CHLORODIPHENYLBORINE

B.M. Mikhailov and N.S. Fedotov

The reaction between esters of organoboron acids and phosphorus pentachloride provides a simple method of preparing organic monochloroborines (I) [3,4] and dichloroborines (II) [5], and also a new type of boron compounds, the chloro esters RBCl·OR' (III) [4,6].

$$R_2BOR' + PCl_5 = R_2BCl + POCl_3 + R'Cl.$$
(I)

$$RB(OR')_2 + 2PCl_5 = RBCl_2 + 2POCl_3 + 2R'Cl.$$
(II)

$$RB(OR')_2 + PCl_5 = RB\begin{matrix}Cl\\OR'\end{matrix} + POCl_3 + R'Cl.$$
(III)

Hence, organic chloroborines are very readily accessible compounds, which is a prerequisite for the study of their chemical properties and their use for synthesis of organoboron compounds.

The present paper gives the results of an investigation of the reactions of chlorodiphenylborine, prepared by the action of phosphorus pentachloride on diphenylborinic ester in presence of organic bases.

When treated with two equivalents of diethylamine in ethereal solution, there is a lively reaction accompanied by boiling of the ether. The products are (diethylamino)diphenylborine (IV) and diethylamine hydrochloride:

$$(C_6H_5)_2BCl + 2(C_2H_5)_2NH = (C_6H_5)_2B-N(C_2H_5)_2 + (C_2H_5)_2NH\cdot HCl.$$
(IV)

Piperidine reacts similarly with chlorodiphenylborine and gives diphenylpiperidinoborine (V):

$$(C_6H_5)_2BCl + 2C_5H_{11}N = (C_6H_5)_2B-NC_5H_{10} + C_5H_{11}N\cdot HCl.$$
(V)

In the reaction of ammonia with an ethereal solution of chlorodiphenylborine at room temperature, chlorine is not replaced by an amino group as it is in the case of secondary amines, but ammonia adds with formation of a chlorodiphenylborine-ammonia complex (VI):

$$(C_6H_5)_2BCl + NH_3 = (C_6H_5)_2B\begin{matrix}Cl\\\leftarrow NH_3\end{matrix}$$
(VI)

Chlorodiphenylborine can also form a stable complex compound with pyridine, and stable complexes with pyridine are formed also be chloro-p-chlorophenylphenylborine and by chlorodi-1-naphthylborine (VII):

*Communication 11, see [1]; Communication 13, see [2].

(VII)

in which Ar = C_6H_5 or 1-$C_{10}H_7$, and Ar' = p-ClC_6H_4.

EXPERIMENTAL

1. (Diethylamino)diphenylborine. A mixture of 6.4 g (0.032 mole) of chlorodiphenylborine [3] and 25 ml of dry ether was prepared in a three-necked flask fitted with reflux condenser, tube for the passage of nitrogen, and dropping funnel. The mixture was stirred while 4.7 g (0.064 mole) of diethylamine diluted with 10 ml of dry ether was added slowly. The ether came to the boil, and a colorless finely crystalline precipitate formed. The crystals were filtered off and washed with 20 ml of dry ether. The product was 3.53 g of diethylamine hydrochloride, m.p. 225-226°, undepressed by admixture of known diethylamine hydrochloride. Ether was distilled from the filtrate, and vacuum distillation of the residue in a current of nitrogen gave 5.47 g of (diethylamino)diphenylborine (71.5% yield), b.p. 159-162° (11 mm) and d_4^{20} 0.9953.

Found %: C 80.95; H 8.46; B 4.60. $C_{16}H_{20}BN$. Calculated %: C 81.07; H 8.44; B 4.56.

(Diethylamino)diphenylborine is a colorless substance which crystallizes when cooled; m.p. 36-37°. It very readily oxidizes in the air. It is readily soluble in acetone, alcohol and ether.

2. Diphenylpiperidinoborine. An ethereal solution of 5 g (0.059 mole) of piperidine was added slowly to a stirred solution of 5.3 g (0.026 mole) of chlorodiphenylborine in 10 ml of ether. The precipitate of piperidine hydrochloride (3.34 g, m.p. 246°) was filtered off. The substance showed no depression of melting point in admixture with a known sample of piperidine hydrochloride. Solvent was distilled from the filtrate, and vacuum distillation of the residue in a current of nitrogen gave 3.5 g (53%) of diphenylpiperidinoborine, b.p. 200-203° (14 mm).

Found %: C 82.09; H 7.96; B 4.35. $C_{17}H_{20}BN$. Calculated %: C 81.98; H 8.03; B 4.34.

Diphenylpiperidinoborine comes over as a thick colorless oil which crystallizes on standing; m.p. 65-66°. It is oxidized in the air.

3. Chlorodiphenylborine-Ammonia Complex. A stream of dry ammonia was passed through an ethereal solution of chlorodiphenylborine (1 g in 20 ml of ether). The colorless crystalline precipitate was filtered off and washed with ether. The product, amounting to 1.14 g (99%), was the chlorodiphenylborine-ammonia complex; it softens at 175-180° and does not melt completely up to 250° (in a sealed capillary).

Found %: B 4.79; Cl 15.93; Ar 71.08. $C_{12}H_{13}BNCl$. Calculated %: B 4.98; Cl 16.29; Ar 70.86.

The substance is readily soluble in alcohol, but poorly soluble in ether, acetone, benzene and chloroform.

4. Chlorodiphenylborine-Pyridine Complex. A solution of 0.88 g of pyridine in 10 ml of ether was added to a solution of 2.22 g of chlorodiphenylborine in 10 ml of ether. The colorless crystalline precipitate was filtered off and washed with ether. The product, amounting to 2.34 g (75.7%) was the chlorodiphenylborine-pyridine complex, m.p. 135-138°.

Found %: B 3.86; Cl 12.83. $C_{17}H_{15}BNCl$. Calculated %: B 3.87; Cl 12.69.

The pyridine complex is sparingly soluble in ether, acetone and benzene, and is readily hydrolyzed by atmospheric moisture.

5. Chloro-p-chlorophenylphenylborine-Pyridine Complex. A solution of 1.25 g of pyridine in 10 ml of ether was added to a solution of 1.55 g of chloro-p-chlorophenylphenylborine (prepared by the action of PCl_5

on isobutyl p-chlorophenylphenylborinate) in 20 ml of ether. The solvent came to the boil, and a precipitate of the pyridine complex of chloro-p-chlorophenylphenylborine formed. The substance was filtered off and washed with ether. The yield of pyridine complex, m.p. 130-132°, was 1.54 g (74.8%).

Found %: C 64.95; H 4.92; B 3.33; N 4.38; Cl* 11.12.
$C_{17}H_{14}BNCl_2$. Calculated %: C 65.04; H 4.81; B 3.44; N 4.46; Cl 11.31.

The substance is sparingly soluble in ether, acetone and benzene, and is readily hydrolyzed by atmospheric moisture.

6. Chlorodi-1-naphthylborine-Pyridine Complex. An ethereal solution of 1.5 g of pyridine was added to an ethereal solution of 1.59 g of chlorodi-1-naphthylborine [3]. The precipitate formed was filtered off and washed with ether. The yield of the pyridine complex of chlorodi-1-naphthylborine, m.p. 243-245°, was 1.5 g (75.3%).

Found %: B 2.74; Cl 9.19. $C_{26}H_{19}BNCl$. Calculated %: B 2.74; Cl 9.35.

The substance is sparingly soluble in organic solvents and is readily hydrolyzed by atmospheric moisture.

SUMMARY

1. By reaction with diethylamine or piperidine, chlorodiphenylborine gives (diethylamino)diphenylborine or diphenylpiperidinoborine, respectively.

2. Chlorodiphenylborine reacts with ammonia at room temperature with formation of a chlorodiphenylborine-ammonia complex.

3. Diarylchloroborines from stable complex compounds with pyridine.
